Preschoolers believe their thoughts are sufficient to cause death; the consequence is the burden of guilt, shame, and punishment. Their egocentricity implies a tremendous sense of self-power and omnipotence. They usually have some understanding of the meaning of death. Death is seen as a departure, a kind of sleep. They may recognize the fact of physical death but do not separate it from living abilities. Death is seen as temporary and gradual; life and death can change places with one another. They have no understanding of the universality and inevitability of death.	If they become seriously ill, they conceive of the illness as a punishment for their thoughts or actions. They may feel guilty and responsible for the death of a sibling. Their greatest fear concerning death is separation from parents. They may engage in activities that seem strange or abnormal to adults. Because they have fewer defence mechanisms to deal with loss, young children may react to a less significant loss with more outward grief than to the loss of a very significant person. The loss is so deep, painful, and threatening that the child must deny it for a time to survive its overwhelming impact. Behaviour reactions such as giggling, joking, attracting attention, or regressing to earlier developmental skills indicate children's need to distance themselves from tremendous loss.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Help parents understand their children's behavioural reactions. Encourage parents to remain near the child as much as possible, to minimize the child's great fear of separation from parents. If a parent has died, promote arrangements for a consistent caregiver for the child. Promote primary nursing.
School-Age Children		
These children still associate misdeeds or bad thoughts with causing death and feel intense guilt and responsibility for the event. Because of their higher cognitive abilities, they respond well to logical explanations and comprehend the figurative meaning of words. They have a deeper understanding of death in a concrete sense. They particularly fear the mutilation and punishment they associate with death.	Because of their increased ability to comprehend, they may have more fears, for example: • The reason for the illness • Communicability of the disease to themselves or others • Consequences of the disease • The process of dying and death itself Their fear of the unknown is greater than their fear of the known. The realization of impending death is a tremendous	Help parents deal with their feelings, allowing them greater emotional reserves to meet their children's needs. Encourage parents to remain near the child as much as possible, yet be sensitive to parents' needs. Because of children's fear of the unknown, anticipatory preparation is important. Because the developmental task of this age is industry, interventions of helping children maintain control over their bodies and increasing their

TABLE 41.3 Children's Understanding of and Reactions to Death—cont'd

Concepts of Death	Reactions to Death	Nursing Care
They personify death as the devil, a monster, or the bogeyman. They may have naturalistic or physiological explanations of death. By age 9–10, children have an adult concept of death, realizing that it is inevitable, universal, and irreversible.	threat to their sense of security and ego strength. They are likely to exhibit fear through verbal uncooperativeness rather than physical aggression. They are interested in postdeath services. They may be inquisitive about what happens to the body.	understanding can enable them to achieve independence, self-worth, and self-esteem and avoid a sense of inferiority. Encourage children to talk about their feelings, and provide aggressive outlets. Encourage parents to honestly answer questions about dying rather than avoiding the subject or fabricating euphemisms. Encourage parents to share their moments of sorrow with their children. Provide preparation for postdeath services.
Adolescents		
Adolescents have a mature understanding of death. They are still influenced by remnants of magical thinking and are subject to guilt and shame. They are likely to see deviations from accepted behaviour as reasons for their illness.	Adolescents straddle the transition from childhood to adulthood. They have the most difficulty in coping with death. They are least likely to accept cessation of life, particularly if it is their own. Concern is for the present much more than for the past or the future. They may consider themselves alienated from their peers and unable to communicate with their parents for emotional support, feeling alone in their struggle. Adolescents' orientation to the present compels them to worry about physical changes even more than the prognosis. Because of their idealistic view of the world, they may criticize funeral rites as barbaric, money making, and unnecessary. They may have strong opinions of what postdeath rituals they want observed for them.	Help parents deal with their feelings, allowing them greater emotional reserves to meet their children's needs. Avoid alliances with either parent or child. Structure hospital admission to allow for maximum self-control and independence. Answer adolescents' questions honestly, treating them as mature individuals and respecting their needs for privacy, solitude, and personal expressions of emotions. Help parents understand their child's reactions to death and dying, especially that concern for present crises, such as loss of hair, may be much greater than for future ones, including possible death.

If given the opportunity, children will tell others how much they want to know. Asking questions such as "If the disease came back, would you want to know?" "Do you want others to tell you everything, even if the news isn't good?" or "If someone were not getting better [or more directly, "were dying"], do you think he would want to know?" helps children set the limits of how much truth they can accept and cope with. Children need time to process many feelings and much information so that they can assimilate and, ideally, accept the inevitable fact of mortality.

Care of the dying adolescent requires the nurse to become knowledgeable about any possible delays or alterations in normal growth and development. Legal and ethical issues, such as informed consent, also need to be addressed with respect to the age at which an adolescent should have autonomy in decision making about care and treatment. Effective communication between the patient, family, and health care team is an important part of optimal care for the dying adolescent.

Treatment Options for Terminally Ill Children

Based on the child and family's decision regarding end-of-life care, they have several options from which to choose.

Hospital Care. Families may choose to remain in the hospital to receive care if the child's illness or condition is unstable and home care is not an option or the family is uncomfortable with providing care at home. If a family chooses to remain at the hospital for end-of-life care, the setting should be made as homelike as possible. Families should be encouraged to bring familiar items from the child's room at home. In addition, there should be a consistent and coordinated care plan for the child and family's comfort that includes interventions for any symptoms (e.g., pain, breathlessness, bleeding, seizures) that may occur during the end-of-life period given the child's underlying condition.

Home Care. Some families prefer to take their child home and receive services from a home care agency. Generally, these services entail periodic nursing visits to administer a treatment or provide medications, equipment, or supplies (see Figure 41.5). Many home care agencies can provide nurses and other health care providers who are specially trained in palliative care support for patients and their families. The child's care frequently continues to be directed by the primary physician. As with end-of-life care provided in the hospital, there should be a plan in place to manage any expected symptoms, and the family should be aware of the symptoms associated with impending death (e.g., decreased interactions, decreased intake and output, changes in colour, and changes in breathing patterns). The family should also have contact information and directions for whom to call if the child experiences symptoms that they are not able to manage or if they need additional support, as well as whom to call when the child dies (e.g., palliative care team, family physician, funeral home).

With children, the opportunity to die at home may benefit the family in a variety of ways. Children who are dying are allowed to remain with those they love and with whom they feel secure. Many children who were thought to be near death have gone home and lived longer than expected. Siblings can feel more involved in the care and often have more positive perceptions of the death. Parental adaptation is often more favourable, demonstrated by their perceptions of how the experience at home affected their relationships, social reorientation, religious beliefs, and views on the meaning of life and death.

Hospice Care. There are only a few pediatric hospices currently available in Canada, but some adult hospices also provide care to children if additional supports are available for their staff. When pediatric hospices are available, some families will choose this option for the location of their child's death. Hospice may be an important alternative for families who are not comfortable being at home or who live in areas where home care services are not available but they do not wish to be in the hospital (Widger et al., 2016). Families may also receive respite care through hospice at earlier stages of an illness. A return to hospice for end-of-life care means the family is in a familiar setting with familiar caregivers. There is space for the family to stay with the child, and they may choose to continue to provide the medical aspects of care as they did at home, or they may allow the staff to take over those aspects of care, allowing them to be "just" a parent. See Additional Resources for resources on palliative care and hospice resources.

Nursing Care of the Child and Family at the End of Life

Regardless of where the child receives end-of-life care, both the child and the family usually experience fear of (1) pain and suffering, (2) dying alone (child) or not being present when the child dies (parent), and (3) actual death. Nurses can help reduce families' fears through attention to the care needs of the child and family (see Evolve website for Nursing Care Plan: The Dying Child).

Fear of Pain and Suffering. The presence of unrelieved pain in an ill child can have detrimental effects on the quality of life experienced by the child and family. Parents believe that having their child in pain is unendurable and results in feelings of helplessness and a sense that they must be present and vigilant to get the necessary pain medications. Persistent pain also creates more stress for the family as a whole. Nurses can alleviate the fear of pain and suffering by providing interventions aimed at treating the pain and symptoms associated with the dying process in children.

Pain and symptom management. Children experience many symptoms during their last month of life. Pain, dyspnea, and fatigue are the most frequently documented symptoms, experienced by most children at the end of life (Mahmood et al., 2015; Vern-Gross et al., 2015). Pain control for children in the terminal stages of illness or injury must be given the highest priority. Despite ongoing efforts to educate physicians and nurses on pain management strategies in children, studies have reported that children continue to be undermedicated for their pain. The involvement of a palliative care plan may enhance successful pain management (Mahmood et al., 2015) (See Chapter 34, Pain and Sedation in End-of-Life Care).

Nearly all children experience some amount of pain in the final stages of their illness. The current standard for treating children's pain follows the World Health Organization's (2020) guidelines on the treatment of chronic pain in children with medical illnesses, which promotes tailoring the pain interventions to the child's level of reported pain. Children's pain should be assessed frequently and medications adjusted as necessary. Pain medications should be given on a regular schedule, and extra doses for breakthrough pain should be available to maintain comfort. Opioid drugs such as morphine should be given for severe pain, and the dose should be increased as necessary to maintain optimal pain relief. Techniques such as distraction, relaxation techniques, and guided imagery should be combined with drug therapy to provide the child and family strategies to control pain (see Chapter 34 for further discussion of pain-management strategies).

In addition to pain, children experience a variety of signs and symptoms during their terminal course as a result of their disease process or as an adverse effect of medicines used to manage pain or other symptoms. These symptoms include pain, fatigue, nausea and vomiting, constipation, anorexia, dyspnea, congestion, anxiety, depression, restlessness, agitation, and confusion (Heath et al., 2010). Each of these symptoms should be aggressively managed with appropriate medications or treatments and with interventions such as repositioning, relaxation, massage, and other measures to maintain the child's comfort and quality of life.

Occasionally, children require very high doses of opioids to control their pain. The child on long-term opioid pain management can develop physical **tolerance** of the medication, meaning that it is necessary to give more medication to maintain the same level of pain relief. This should not be confused with **addiction**, which is a psychological dependence on the adverse effects of opioids. Other obvious reasons for requiring increased doses of opioids include progression of disease and other physiological experiences of pain. It is important to understand that there is no maximum dose that can be given to control pain. Nurses often express concern that administering doses of opioids that exceed what they are familiar with will hasten the child's death. In cases where the child is terminally ill and in severe pain, use of large doses of opioids and sedatives to manage pain is justified when no other treatment options are available that would relieve the pain but make the risk of death less likely.

A multipronged approach to help relieve physical as well as psychological and spiritual distress is necessary to provide optimum care to this very vulnerable population and their families. It is important to engage with patients and families, facilitate open communication and good relationships, and involve patients and families in the decision-making process as much as possible about needed services and treatment interventions (Epelman, 2012).

Parents' and siblings' need for education and support. Nurses providing care to the child and family need to teach the family about the medications being given to the child, how to administer medications, and the use of nonpharmacological techniques to control pain and other symptoms. The family should be encouraged to participate in the child's care to the extent that they desire. This empowers parents and provides a sense of control over the child's comfort and well-being, reducing their fear that their child will be in pain or suffering as they are dying. Additionally, better bereavement outcomes (e.g., resilience; adaptive coping; family cohesion; less anxiety, stress, and depression) have been reported by parents who were actively involved in their child's care and who had positive interactions and open communication with health providers (Rosenberg et al., 2014).

Providing psychological support to parents and siblings prior to the child's death may facilitate the grieving process. Recognizing that parents experience bereavement and grief in varying ways will assist the nurse in providing appropriate and focused education and support.

Siblings may feel isolated and displaced while their brother or sister is dying. Parents may devote most of their time to the dying child's care and comfort, causing siblings to feel left out of the parent–sick child relationship. Siblings may become resentful of their sick sibling and begin to feel guilty or ashamed about such feelings. Nurses can assist the family by helping the parents identify ways to involve siblings in the caring process, perhaps by bringing some supplies or a favourite toy, game, or food item. Parents should also be encouraged to schedule time to spend with the other children where their focus is on them. Helping parents identify a trusted friend or family member who can sit with the ill child for a short period will allow them to attend to their own needs or those of their other children.

Children, parents, and siblings can engage in certain activities to help prepare for end of life. One such activity is legacy building. Several legacy-building activities that families can use to create lasting memories of their loved ones include creating three-dimensional hand moulds of the child and family members, creating a photo album or

having professional photos taken with the dying child, creating artwork such as hand or foot prints on canvas, or making a recording to capture the child's heartbeat or voice. Legacy building can also occur after death, such as making donations or hosting fundraisers in the name of a loved one, creating a memento space in the home where legacy-building creations can be placed, or creating a quilt or pillow using the clothes and blankets of the child. These activities create a safe space for children and siblings to express themselves, provide an opportunity for family coping, and leave families with tangible memories of their child (Foster et al., 2012).

Fear of Dying Alone or of Not Being Present When the Child Dies. When a child is being cared for at home, the burden of care on parents and family members can be great. Often, as the child's condition declines, family members begin the "death vigil." Rarely is a child left alone for any length of time. This can be exhausting for family members, and nurses can assist the family by helping them arrange shifts so that friends or family members can be present with the child and allow others to rest. If the family has limited resources, community organizations, such as hospice or churches, often have volunteers who are willing to visit and sit with children. It is important that whoever is sitting with the child be aware of when the parent(s) would like to be notified to return to the child's bedside (Figure 41.6).

When a child is dying in the hospital, parents should be allowed to visit the child at all times. If the parents need to leave, they should be provided with a pager or other means of immediate communication and alerted if staff members note any change in the child's condition that may indicate imminent death. Nurses must advocate for parents' presence in critical care and emergency departments and attend to parents' needs for food, drinks, comfortable chairs, blankets, and pillows.

Home Deaths. The majority of children receiving palliative care die at home; they often die in their own room with family, pets, and loved possessions around them. The physical process of dying can be distressing to parents because often the child slowly becomes less alert in the days before the actual death. The nurse can assist the family by providing them with information about what changes will occur as the child progresses through the dying process (Box 41.11). During this time, nursing visits often become more frequent and longer in duration to provide the family with additional support as the death nears. The most distressing change for parents to observe is the change in the respiratory pattern. In the final hours of life, the dying patient's respirations may become laboured, with deep breaths and long periods of apnea, referred to as *Cheyne-Stokes respirations*. Families need to be reassured that this is not distressing to the child and that it is a normal part of the dying process. However, the use of opioids can slow the respirations to make the child breathe more easily, and scopolamine, usually applied as a topical patch, can help reduce noisy respirations known as the "death rattle." Noisy respirations are more likely to occur if the child is overhydrated.

If the child is at home, arrangements for pronouncement of the death and whom to call when the child dies (e.g., a particular funeral home) should be in place. Funeral arrangements can also be made prior to death no matter where it occurs.

Hospital Deaths. Children dying in the hospital who are receiving supportive care interventions experience a similar process. Death resulting from accident, trauma, or acute illness in settings such as the emergency department or critical care unit often requires the active withdrawal of some form of life-supporting intervention, such as a ventilator or bypass machine. These situations often raise difficult ethical issues, and parents are often less prepared for the actual moment of death. Nurses can assist these parents by providing detailed information about what will happen as supportive equipment is withdrawn, ensuring that appropriate pain medications are administered to prevent pain during the dying process, and allowing the parents time before the start of the withdrawal to be with and speak to their child. It is important that the nurse attempt to control the environment around the family at this time by providing privacy, asking if they would like to play music, softening lights, monitoring noises, encouraging the family to get into bed with or hold the child, and arranging for any religious or cultural rituals that the family may want performed.

BOX 41.11 Physical Signs of Approaching Death

Loss of sensation and movement in the lower extremities, progressing toward the upper body
Sensation of heat, although body feels cool
Loss of senses:
- Tactile sensation decreasing
- Sensitivity to light
- Hearing is the last sense to fail

Confusion, loss of consciousness, slurred speech
Muscle weakness
Loss of bowel and bladder control
Decreased appetite and thirst
Difficulty swallowing
Change in respiratory pattern:
- Cheyne-Stokes respirations (waxing and waning of depth of breathing with regular periods of apnea)
- "Death rattle" (noisy chest sounds from accumulation of pulmonary and pharyngeal secretions)

Weak, slow pulse; decreased blood pressure

Fig. 41.6 For the dying child there is no greater comfort than the security and closeness of a parent.

After the child's death, the family should be allowed to remain with the body and hold or rock the child if they desire. After the nurse has removed all tubes and equipment from the body, parents should be given the option of assisting with the preparation of the body, such as bathing and dressing. It is important for the nurse to determine whether the family has any specific needs, since many cultures have adopted specific methods for coping with death and mourning, and impeding these practices may interfere with the grieving process. The nurse should also determine if siblings or other family members not already present need to be called to see the child before the child is moved to the funeral home. If the death is sudden, following an accident or acute illness, parents may need assistance with identifying and contacting a funeral home.

Postdeath Preparations. Parents often have concerns about the funeral, such as siblings' involvement in the death rituals. Although there are no absolute answers to the question of siblings attending the funeral or burial services, the consensus is that the surviving children benefit from being involved in these events. Children need preparation for postdeath services. They should be told what to expect, particularly how the deceased person will look if the coffin is open; allowed their private time to say goodbye; and permitted to stay as long as they wish. Ideally, the parents should prepare the siblings. If the parents' grief prevents this communication, a significant family member or friend should prepare the siblings (see Family-Centred Care box: Children Need to Say Goodbye).

FAMILY-CENTRED CARE

Children Need to Say Goodbye

As a nurse and grief counsellor, I conduct grief workshops with children who have experienced the death of someone special. Children often communicate their feelings of being excluded through drawings. They may draw a picture of the dying person in a hospital bed that is raised too high for them to see the person's face clearly. Sometimes children reveal that they did not get to say goodbye because a family member told them, for example, "You don't want to see your grandma this way. She is too sick for you to visit." If the special person died at home, the children had to stay in their room when the funeral home staff took away the body.

I have learned to never underestimate the importance of allowing children to be involved with the dying person and the significance of a child's loss. Once, when I asked a 6-year-old girl to draw a picture with the theme "This is what I was doing when my _____ died," she drew a picture and completed the sentence with "when my home died." Her grandmother had been like her mother; to the child, her home was gone. We need to give children the choice of being included in the family's activities of saying goodbye.

Organ or Tissue Donation and Autopsy

For some families, organ or tissue donation may be a meaningful act—one that benefits another human being despite the loss of their child. Unfortunately, initiating a discussion about organ or tissue donation is often stressful for staff, and there may be confusion regarding whose responsibility this is. In centres in which transplants are performed, a transplant coordinator is usually available to inform the family about organ or tissue donation and to take care of details. If such services are not available, the staff need to determine which members should discuss this topic with the family. Ideally, the person who knows the family best, knows when the death is expected, or has the opportunity to spend time with the family when the death is unexpected takes this role. Often nurses are in an optimal position to suggest organ or tissue donation after consultation with the attending physician. When possible, the topic should be raised before death occurs. The request should be made in a private and quiet area of the hospital and should be simple and direct, with questions such as "Are you a donor family?" or "Have you ever considered organ donation?"

Some provinces and territories have guidelines concerning requests for organ or tissue donation when a child dies, especially if the patient is brain dead. In Canada, there is a list of provincial tissue and organ donor agencies. Written consent from the family is required before donation can proceed. When requests for organ donation are made, health care providers must address common misunderstandings families have about neurological determination of death and organ donation. Training health care providers on sensitive approaches to requests for organ donation has been shown to increase families' willingness to consent to organ donation. The option to donate organs should always be separate from the communication of impending or actual death. Organ donation organizations and organ recovery and transplant teams can be consulted by health care providers for support and to clarify eligibility; however, they should not have direct contact with the patient's decision makers until there is a decision to pursue organ donation.

Sometimes, antemortem or postmortem interventions may need to be done to ensure successful organ or tissue donation, for example, reintubating a patient after circulatory determination of death. Organ-specific transplant teams should be consulted regarding any ante- or postmortem intervention that may be required, and thorough discussion of these interventions should be included in the consent process with decision makers.

Nurses need to be aware of common questions about organ donation in order to help families make an informed decision. Healthy children who die unexpectedly are excellent candidates for organ donation. Children with cancer, chronic disease, or infection or those who have suffered prolonged cardiac arrest may not be suitable candidates for organ donation but may be able to donate tissues, although this is individually determined. The nurse should ask whether organ donation was discussed with the child or whether the child ever expressed such a wish. For adolescents, their wishes may be indicated on their provincial driver's license. Any number of body tissues or organs can be donated (for example, skin, corneas, bone, kidney, heart, liver, pancreas), and their removal does not mutilate or desecrate the body or cause any suffering. The family may still have an open casket, and there is no delay in the funeral. While there is no cost to the donor family, organ donation does not eliminate funeral or cremation responsibilities. Most religions permit organ donation as long as the recipient benefits from the transplant, although Orthodox Judaism forbids it. According to provincial laws, coroners may need to be notified prior to the consent discussion taking place with parents or caregivers (Weiss et al., 2017).

Grief and Mourning

Grief is a process, not an event, of experiencing physiological, psychological, behavioural, social, and spiritual reactions to a personal loss—in this case, the loss of a child. Grief is highly individualized, encompassing a broad range of manifestations from person to person. It is a natural and expected reaction to loss. It is neither orderly nor predictable. Grieving in any form is necessary for healing to occur. When death is the expected or a possible outcome of a disorder, the child and family members may experience *anticipatory grief*. Anticipatory grief may be

manifested in varying behaviours and intensities and may include denial, anger, depression, and other psychological and physical symptoms.

Anticipatory guidance may assist grieving family members. Health care providers should emphasize that grief reactions such as hearing the dead person's voice, feeling distant from others, or seeking reassurance that they did everything possible for the lost person are normal, necessary, and expected. In no way do these reactions signify poor coping, insanity, or an approaching mental breakdown. On the contrary, such behaviours signify that the survivor is working through the acute grief. Anticipatory guidance regarding the mourning process may help families recognize the normalcy of their experiences.

It is important to recognize that some family members may experience complicated grief. *Complicated grief* reactions (more than a year after the loss) include such symptoms as intense intrusive thoughts, pangs of severe emotion, distressing yearnings, feelings of excessive loneliness and emptiness, unusual sleep disturbance, and maladaptive levels of loss of interest in personal activities (Bruce et al., 2011). Bereaved persons experiencing such prolonged and complicated grief should be referred to an expert in grief and bereavement counselling.

Another important aspect of grief is the individual nature of the grief experience. Each member of the family will experience grief of the child's death in their own way, based on their particular relationship with that child. This can create potential conflict for families, since each family member can have expectations that the other family members should feel and grieve as they do. Nurses caring for families experiencing grief should be aware of the different grieving styles and help the family learn to recognize and support the uniqueness of each other's grief.

Parental Grief. Parental grief after the death of a child can be the most intense, complex, long-lasting, and fluctuating grief experience compared with that of other bereaved individuals. Although parents experience the primary loss of their child, many secondary losses are also felt, such as the loss of part of one's self, hopes and dreams for the child's future, the family unit, prior social and emotional community supports, and often spousal support. It is common for each parent of a child to experience different grief reactions.

Studies of bereaved parents have shown that grieving does not end with the severing of the bond with the deceased child, but rather involves a continuing bond between the parent and the deceased child (Foster et al., 2011). Parental resolution of grief is a process of integrating the dead child into daily life, where the pain of losing a child is never completely gone but lessens in intensity. There are occasions of brief relapse, but not to the degree experienced when the loss initially occurred. Thus parental grief work is never completed and is a timeless process of accommodating the new reality of being without a child, as it changes over time. A child's death can also challenge the relationship between partners and spouses in several ways. Different grieving styles between the couple may hinder communication and support for each other. Differing needs and expectations can place a strain on the relationship.

At times, family members may need assistance in their grieving (see Guidelines box: Supporting Grieving Families). Communication with the bereaved family is essential, but often nurses do not know what to say and feel helpless in offering words of comfort. The most supportive approach is to avoid judging the family's reactions or offering advice or rationalizations and to focus on feelings. Perhaps the most valuable supportive measure the nurse can provide for families is to listen. Families understand that no words will relieve their pain; all they want is acceptance, understanding, and respect for their grief.

GUIDELINES

*Supporting Grieving Families**

General

- Stay with the family; sit quietly if they prefer not to talk; cry with them if that is acceptable to them.
- Accept the family's grief reactions; avoid judgemental statements (e.g., "You should be feeling better by now").
- Avoid offering rationalizations for the child's death (e.g., "Your child isn't suffering anymore").
- Avoid artificial consolation (e.g., "I know how you feel," or "You are still young enough to have another baby").
- Deal openly with feelings such as guilt, anger, and loss of self-esteem.
- Focus on feelings by using a feeling word in the statement (e.g., "You're still feeling all the pain of losing a child").
- Refer the family to an appropriate support group or for professional help, if needed.

At the Time of Death

- Reassure the family that everything possible is being done for the child, if they want lifesaving interventions.
- Do everything possible to ensure the child's comfort, especially relieving pain.
- Provide the child and family with the opportunity to review special experiences or memories in their lives.
- Express personal feelings of loss (e.g., "We will miss him so much," "We tried everything; we feel sad that we couldn't save her").
- Provide information that the family requests, and be honest.
- Respect the emotional needs of family members, such as siblings, who may need brief respites from the dying child.
- Make every effort to arrange for family members, especially parents, to be with the child at the moment of death, if they want to be present.
- Allow the family to stay with the dead child for as long as they wish and to rock, hold, or bathe the child.
- Provide practical help when possible, such as collecting the child's belongings.
- Arrange for spiritual support, based on the family's religious beliefs; pray with the family if no one else can stay with them.

After Death

- Attend the funeral or visitation if there was a special closeness with the family.
- Initiate and maintain contact (e.g., sending cards, telephoning, inviting them back to the unit, making a home visit).
- Refer to the dead child by name; discuss shared memories with the family.
- Discourage the use of drugs or alcohol as a method of escaping grief.
- Encourage all family members to communicate their feelings rather than remaining silent to avoid upsetting another member.
- Emphasize that grieving is a painful process that often takes years to resolve.

**Family* here refers to all significant persons involved in the child's life, such as the parents, siblings, grandparents, or other close relatives or friends.

It is important for families to understand that mourning takes a long time. Whereas acute grief may last only weeks or months, resolving the loss is measured in years. Holidays and anniversaries can be particularly difficult, and people who previously had been supportive may now expect the family to have "adjusted." Consequently, prolonged mourning is often silent and lonely.

Many families never receive the support and guidance that could help them resolve the loss. A plan for regular follow-up with bereaved families can be beneficial. At minimum, one follow-up phone call or meeting with the family should be arranged. Families can also be referred to support groups. When such groups are not available, nurses can be instrumental in bringing families together or facilitating parent and sibling groups. Formal bereavement programs or bereavement counselling can be helpful as well.

Sibling Grief. Each child grieves in their own way and on their own timeline. Children, even adolescents, grieve differently than adults. Adults and children differ more widely in their reactions to death than in their reactions to any other phenomenon. Children of all ages grieve the loss of a loved one, and their understanding of and reactions to death depend on their age and developmental level. Children often revisit their grief as they grow and develop new understandings of death. They grieve in spurts and can be emotional and sad in one instance and then, just as quickly, off and playing. Children can be exquisitely attuned to their parents' grief and will try to protect them by not asking questions or by trying not to upset them. This can set the stage for a sibling to try to become the "perfect child." Children exhibit many of the grief reactions of adults, including physical sensations and illnesses, anger, guilt, sadness, loneliness, withdrawal, acting out, sleep disturbances, isolation, and search for meaning. Again, nurses should be attentive to signs that siblings are struggling with their grief and provide guidance to parents when possible.

Nurses' Reactions to Caring for Dying Children

The death of a patient can be one of the most stressful aspects of nursing (see Family-Centred Care box: A Dying Child: A Nurse's Perspective). Nurses experience reactions to a fatal illness that are very similar to the responses of family members, including denial, anger, depression, guilt, and ambivalent feelings. It is acceptable and important to seek support from colleagues and other resources in the workplace. Seeking support from the child's family is not acceptable, as it puts the therapeutic relationship at risk and crosses professional boundaries for appropriate nurse–patient relationships.

FAMILY-CENTRED CARE

A Dying Child: A Nurse's Perspective

Claire was unresponsive with slow, gasping breathing. Her mother asked me what I thought was happening. I replied honestly, "Your baby is dying because of her brain tumour." The mother put her arms around me and cried. We arranged for Claire to be baptized.

Honesty. As painful as the loss of a child is, my job is to assist the family through this experience. Although I usually wait until a private moment, such as driving home, I found tears streaming down my face as family and friends gathered for Claire's baptism. I went into the kitchen to compose myself, only to find several of my colleagues crying as well. Saying goodbye to a dying child will always be a difficult but shared experience.

—Jeanne O'Connor Egan, RN, MSN, Pediatric Clinical Specialist, Children's Hospital Washington, DC

Strategies that can assist the nurse in remaining able to work effectively in these settings include maintaining good general health, developing well-rounded interests, using distancing techniques such as taking time off when needed, developing and using professional and personal support systems, cultivating the capacity for empathy, focusing on the positive aspects of the caregiver role, and basing nursing interventions on sound theory and empirical observations. Attending shared-remembrance rituals can assist some nurses in resolving grief. Similarly, attending the funeral service for a patient who has died can be a supportive act for both the family and the nurse and in no way detracts from the professionalism of care.

KEY POINTS

- Trends in the treatment of children with chronic illness or complex conditions have focused on developmental age, the child's strengths and uniqueness, family-centred care, normalization, early discharge, home care, mainstreaming, and early intervention.
- Families' reactions to chronic illness or complex conditions are manifested in the following stages: shock and denial, adjustment, reintegration, and acknowledgement.
- The child's reaction to chronic illness or complex conditions depends on the child's developmental level, coping mechanisms, others' reactions, and the illness itself.
- In response to the child with chronic illness or a complex condition, parents may be affected by feelings of inadequacy and failure; excessive demands on time, energy, and financial resources; and strain on their relationship.
- Assessment of the family's adjustment to a child's chronic illness, complex condition, or death includes the availability of a support system, their perception of the event, their coping mechanisms, concurrent stressors, and their response to the child.
- To help parents cope with their child's chronic illness or complex condition, nurses must be attentive to parents' needs, give empathic support, solicit suggestions for care, facilitate communication, provide an opportunity to express feelings, and provide referrals to volunteer and community agencies.
- Supporting the child involves encouraging self-expression, alleviating feelings of being different, and strengthening the child's self-image.
- Effective home care depends on many factors, including a shared decision-making model, the child's medical stability, the family's knowledge of the care required and ability to accommodate the child's care requirements, and professional, financial, and community support.
- Comprehensive, interprofessional discharge planning should begin early and should include the family and a home care coordinator in addition to hospital personnel.
- Appropriate education of the family or primary caregiver can ease the transition to home.
- Care coordination ensures continuity of care, prevents duplication of services, and reduces fragmentation of services. The family often assumes responsibility for care coordination over time.
- The home care nurse must possess a high level of technical expertise while being able to adapt equipment, procedures, and the nursing process to the home setting.
- Collaborative relationships among parents, home care providers, and other health care providers are characterized by effective communication strategies, including open discussion, active listening, awareness and acceptance of differences, and negotiation.
- The nursing process should be adapted to involve the family in each step and to preserve the family's central role in decision making.
- House rules agreed on by the nurse, child, and family enable the family to maintain a feeling of control over their own environment when health care providers are present.

- Individualized home care plans are designed to promote optimum development of the child and to focus on normalization—assessing and incorporating the impact of the child's medical condition and technological requirements on development and self-care.
- Safety in the provision of home care services involves emergency preparations and protocols, appropriate training of family and home care personnel, and the safe use and childproofing of medical equipment.
- Palliative care focuses on improving the quality of lives of children and families who are facing a life-threatening illness and should be instituted early in the management of care of a dying child.
- Children's concept of death is determined by their cognitive ability and their experience with life-threatening illness.
- Siblings have special needs, including the need for information, reassurance about their own health status, assurance that they are not responsible for the illness or death, and support for their own grieving process.
- Special needs of the family facing the unexpected death of a child include support while awaiting news of the child's status; a sensitive pronouncement of death; acknowledgement of feelings of denial, guilt, and anger; an opportunity to view the body; and referrals for support.
- Acute grief is a syndrome with intense and distressing psychological and somatic symptoms that appear at the time of the loved one's death.
- Complicated grief is a prolonged, intense grief that can impede an individual's ability to function on a daily basis.
- In dealing with the stress related to a dying young patient, the nurse can cope successfully through self-awareness, knowledge and practice, an available support system, and maintenance of general good health and by focusing on the rewards of involvement with dying children and their families.

Impact of Intellectual Disability or Sensory Impairment on the Child and Family

Cheryl Sams
Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Define the classifications of intellectual disability.
2. Outline nursing interventions for the child with intellectual disability that promote optimum development, including during hospitalization.
3. Identify the major biological and cognitive characteristics of the child with Down syndrome.
4. Outline nursing interventions for the child with Down syndrome.
5. Identify the major characteristics associated with fragile X syndrome.
6. Describe the general classifications of hearing impairment and the effect on speech.
7. Outline nursing interventions for the child with hearing impairment, including during hospitalization.
8. Describe the common types of visual impairments in children.
9. Outline nursing interventions for the child with visual impairment, including during hospitalization.
10. Outline nursing interventions for the child with retinoblastoma.
11. Outline nursing interventions for the child with autism spectrum disorder.

This chapter discusses the characteristics and diagnosis of specific types of intellectual disability as well as the nursing care required for children with intellectual disability. Although the family's needs and concerns are also a primary focus throughout the chapter, the reader is encouraged to review Chapter 41, which details the family's adjustment to chronic illness and complex conditions in general. Also discussed here are sensory impairments in children (e.g., vision or hearing) and how to adapt care for these children and their families.

INTELLECTUAL DISABILITY

General Concepts

Intellectual disability (ID) is a general term that encompasses any type of mental difficulty or deficiency and is used in place of the term *cognitive impairment*. The term *mental retardation* should never be used as it is stigmatizing and degrading.

The definition of ID in children includes significant impairment in general intellectual function (reasoning, learning, problem solving), social skills, and adaptive behaviour. This focus on conceptual, social, and practical skills enables the development of individual treatment plans designed to enhance functioning. Consistent across these definitions is onset of symptoms before age 18 years (Shapiro & O'Neill, 2020). *Adaptive behaviour* refers to the skills required for people to function in everyday life and include the following:

- Conceptual skills: language, reading, writing, time, number concepts, and self-direction
- Social skills: interpersonal skills, personal and social responsibility, self-esteem, gullibility, naiveté, and ability to follow rules, obey laws, and avoid victimization
- Practical skills: performance of activities of daily living (dressing, feeding, toileting/bathing, mobility), instrumental activities of daily living (e.g., housework, managing money, taking medication, shopping, preparing meals, using a phone), occupational skills, and maintenance of a safe environment

When determining a deficit in adaptive behaviour, a significant delay in at least one of these three skill areas must be present. Children with ID can have varying patterns of ability and may not have deficits in all three areas (Shapiro & O'Neill, 2020).

Diagnosis and Classification. The diagnosis of ID is usually made after professionals or the family suspect that the child's developmental progress is delayed. In some children, it is confirmed at birth because of recognition of distinct syndromes, such as Down syndrome and **fetal alcohol spectrum disorder**. At the other extreme, the diagnosis is made when issues such as speech delays arouse concern. In all cases a high index of suspicion for developmental delay and behavioural signs

BOX 42.1 Early Signs Suggestive of Intellectual Disability

- Dysmorphic features (e.g., Down syndrome, fragile X syndrome)
- Major organ system dysfunction (e.g., difficulty feeding and breathing)
- Unusual muscle tone (e.g., hypotonia or hypertonia) or posture
- Failure to interact with the environment
- Concerns about hearing or vision impairment
- Gross motor delay
- Decreased alertness to voice or movement
- Language difficulties or delay

Adapted from Shapiro, B., & O'Neill, M. E. (2020). Developmental delay and intellectual disability. In R. M. Kliegman, J. St. Geme, N. J. Blum, et al. (Eds.), *Nelson textbook of pediatrics* (21st ed.). Elsevier.

(Box 42.1) is necessary for early diagnosis; routine developmental screening can assist in early identification (see Chapter 33). Delays are typically seen in gross and fine motor and speech development, although the latter is most predictive. *Developmental delay* can be described as any significant lag in a child's physical, cognitive, behavioural, emotional, or social development, when compared against developmental norms.

ID is a permanent impairment encompassing cognitive ability and adaptive behaviour that are functioning significantly below average. The formal diagnosis of ID requires the administration of individual tests of intelligence and adaptive functioning. Results of standardized tests are used in making the diagnosis of ID based on cognitive deficits. The *Bayley Scales of Infant and Toddler Development* (BSID-III) is the most commonly used infant intelligence scale that provides an assessment of cognitive, language, motor, behaviour, social-emotional, and general adaptive abilities for children up to the age of 3½ years (Shapiro & O'Neill, 2020). In the absence of clear-cut evidence of ID, it is more appropriate to use a diagnosis of developmental delay. For children older than 3 years the most commonly used psychological tests are the *Wechsler Scales* (Shapiro & O'Neill, 2020). Tests for assessing adaptive behaviours include the *Vineland Adaptive Behavior Scale* (VABS-3), which involves semistructured interviews with parents and/or caregivers and teachers that assess adaptive behaviour in four domains: communication, daily living skills, socialization, and motor skills (Shapiro & O'Neill, 2020). Informal appraisal of adaptive behaviour may be made by those fully familiarized with the child (e.g., teachers, parents, other care providers). Frequently these observations lead parents to seek evaluation of the child's development.

Global developmental delay (GDD) is a term often used to describe children under 5 years of age whose limitations have not yet resulted in a formal diagnosis of ID. GDD is a diagnosis given to children less than 5 years of age who display significant delay in acquiring early childhood developmental milestones in two or more domains of development. These domains include receptive and expressive language, gross and fine motor function, cognition, social and personal development, and activities of daily living (American Psychological Association [APA], 2013).

A more useful approach for clinical application is classification based on educational potential or symptom severity. For educational purposes the term *educable ID* corresponds to the mildly impaired group, which constitutes about 85% of all people with ID. *Trainable ID* generally applies to children with moderate levels of ID and accounts for about 10% of the intellectually disabled population (APA, 2013).

Etiology. The causes of severe ID are primarily genetic, biochemical, and infectious. Although the etiology is unknown in most cases, familial, social, environmental, and organic causes may predominate. Among individuals with ID, a sizable proportion of cases are linked to Down syndrome, fragile X syndrome, or fetal alcohol spectrum disorder. General categories of events that may lead to intellectual disability include the following (Shapiro & O'Neill, 2020):

- Infection and intoxication, such as congenital rubella, syphilis, Zika virus, maternal drug consumption (e.g., fetal alcohol spectrum disorder), chronic lead ingestion, or **kernicterus**
- Trauma or physical agent (i.e., injury to the brain suffered during the perinatal period)
- Inadequate nutrition and metabolic disorders, such as phenylketonuria or congenital hypothyroidism
- Gross postnatal brain disease, such as neurofibromatosis and tuberous sclerosis
- Unknown prenatal influence, including cerebral and cranial malformations, such as microcephaly and hydrocephalus
- Chromosomal abnormalities resulting from radiation, viruses, chemicals, parental age, and **genetic mutations**, such as Down syndrome and fragile X syndrome
- Gestational disorders, including prematurity, low birth weight, and postmaturity
- Psychiatric disorders that have their onset during the child's developmental period up to age 18 years, such as autism spectrum disorders (ASDs)
- Environmental influences, including evidence of a stressed environment associated with a history of ID among parents and siblings

Prenatal diagnosis and subsequent pregnancy interruptions has led to a decreasing incidence of Down syndrome. Newborn screening with early treatment has virtually eliminated ID caused by phenylketonuria and congenital hypothyroidism. However, a continued high prevalence of fetal exposure to illicit substances and improved survival of very-low-birthweight premature infants has counterbalanced this effect.

Nursing Care. Nurses play a major role in identifying children with ID. In the newborn and early infancy periods, few signs are present, with the exception of Down syndrome (see discussion later in the chapter). After this age, however, delayed **developmental milestones** are the major clues to ID. In addition, nurses must have a high index of suspicion for early behavioural patterns that may suggest ID (see Box 42.1). Parental concerns, such as delayed development compared with that of siblings, need to be taken seriously. All children should receive regular developmental assessment, and the nurse is often the person responsible for performing such assessments (see Chapter 33). When delays are found, the nurse must use sensitivity and discretion in revealing this finding to parents.

Educating the child and family. To teach children with ID, it is necessary to investigate their learning abilities and deficits. This is important for the nurse who may be involved in a home care program or who may be caring for the child in a health care setting. The nurse who understands how these children learn can effectively teach them basic skills or prepare them for various health-related procedures.

Children with ID have a marked deficit in their ability to discriminate between two or more stimuli because of difficulty in recognizing the relevance of specific cues. However, these children can learn to discriminate if the cues are presented in an exaggerated, concrete form and if all extraneous stimuli are eliminated. For example, the use of colours to emphasize visual cues or the use of singing or rhymes to stress auditory cues can help them learn. Their deficit in discrimination also implies that concrete ideas are learned much more effectively than abstract ideas. Therefore, demonstration is preferable to verbal explanation, and learning should be directed toward mastering a skill rather than understanding the scientific principles underlying a procedure.

Another cognitive deficit is in short-term memory. Whereas children of average intelligence can remember several words, numbers, or directions at one time, children with ID are less able to do so. Therefore, they need simple, one-step directions. Learning through a step-by-step process requires a task analysis, in which each task is separated into its necessary components and each step is taught completely before proceeding to the next activity.

One critical area of learning that has had a tremendous impact on education for individuals with ID is motivation. Programs based on the motivational principles of behaviour modification, employing positive reinforcement for specific tasks or behaviours, have demonstrated marked improvement in children's ability to learn. Advances in technology have greatly aided in providing reinforcement, especially in children with severe disabilities and who may have physical disabilities that limit their range of capabilities. For example, with the use of specially designed switches, children can be given control of some event in the environment, such as turning on the computer or television. The screen becomes reinforcement for activating the switch. Repetitive use of these switches provides an early, simple association with a technical device that may progress to increasingly complex aids.

The care strategies for children with an ID should be multimodal, with efforts directed at all aspects of the child's life: health, education, social and recreational activities, behaviour issues, and associated impairments. Support for parents and siblings should also be provided (Shapiro & O'Neill, 2020). Early intervention programs comprise a systematic program of therapy, exercises, and activities designed to address developmental delays in children with disabilities in order to help them achieve their full potential (Canadian Down Syndrome Society, 2019). Nurses working with these families need to be aware of the types of programs in their community. Under the *Education Act* (1956–1996) and the *Canadian Human Rights Act* (1977), provinces and territories are required to provide educational opportunities for all children with disabilities (see Additional Resources at the end of this chapter). Although early intervention programs are available in Canada, Canadian provinces and territories vary widely in their support, thus many expenses may fall to the parents. Services may be provided by private organizations such as the Canadian Down Syndrome Society and Easter Seals Canada (see Additional Resources). Parents should inquire about these programs by contacting the appropriate agencies.

The child's education should begin as soon as possible. As children grow older, their education should be directed toward vocational training that prepares them for as independent a lifestyle as possible that is within their scope of abilities and interest. When school age, children with ID often will have an individualized education plan (IEP) developed for the school setting. IEPs are created on a case-by-case basis, identifying specific learning needs and outlining any accommodations required for the student, including how the school will ensure that these are met. These plans require communication and collaboration between the parents, health care team and teaching team, and the child if they are to be successful (see Additional Resources for links to information related to IEP).

Teaching the child self-care skills. Parents of a child with ID need assistance in promoting normal developmental skills that are almost automatically learned by other children. There is no way to predict when a child should be able to master self-care skills, such as feeding, toileting, dressing, and grooming, because the age at which children with ID are able to accomplish such functions varies significantly.

Teaching self-care skills also requires a working knowledge of the individual steps needed to master a skill. For example, before beginning a self-feeding program, the nurse needs to perform a task analysis. After a task analysis, the child is observed in a particular situation, such as eating, to determine what skills are possessed and the child's developmental readiness to learn the task. Family members are included in this process because their "readiness" is as important as the child's. Numerous self-help aids are available to facilitate independence and can help eliminate some of the difficulties of learning, such as using a plate with suction cups to prevent accidental spills (see Additional Resources at the end of this chapter).

Promoting the child's optimum development. Optimum development involves more than achieving independence. It requires appropriate guidance for establishing acceptable social behaviour and personal feelings of self-esteem, worth, and security. These attributes are not simply learned through a stimulation program. Rather, they must arise from the genuine love and caring of family members. However, families need guidance in providing an environment that fosters optimum development. Often the nurse can provide this help.

Another important area for promoting optimum development and self-esteem is ensuring the child's physical well-being. Any congenital defects, such as cardiac, gastrointestinal, or orthopedic anomalies, should be repaired, if possible. Plastic surgery may be considered when the child's appearance can be substantially improved. Dental health is significant, and orthodontic and restorative procedures can often improve facial appearance immensely.

Encouraging play and exercise. Children who are intellectually disabled have the same needs for recreation and exercise as other children. However, because of the children's slower development, parents may be less aware of the need to provide such activities (Figure 42.1). Therefore, the nurse needs to guide parents toward selection of suitable play and exercise activities. Because play for children in each age group has been discussed in earlier chapters (see Chapter 32, Role of Play in Development, and Chapters 36–39), only the exceptions are presented here.

The type of play is based on the child's developmental age, although the need for sensorimotor play may be prolonged for several years. Parents should use every opportunity to expose the child to as many different sounds, sights, and sensations as possible. Appropriate play includes musical mobiles, stuffed toys, water play, floating toys, a rocking chair or horse, a swing, bells, and rattles. The child should be taken on outings, such as trips to the grocery store or shopping centre. Other people should be encouraged to visit in the home, and the child should be related to directly, such as by cuddling, holding, and rocking the child and talking to the child in the en face (face-to-face) position.

Toys can be selected for their recreational and educational value. For example, a large inflatable beach ball is a good water toy; it

Fig. 42.1 Placing an attractive object outside the child's reach encourages crawling movements. (iStock.com/twinsterphoto)

encourages interactive play and can be used to learn motor skills, such as balance, rocking, kicking, and throwing. A doll with removable clothes and different types of closures can help the child learn dressing skills. Musical toys that mimic animal sounds or respond with social phrases are excellent ways of encouraging speech. Toys should be simple in design so that the child can learn to manipulate them without help. For children with severe cognitive and physical impairment, electronic switches can be used to allow them to operate toys.

Suitable activities for physical activity should be based on the child's size, coordination, physical fitness and maturity, motivation, and health (Figure 42.2). Some children may have physical challenges that prevent participation in certain sports, such as atlantoaxial instability in children with Down syndrome. These children often have greater success in individual and dual sports than in team sports and enjoy themselves most with children of the same developmental level. The Special Olympics provides children with a unique competitive opportunity (see Additional Resources section at the end of this chapter).

Safety is a major consideration in selecting recreational and exercise activities. For example, toys that may be appropriate developmentally may present dangers to a child who is strong enough to break them or use them incorrectly.

Providing means of communication. Verbal skills are typically delayed more than other physical skills. Speech requires hearing and interpretation (receptive skills) and facial muscle coordination (expressive skills). Because both types of skills may be impaired, these children need frequent audiometric testing and should be fitted with hearing aids if indicated. In addition, they may need help in learning to control their facial muscles. For example, some children may need tongue exercises to correct the tongue thrust or gentle reminders to keep the lips closed.

Fig. 42.3 A child with intellectual and physical impairments can activate electronic and communication equipment by moving a device near her head.

Nonverbal communication may be appropriate for some of these children, and various devices are available. For the child without associated physical disabilities, a talking picture board is helpful. For children with physical limitations, several adaptations or types of communication devices are available to facilitate selection of the appropriate picture or word (Fig. 42.3). Some children may be taught sign language or Blissymbols—a highly stylized system of graphic symbols that represent words, ideas, and concepts. Although the symbols require education to learn their meaning, no reading skill is needed. The symbols are usually arranged on a board, and the person points or uses some type of selector to convey a message.

Establishing discipline. Discipline must begin early. Limit-setting measures need to be simple, consistently applied, and appropriate for the child's mental age. Control measures are based primarily on teaching a specific behaviour rather than on understanding the reasons behind it. Stressing moral lessons is of little value to a child who lacks the cognitive skills to learn from self-criticism or from a lesson based on previous wrong-doing. Behaviour modification, especially reinforcement of desired actions, and time-out are appropriate forms of behaviour control.

Encouraging socialization. Acquiring social skills is a complex task. Active rehearsal with role-playing and practice sessions and positive reinforcement for desired behaviour have been the most successful approaches. Parents should be encouraged early to teach their child socially acceptable behaviour: waving goodbye, saying "hello" and "thank you," responding to the child's name, greeting visitors, and sitting modestly. The teaching of socially acceptable sexual behaviour is especially important in order to minimize sexual exploitation. Parents also need to expose the child to strangers so they can practise manners, as there is generally no automatic transfer of learning from one situation to another.

Dressing and grooming are also important aspects of socialization. A child who is dressed in age-appropriate clothing and is well groomed is much more likely to be accepted and to develop healthy

self-esteem. Many attractive outfits can be adapted with self-adhering fasteners and elastic openings to facilitate self-dressing.

Opportunities for social interaction and infant stimulation programs should begin at an early age. As soon as possible, parents should enroll the child in an appropriate preschool program. Not only do these programs provide education and training, but they also offer an opportunity for social experiences among children. As children grow older, they need to have peer experiences similar to those of other children, including group outings, sports, and organized activities such as Scouts and Special Olympics. Nurses should assess the child's abilities and encourage others (e.g., parents, teachers) to promote developmentally appropriate peer interaction, such as classroom and school activities, dance classes, clubs, vacations, and family outings (Shapiro & O'Neill, 2020).

Providing information on sexuality. Adolescence may be a particularly difficult time for the family, especially regarding the child's sexual behaviour, possibility of pregnancy, future plans to marry, and ability to be independent. Frequently, little anticipatory guidance has been offered to parents to prepare the child for physical and sexual maturation. The nurse can help in this area by providing parents with information about sexuality education that is geared toward the child's developmental level. For example, the adolescent girl needs a simple explanation of menstruation and instructions on personal hygiene during the menstrual cycle.

These adolescents also need practical sexual information regarding anatomy, physical development, and conception. Because of their easy persuasion and lack of judgement, they need a well-defined, concrete code of conduct. The subtleties of social sexual behaviour are less beneficial than specific instructions for handling certain situations. For example, an adolescent should be firmly told never to go alone anywhere with any person they do not know well. To protect children from abusive sexual activities, parents must closely observe their teenager's activities and associates. Contraceptive protection for these adolescents is often a parental concern.

Parents of these adolescents are often concerned about the advisability of marriage between two individuals with significant ID. There is no conclusive answer for this situation; each must be judged individually. In some instances, marriage is possible. The nurse can discuss this topic with parents and with the prospective couple, stressing suitable living accommodations and contraceptive methods to prevent pregnancy. If children are conceived, the parents require specialized assistance in learning to meet the needs of their offspring.

Helping the family adjust to future care. Not all families are able to cope with home care of their affected child, especially one who is severely or profoundly impaired or has multiple disabilities (see Chapter 41 for strategies to support families of children with chronic illnesses). Older parents may not be able to assume care responsibilities after they reach retirement or older age. For these parents, the decision regarding residential placement is a difficult one, and the availability of such facilities varies widely. The nurse working with a family of a child with ID should help them investigate and evaluate various programs, in addition to assisting them in adjusting to the decision for placement.

Caring for the child during hospitalization. Caring for the child during hospitalization can be a special challenge. Frequently, nurses are unfamiliar with caring for a child with ID, and they may cope with their feelings of insecurity and fear by ignoring or isolating the child. Not only is this approach nonsupportive, it may also be harmful to the child's sense of self-esteem and optimum development, and it may hamper the parents' ability to cope with the stress of hospitalization. A more successful approach is to use a mutual participation model in planning the child's care. Parents are encouraged to stay with their child but should not be made to feel as if the responsibility is theirs alone.

When the child is admitted, a detailed history should be taken, especially documentation of all self-care activity. Questions about the child's abilities are approached positively. For example, rather than asking, "Is your child toilet trained yet?" the nurse may state, "Tell me about your child's toileting habits." The assessment should also focus on any special devices the child uses, effective measures of limit-setting, unusual or favourite routines, and any behaviours that may require intervention. If the parent states that the child engages in self-injurious activities (such as head banging or self-biting), the nurse should inquire about events that precipitate them and techniques that the parents use to manage them. The use of a risk-informed, early-intervention strategy for addressing self-injurious, aggressive, and destructive behaviours in children with severe ID may help to better manage and prevent this behaviour (Davies & Oliver, 2016).

The nurse also needs to assess the child's functional level of eating and playing; ability to express needs verbally; progress in toilet independence; and relationship with objects, toys, and other children. The child should be encouraged to be as independent as possible in the hospital.

Realizing that the child may be lonely in the hospital, the nurse can make certain that toys and other activities are provided. The child should be placed in a room with other children of approximately the same developmental age, preferably a room with only two beds, to avoid overstimulation. The nurse should treat the child with dignity and respect in a manner that promotes acceptance and understanding by other children, parents, and those with whom the child comes in contact in the hospital.

Procedures should be explained to the child through methods of communication that are at the appropriate cognitive level. Generally, explanations should be simple, short, and concrete, emphasizing what the child will experience physically. Demonstration either through actual practice or with visual aids is always preferable to verbal explanation. The nurse needs to repeat instructions often and evaluate the child's understanding by asking questions such as "What will it feel like?" "Show me how you must lie," or "Where will the dressing be?" Parents should be included in preprocedural teaching for their own learning and to help the nurse learn effective methods of communicating with the child.

During hospitalization, the nurse should also focus on growth-promoting experiences for the child. For example, hospitalization may be an excellent opportunity to emphasize to parents the abilities that the child does have but has not had the opportunity to practise, such as self-dressing. It may also be an opportunity for social experiences with peers, group play, or new educational and recreational activities. For example, one child who had the habit of screaming and kicking demonstrated a decrease in these behaviours after he learned to pound pegs and use a punching bag. Through social services, the parents may become aware of specialized programs for the child. Hospitalization may also offer parents a respite from everyday care responsibilities and an opportunity to discuss their feelings with a caring professional.

Assisting in measures to prevent intellectual disability. Besides having a responsibility to families who have a child with ID, nurses also need to be involved in programs aimed at preventing ID. Many of the familial, social, and environmental factors known to cause mild impairment are preventable. Counselling and education of pregnant patients and of people considering pregnancy can reduce or eliminate factors that increase the risk of prematurity and intrauterine growth restriction. Prenatal factors that have been associated with increased risk of ID include advanced maternal age, low education level, third or more parity, alcohol use, tobacco use, diabetes, hypertension, epilepsy, and

asthma. Preterm birth along with low birth weight and male sex have been associated with an increased risk of ID (Huang et al., 2016).

Interventions should be directed toward improving maternal health by educating people of childbearing age about the dangers of exposure to chemicals, including prenatal alcohol use, which affects organogenesis, craniofacial development, and cognitive ability. Other important preventive strategies include adequate prenatal care; optimal medical care of high-risk newborns; rubella immunization; genetic counselling and prenatal screening, especially for Down or fragile X syndrome; use of folic acid supplements to prevent neural tube defects during pregnancy and during the childbearing years; newborn screening for treatable inborn errors of metabolism, such as congenital hypothyroidism, phenylketonuria, and galactosemia; and early appropriate therapies and rehabilitation services for children with ID.

Down Syndrome

Down syndrome is the most common chromosomal abnormality of a generalized syndrome. In Canada, the number of children born with Down syndrome averages approximately 1 in every 750 newborns (Government of Canada, 2017). It occurs in people of all ethnicities and economic levels. Despite the national increasing rates of advanced maternal age at birth, the Down syndrome national birth prevalence rates have remained stable over the past decade. This stability has most likely resulted from increased access to and utilization of prenatal screening and testing and subsequent termination of pregnancies affected by Down syndrome (Government of Canada, 2017).

Etiology. While the cause of Down syndrome is not known, evidence from cytogenetic and epidemiological studies supports the concept of multiple causality. Approximately 95% of all cases of Down syndrome are attributable to an extra **chromosome** 21, thus the name *nonfamilial* **trisomy** *21* (Government of Canada, 2017). Although children with trisomy 21 are born to parents of all ages, there is a statistically greater risk among older women, particularly those older than 35 years of age (see Chapter 9, Abnormalities of Chromosome Number). For example, in child-bearing persons 35 years of age, the chance of conceiving a child with Down syndrome is about 1 in 350 live births, but in child-bearing persons age 45 it is about 1 in 30. However, the majority (about 50%) of infants with Down syndrome are born to persons younger than age 35, because younger people have higher fertility rates (Government of Canada, 2017). Approximately 3 to 4% of cases may be caused by translocation of chromosomes 15 and 21 or 22. This type of genetic aberration is usually hereditary and is not associated with advanced parental age. Between 1 and 2% of affected persons demonstrate *mosaicism*, which refers to the mixture of normal and abnormal cell types. The degree of cognitive and physical impairment is related to the percentage of cells with the abnormal chromosome makeup.

Diagnostic Evaluation. Down syndrome can usually be diagnosed by the clinical manifestations alone (Box 42.2 and Figure 42.4), but a chromosome analysis should be done to confirm the genetic abnormality.

Several health conditions are associated with Down syndrome. Many of these children have congenital heart malformations, the most common being septal defects. Congenital heart defects were reported in 40.9% of Down syndrome cases, of which 98% were reported as live births in Canada (Irvine et al., 2015). Respiratory tract infections are prevalent and, when combined with cardiac anomalies, are the chief cause of death, particularly during the first year of life. Hypotonicity of chest and abdominal muscles and dysfunction of the immune system probably predispose the child to the development of respiratory tract infections. Other physical challenges include thyroid dysfunction, especially congenital hypothyroidism, and an increased incidence of leukemia.

Therapeutic Management. Although no cure exists for Down syndrome, a number of therapies are advocated, such as surgery to correct some congenital anomalies (e.g., heart defects, strabismus). These children also benefit from an evaluative echocardiogram soon after birth and regular medical care. Evaluation of sight and hearing is essential, and treatment of otitis media is required to prevent auditory impairment, which can influence cognitive function. Periodic testing of thyroid function is recommended, especially if growth is severely delayed.

Some additional nursing considerations include providing ongoing assessment and monitoring of specific systems, including heart, gastrointestinal, and orthopedic, throughout early childhood. Therefore, the nurse should be aware of specific ailments that are most closely associated with Down syndrome. About 15% of children with Down syndrome have atlantoaxial instability; almost all of the children are asymptomatic. Symptoms of the disorder include neck pain, weakness, and torticollis. Affected children are at risk for spinal cord compression (Ivan & Cromwell, 2014).

! NURSING ALERT

Report immediately any child with the following signs of spinal cord compression:

- Persistent neck pain
- Loss of established motor skills and bladder or bowel control
- Changes in sensation

Prognosis. Life expectancy for persons with Down syndrome has improved in recent years but remains lower than for the general population. The life expectancy of a person with Down syndrome continues to increase because more services and supports are available. Quality of life is a significant factor for this group; many people with Down syndrome live beyond 60 years of age and will require assistance in having their long-term health care, social, and leisure needs met (Canadian Down Syndrome Society, 2019).

Nursing Care

Supporting the family at the time of diagnosis. Because of the unique physical characteristics, the newborn with Down syndrome is usually diagnosed at birth if a prenatal diagnosis had not already been established. Parents should be informed of the diagnosis at this time. Parents usually prefer that both of them be present if possible during the informing interview so that they can support one another emotionally. They appreciate receiving reading material about the syndrome and being referred to parent groups or professional counselling for help or advice (see Additional Resources section at the end of this chapter). It is recommended that "Congratulations!" be the health care providers' first words to any new parent; this can have a lifelong impact when speaking to the family of a child determined to have Down syndrome. The use of positive words and value-neutral language—not saying "I'm sorry" or "I have bad news"—can create a lasting impression with families. Nurses need to ensure that they include the positive aspects of having a child with Down syndrome, such as most children with this syndrome are healthy (see Chapter 41 for more information on how to help parents cope with chronic illness in their child).

After parents are aware of the diagnosis, they are confronted with the fact of losing their "perfect" or "dream" child and accepting the

BOX 42.2 Clinical Manifestations of Down Syndrome

Head and Eyes
Separated sagittal suture
Brachycephaly
Rounded and small skull
Flat occiput
Enlarged anterior fontanel
Oblique palpebral fissures (upward, outward slant)
Inner epicanthal folds
Speckling of iris (Brushfield's spots)

Nose and Ears
Small nose
Depressed nasal bridge (saddle nose)
Small ears and narrow canals
Short pinna (vertical ear length)
Overlapping upper helices
Conductive hearing loss

Mouth and Neck
High, arched, narrow palate
Protruding tongue
Hypoplastic mandible
Delayed tooth eruption and microdontia
Abnormal alignment of teeth common
Periodontal disease
Neck skin excess and laxity
Short and broad neck

Chest and Heart
Shortened rib cage
Twelfth rib anomalies
Pectus excavatum or carinatum
Congenital heart defects are common (e.g., atrial septal defect, ventricular septal defect)

Abdomen and Genitalia
Protruding, lax, and flabby abdominal muscles
Diastasis recti abdominis
Umbilical hernia
Small penis
Cryptorchidism
Bulbous vulva

Hands and Feet
Broad, short hands and stubby fingers
Incurved little finger (clinodactyly)
Transverse palmar crease
Wide space between big and second toes
Plantar crease between big and second toes
Broad, short feet and stubby toes

Musculoskeletal and Skin
Short stature
Hyperflexibility and muscle weakness
Hypotonia
Atlantoaxial instability
Dry, cracked, and frequent fissuring
Cutis marmorata (mottling)

Other
Reduced birth weight
Learning difficulty (average intelligence quotient of 50)
Hypothyroidism common
Impaired immune function
Increased risk of leukemia
Early-onset dementia (in one third)
Increased prevalence of gastrointestinal disorders/complications (i.e., Hirschsprung disease, tracheoesophageal fistula, imperforate anus, celiac disease, constipation, decreased motility)

Adapted from Bacino, C. A., & Lee, B. (2020). Cytogenetics. In R. M. Kliegman, J. St. Geme, N. J. Blum, et al. (Eds.), *Nelson textbook of pediatrics* (21st ed.). Elsevier.

Fig. 42.4 Down syndrome in an infant. Note small, square head with upward slant to eyes, flat nasal bridge, protruding tongue, mottled skin, and hypotonia.

child that they have. Parents' responses to the child may greatly influence decisions regarding future care. The nurse must carefully answer questions concerning the child's developmental potential. Institutionalization is no longer an option. For families unable or unready to take the newborn home, specialized foster care or adoption are other options (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Diagnosis of Down Syndrome

The parents of Melissa, a newborn diagnosed as having Down syndrome, ask the nurse, "What are we supposed to do with her?" They further state that they already have three other children at home.

Questions
1. What evidence should you consider regarding this condition?
2. What additional information is required at this time?
3. List the nursing intervention(s) that have the highest priority.
4. Identify important patient-centred outcomes with reference to your nursing interventions.

Assisting the family in preventing physical challenges. Many of the physical characteristics of infants with Down syndrome present nursing challenges. The hypotonicity of muscles and hyperextensibility of joints complicate positioning. The limp, flaccid extremities resemble the posture of a rag doll; as a result, holding the infant can be cumbersome. Sometimes parents perceive this lack of moulding to their bodies as evidence of inadequate parenting. The extended body position promotes heat loss, because more surface area is exposed to the environment. Encourage the parents to swaddle or wrap the infant snugly in a blanket before picking up the child, to provide security and warmth. The nurse can also discuss with parents their feelings concerning attachment to the child, emphasizing that the child's lack of clinging or moulding is a physical characteristic and not a sign of detachment or rejection.

Decreased muscle tone compromises respiratory expansion. In addition, the underdeveloped nasal bone causes a chronic issue of inadequate drainage of mucus. The constant stuffy nose forces the child to breathe by mouth, which dries the oropharyngeal membranes, increasing the susceptibility to upper respiratory tract infections. Measures to lessen these challenges include clearing the nose with a bulb-type syringe, rinsing the mouth with water after feedings, increasing fluid intake, and using a cool-mist vaporizer to keep the mucous membranes moist and the secretions liquefied. Other helpful measures include changing the child's position frequently, performing postural drainage with percussion if necessary, practising good hand hygiene, and properly disposing of soiled articles such as tissues. If antibiotics are ordered, the nurse needs to stress to the parents the importance of completing the full course of therapy for successful eradication of the infection and prevention of the growth of resistant organisms.

Inadequate drainage resulting in pooling of mucus in the nose also interferes with feeding. Because the child breathes by mouth, sucking for any length of time is difficult. When eating solids, the child may gag on the food because of mucus in the oropharynx. Parents are advised to clear the nose before each feeding; give small, frequent feedings; and allow opportunities for rest during mealtime.

The protruding tongue may interfere with breastfeeding and with eating solid foods. Parents need to know that the tongue thrust is not an indication of refusal to feed but a physiological response. For optimum growth and immune protection, breastfeeding is recommended for all infants and is particularly important for an infant with Down syndrome, given their susceptibility to respiratory infections. In addition to increased nutrition, the repetitive sucking action during breastfeeding will strengthen the infant's lips, tongue, and face, which will help in the future with speech development. Infants with Down syndrome often have low muscle tone, which reduces muscle strength in their tongue and lips; thus they need good head, neck, and upper back support during feeding. A gentle, steady pressure on the base of the infant's head will help to improve sucking and decrease fatigue. Different holds, such as the cross-cradle and football holds, may provide better support. Some infants with Down syndrome have bouts of gulping and coughing when feeding. To avoid such challenges, the mother can hold the infant so that the throat and neck are above the nipple line, or they can lean back farther, such as in a rocking chair. See Chapter 27 and Additional Resources for more breastfeeding tips. For feeding of solid foods, parents are advised to use a small but long, straight-handled spoon to push the food toward the back and side of the mouth. If food is thrust out, it should be refed.

Dietary intake also needs supervision. Decreased muscle tone affects gastric motility, predisposing the child to constipation. Dietary measures such as increased fibre and fluid promote evacuation. The child's eating habits may need careful scrutiny to prevent obesity. Height and weight measurements should be obtained on a serial basis, especially during infancy. Because these children grow more slowly than the general pediatric population, their growth should be assessed using the Canadian growth charts, which were adapted from the World Health Organization (WHO) (Zemel et al., 2015).

During infancy the child's skin is pliable and soft. However, it gradually becomes rough and dry and is prone to cracking and infection. Skin care involves the use of minimal soap and application of lubricants. Lip balm should be applied to the lips, especially when the child is outdoors, to prevent excessive chapping.

Assisting in prenatal diagnosis and genetic counselling. The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends that all pregnant patients in Canada, regardless of age, be informed and offered the choice of a prenatal screening test for the most common clinically significant fetal aneuploidies, which include Down syndrome (Audibert et al., 2017) (see Chapter 13, First-Trimester Screening). If prenatal testing indicates that the fetus is affected, the nurse should encourage the parents to express their feelings about considering elective abortion and support their decision to terminate or proceed with the pregnancy.

Fragile X Syndrome

Fragile X syndrome (FXS) is the most common identifiable genetic cause of ID and autism spectrum disorders (Berry-Kravis, 2014). The prevalence of FXS has been estimated at 1 in 4 000 males and 1 in 5 000 to 8 000 females. In Canada, between the years, 2012 and 2014, 41 cases of FXS were reported, the majority being male (Aubertin, 2015). The average age of diagnosis in Canada is 3.5 years. It has been described in all ethnic groups. Because the clinical phenotype is often nonspecific in infants and young children with FXS, the Canadian Paediatric Society (CPS) recommends that all boys and girls with GDD and ID be tested for FSX (Bélanger et al., 2018). Children often have comorbid diagnoses, including speech and communication challenges (71%) and autism (50%) (CPS & Public Health Agency of Canada, 2013).

The syndrome is caused by an abnormal gene on the lower end of the long arm of the X chromosome. Chromosome analysis may demonstrate a fragile site (a region that fails to condense during mitosis and is characterized by a nonstaining gap or narrowing) in the cells of affected males and females and in carrier females. This fragile site has been determined to be caused by a gene mutation that results in excessive repeats of nucleotide in a specific DNA segment of the X chromosome. The number of repeats in a normal individual is between 6 and 50. An individual with 50 to 200 base-pair repeats is said to have a permutation and is thus a carrier. When passed from parent to child, these base-pair repeats can expand to 200 or more, which is termed a *full mutation*. This expansion occurs only when a carrier mother passes the mutation to offspring; it does not occur when a carrier father passes the mutation to daughters.

The inheritance pattern has been termed *X-linked dominant with reduced penetrance*. This is in distinct contrast to the classic *X-linked recessive pattern,* in which all carrier females have normal features and all affected males have symptoms of the disorder; no males are carriers. Therefore, genetic counselling of affected families is more complex than for families with a classic X-linked disorder such as hemophilia. Both affected sexes are capable of transmitting FXS. Prenatal diagnosis of the fragile X gene mutation is now possible with direct DNA testing in a family with an established history, using amniocentesis or chorionic villus sampling. The *FMR1* mutation testing is highly accurate and is being researched for incorporation into the newborn universal screening program. In Canada, newborn genetic screening for FXS is available. Such screening must be accompanied by genetic counselling for future pregnancy planning and can aid in early intervention treatment. Guidelines for genetic testing in healthy children are provided in Box 42.3.

BOX 42.3 Guidelines for Genetic Testing of Healthy Children

- Parents need to be informed of potential psychological and social risks when genetic testing of healthy children is being considered.
- Open discussion of familial genetic risk should be encouraged within the context of the family unit and done in an age-appropriate manner.
- The best interests of the child should be the primary consideration when contemplating testing.
- Genetic testing should be done to confirm a diagnosis in a child with symptoms, to allow for adequate medical monitoring, prophylaxis, or treatment.
- Genetic testing should be deferred if it is predicted that a genetic condition will not be present until adulthood, until the child is competent to decide if the genetic information is wanted.
- For carrier status for conditions that will be important in reproductive decision making, the testing should be discouraged until the child can fully participate in the decision to be tested.
- A request for genetic testing by a competent, well-informed adolescent for the purpose of reproductive decision making should be considered, accompanied by appropriate counselling. The decision to include their family in the decision making should be made by the adolescent.
- Parents rarely insist that genetic testing of healthy children be carried out when there is no medical or other benefit to the child; in this instance, the health care provider is not obligated to carry out testing that is not in the best interests of the child. In exceptional circumstances, not testing may create more harm than testing, and in these cases a referral for ethics or legal opinion may be appropriate.
- Infants and children being considered for adoption should not be subjected to genetic testing when there is no timely medical benefit.

Adapted from Arbour, L., & Canadian Paediatric Society Bioethics Committee. (2003). Guidelines for genetic testing of healthy children. *Paediatrics & Child Health, 8*(1), 42–45 Addendum. Reaffirmed 2017.

Clinical Manifestations. The classic trend of physical findings in adult men with FXS consists of a long face with a prominent jaw (prognathism); large, protruding ears; and large testes (macroorchidism). In prepubertal children, however, these features may be less obvious, and behavioural manifestations may initially suggest the diagnosis (Box 42.4). In carrier females the clinical manifestations vary greatly.

Therapeutic Management. FXS has no cure. Medical treatment may include the use of serotonin agents such as carbamazepine (Tegretol) or fluoxetine (Prozac) to control violent temper outbursts and the use of central nervous system stimulants or clonidine (Catapres) to improve attention span and decrease hyperactivity. Recent pharmacological targeted treatments to correct underlying neural dysfunction for FXS have been unsuccessful in clinical trials and further research is needed (Westmark, 2019). For example, metformin may correct core symptoms of FXS and other neurological disorders, but further research is needed to assess the effectiveness for this treatment as well (Gantois et al., 2019).

All affected children require referral to early intervention programs (speech and language therapy, occupational therapy, and special education assistance) and multidisciplinary assessment, including cardiology (i.e., mitral valve prolapse), neurology (i.e., seizures), and orthopedic anomalies.

BOX 42.4 Clinical Manifestations of Fragile X Syndrome

Physical Features

Increased head circumference
Long, wide, and protruding ears
Long, narrow face with prominent jaw
Strabismus
Mitral valve prolapse, aortic root dilation
Hypotonia
Enlarged testicles (especially postpubertally)

Behavioural Features

Mild to severe cognitive impairment
Speech delay; may have rapid speech with stuttering, word repetition
Short attention span, hyperactivity
Hypersensitivity to taste, sounds, and touch
Intolerance to change in routine
Autistic-like behaviours such as social anxiety and gaze aversion

Prognosis. Individuals with FXS are expected to have a normal lifespan. Their ID may be improved through behavioural and educational interventions that usually begin in preschool-age children.

Nursing Care. Because ID is a fairly consistent finding in individuals with FXS, the care given to these families is the same as for any child with ID. Because the disorder is hereditary, genetic counselling is necessary to inform parents and siblings of the risks of transmission. In addition, any male or female with unexplained or nonspecific ID should be referred for genetic testing and, if needed, counselling. Families with a member affected by the disorder should be referred to the Fragile X Research Foundation of Canada (see Additional Resources at the end of this chapter).

COMMUNICATION IMPAIRMENT

Autism Spectrum Disorders

Autism spectrum disorders (ASDs) are lifelong complex, neurodevelopmental disorders of unknown etiology. ASD is characterized by impairments in social communication, repetitive, restricted patterns of behaviour, and unusual sensory sensitivities or interests (Zwaigenbaum et al., 2019). In Canada, ASD occurs in 1 in 66 children and youth. It is four times more common in males than in females (although females are more severely affected) and is not related to socioeconomic level, ethnicity, or parenting style. The number of individuals with ASD is increasing globally as well as in Canada (Government of Canada, 2018). Evidence suggests that ASD can be reliably diagnosed by 2 years of age in some children, though subtler cases may not present fully until later. Despite increasing awareness of early signs, the mean age of diagnosis remains 4 to 5 years of age (Zwaigenbaum et al., 2019). The CPS recommends that all Canadian children be monitored for early behavioural signs of ASD as part of general developmental surveillance (Zwaigenbaum et al., 2019). This can be started at the 18-month well-baby visit.

Etiology. The cause of ASD is unknown. Researchers are investigating a number of theories, including a link between hereditary and medical factors. Immune and environmental factors (e.g., viral infections) may interact with the genetic susceptibility to increase the incidence of ASD.

Hereditary factors, parental history of psychiatric disorders, preterm births, and fetal exposure to psychotropic drugs or insecticides have all been linked to higher risk of ASD (Sharma et al., 2018). Individuals with ASD may have abnormal electroencephalograms, epileptic seizures, delayed development of hand dominance, persistence of primitive reflexes, metabolic abnormalities (elevated blood serotonin), cerebellar vermal hypoplasia (part of the brain involved in regulating motion and some aspects of memory), abnormal head enlargement in the infant (Rutter, 2013).

The strong evidence for a genetic basis in twins is consistent with an autosomal recessive pattern of inheritance. Researchers have discovered that identical twins are much more likely to have similar levels of autistic symptoms than fraternal twins. In addition, higher severe levels of autism symptoms are genetic in origin, whereas less severe symptoms are not as likely (Frazier et al., 2014). There is a relatively high risk of recurrence of ASD in families with one affected child.

The current scientific evidence confirms that there is no link between ASD and the measles-mumps-rubella (MMR) and thimerosal-containing vaccines. ASD has been reported in association with a number of conditions such as FXS, tuberous sclerosis, metabolic disorders, fetal rubella syndrome, Prader-Willi syndrome, *Haemophilus influenzae* meningitis, and structural brain anomalies. Researchers have retrospectively tied ASD to prenatal and perinatal events such as older maternal or paternal age. In addition, factors influencing the intrauterine environment, such as maternal obesity or overweight, short interval from prior pregnancy, premature birth, and certain prenatal infections (e.g., cytomegalovirus), have also been associated with ASD, although caution is urged in interpreting these results. Individuals with genetic vulnerability may be more sensitive to environmental factors influencing early brain development (Bridgemohan, 2020).

Clinical Manifestations and Diagnostic Evaluation. Children with ASD demonstrate core deficits primarily in social interactions, communication, and behaviour. Failure of social interaction and communication development is one of the hallmarks of ASD. Parents of autistic children have reported their children showing less interest in social interaction (e.g., abnormal eye contact, decreased response to own name, decreased imitation, unusual repetitive behaviour) and having verbal and motor delay. Children with ASD may have significant gastrointestinal issues. Constipation is a common symptom and can be associated with acquired megarectum in children with ASD.

Children with autism do not always have the same manifestations; mild forms require minimal supervision, and in severe forms self-abusive behaviour is common. The majority of children with autism have some degree of ID, with scores typically in the moderate to severe range. Despite their relatively moderate to severe disability, some children with autism (known as **savants**) excel in particular areas, such as art, music, memory, mathematics, or perceptual skills, such as puzzle building.

Communication impairments are common in children with ASD and may range from absent to delayed speech. Any child who does not display such language skills as babbling or gesturing by 12 months, single words by 16 months, and two-word phrases by 24 months should undergo hearing and language evaluation. Autism regression is when the child seems to develop normally then regresses suddenly; this is a red-flag event that has been frequently displayed in expressive language.

Diagnosis is based on the diagnostic criteria of the APA (2013). Early recognition, referral, diagnosis, and intensive early intervention tend to improve outcomes for children with ASD (Bridgemohan, 2020; Zwaigenbaum et al., 2019). Unfortunately, diagnosis is often not made until 2 to 3 years after symptoms are first recognized. Increasingly, older children and adults whose ASD was not previously identified are now being diagnosed.

Nearly 75% of individuals with ASD have comorbid psychiatric illnesses or conditions, which may include attention-deficit/hyperactivity disorder (ADHD), anxiety, bipolar disorder, depression, Tourette syndrome, and others (Sharma et al., 2018).

Prognosis. Even though ASD is usually a severely disabling condition, the symptoms associated with autism can be greatly improved with early and intensive interventions, and reported symptoms have been completely overcome in some cases (Bridgemohan, 2020). Some individuals ultimately achieve independence, but most require lifelong adult supervision. Aggravation of psychiatric symptoms occurs in about half of children during adolescence, with girls having a tendency for continued deterioration.

Early recognition of behaviours associated with ASD is critical to implementing appropriate interventions and family involvement (Box 42.5). There is a growing body of evidence that parent-delivered interventions are associated with some improved outcomes, yet further research is needed in this area, incorporating consistent measures (Bearss et al., 2015; Oono et al., 2013). The prognosis is most favourable for children with higher intelligence, functional speech, and fewer behavioural issues (Solomon et al., 2011).

Therapeutic Management. Pharmacological treatments include psychostimulants, atypical antipsychotics, antidepressants, and alpha-2 adrenergic receptor agonists. These medications provide partial symptomatic relief of core symptoms of ASD or manage the symptoms of comorbid conditions. Nonpharmacological interventions, which show promising evidence in improving social interaction and verbal communication of ASD patients, include music therapy, cognitive behavioural therapy, and social behavioural therapy. Hormonal therapies with oxytocin or vasopressin receptor antagonists have also shown some promise in improving core ASD symptoms. The use of vitamins, herbal remedies, and nutritional supplements in conjunction with pharmacological and behavioural treatment appears to have some effect in symptomatic improvement in ASD, though additional studies are needed to confirm these benefits (Sharma et al., 2018).

BOX 42.5 Early Signs of Autism Spectrum Disorder in Young Children

- Emotional disconnection with others, such as having difficulties picking up on facial social cues and not smiling in response to others
- Sensitivity to external stimuli, such as becoming agitated to certain noises, lights, smells, tastes, or textures
- Ostensible lack of empathy with others, with limited range of emotions
- Unresponsiveness to the usual human interactions, such as socializing and imitating others
- Difficulties in controlling emotions and physical reactions, particularly in stressful circumstances, such as throwing temper tantrums or physical aggression on themselves with head banging and biting
- Delayed language development, such as lack of mimicking and babbling
- Tendency to use nonverbal instead of verbal communication, such as use of gestures or drawings
- Diminished ability to decipher the meaning of others' facial expression or demeanor
- Tendency to exhibit repetitive behaviours, such as reorganizing the same toys, rocking themselves frequently, repeating the same hand gestures, and repeating the same words

Nursing Care. Therapeutic intervention for the child with ASD is a specialized area involving professionals with advanced training. Although there is no cure for ASD, numerous therapies have been used. The most promising results have been through highly structured and intensive behaviour modification programs. In general, the objective in treatment is to promote positive reinforcement, increase social awareness of others, teach verbal communication skills, and decrease unacceptable behaviour. Providing a structured routine for the child to follow is key in the management of ASD.

When children with ASD are hospitalized, the parents are essential to planning care and, ideally, should stay with the child as much as possible. Nurses should recognize that not all children with ASD are the same; they will require individual assessment and treatment. Decreasing stimulation by placing the patient in a private room, avoiding extraneous auditory and visual distractions, and encouraging the parents to bring in possessions the child is attached to may lessen the disruptiveness of hospitalization. Because physical contact often upsets these children, minimal holding and eye contact may be necessary to avoid behavioural outbursts. Care must be taken when performing procedures on, administering medicine to, or feeding these children, since they may be either fussy eaters who willfully starve themselves or gag to prevent eating or are indiscriminate hoarders, swallowing any available edible or inedible items, such as a thermometer. Eating habits of children with ASD may be particularly challenging for families and may involve food refusal accompanied by mineral deficiencies, mouthing objects, eating nonedibles, and smelling and throwing food (Herndon et al., 2009).

Children with ASD need to be introduced slowly to new situations; visits with staff caregivers should be kept short whenever possible. Because these children have difficulty organizing their behaviour and redirecting their energy, they need to be told directly what to do. Communication should be at the child's developmental level—brief and concrete.

Supporting the family. As with so many other chronic conditions, ASD involves the entire family and often becomes "a family disease." Nurses can help alleviate the guilt and shame often associated with this disorder by stressing what is known from a biological standpoint and by providing family support. It is imperative to help parents understand that they are not the cause of the child's condition.

Parents need expert counselling early in the course of the disorder and should be referred to Autism Canada, which provides information about education, treatment programs and techniques, and facilities such as camps and group homes (see Additional Resources at the end of this chapter).

As much as possible, the family should be encouraged to care for the child in the home. With the help of family support programs, which are in some provinces and territories, families are often able to provide home care and assist with the educational services the child needs. As the child approaches adulthood and parents become older, the family may require assistance in locating a long-term live-in facility. Autism groups and parents of autistic children are lobbying the Canadian government through the courts to provide more financial support to help families pay for the comprehensive treatment costs.

SENSORY IMPAIRMENT

Hearing Impairment

Hearing impairment is one of the most common congenital conditions in Canada. It is more common than all other conditions for which newborns are screened. About 3 in 1 000 babies are born severely deaf and another 3 in 1 000 have serious hearing impairment (CPS, 2020). Most hearing-impaired children are healthy and born to hearing parents.

Definition and Classification. *Hearing impairment* is a general term indicating disability that may range in severity from slight to profound hearing loss. *Slight to moderately severe hearing loss* describes a person who has residual hearing sufficient enough to enable successful processing of linguistic information through audition, generally with use of a hearing aid. *Severe to profound hearing loss* describes a hearing disability that precludes a person's successful processing of linguistic information through audition with or without a hearing aid. Hearing-impaired persons who are speech impaired tend not to have a physical speech challenge other than that caused by the inability to hear.

Hearing impairments may be classified according to etiology, pathology, or symptom severity. Each is important in terms of treatment, possible prevention, and rehabilitation.

Etiology. Hearing impairment may be caused by a number of prenatal and postnatal conditions. Most newborn hearing impairment is sensorineural; a known genetic cause is found in 50% of children. The remaining causes of newborn sensorineural hearing impairment include congenital infections (cytomegalovirus, rubella, herpes, syphilis, toxoplasmosis, bacterial meningitis), hyperbilirubinemia, and ototoxic medications (Patel et al., 2011/2018). Other risk factors include a family history of childhood hearing impairment, anatomical malformations of the head or neck, chronic ear infection, and cerebral palsy,

Admission to a neonatal intensive care unit is an established risk factor for hearing impairment in newborns, particularly for auditory neuropathy. High-risk newborns who survive formerly fatal prenatal or perinatal conditions may be susceptible to hearing impairment from the disorder or its treatment. For example, sensorineural hearing impairment may be a result of continuous humming noises or high noise levels associated with isolettes, oxygen hoods, or intensive care units, especially when combined with the use of potentially ototoxic antibiotics.

Environmental noise is a special concern. Sounds loud enough to damage sensitive hair cells of the inner ear can produce irreversible hearing loss. Very loud, brief noise, such as gunfire, can cause immediate, severe, and permanent loss of hearing. Longer exposure to less intense but still hazardous sounds, such as loud persistent music via headphones, sound systems, concerts, or industrial noises, can also produce hearing impairment (Haddad et al., 2020). Loud noises combined with toxic substances such as smoking or secondhand smoke produce a synergistic effect on hearing that causes hearing impairment. Overall, known risk factors are present in only 50% of infants born with hearing impairment. Because a substantial proportion of newborns have no risk factors, universal screening has replaced selective screening in most developed nations.

Pathology. Disorders of hearing are divided according to the location of the defect. **Conductive** (or middle-ear) **hearing loss** results from interference of transmission of sound to the middle ear. It is the most common of all types of hearing impairment and most frequently a result of recurrent serous otitis media. Conductive hearing impairment involves mainly interference with the loudness of sound.

Sensorineural hearing loss involves damage to the inner ear structures or the auditory nerve. The most common causes are congenital defects of inner ear structures or consequences of acquired conditions, such as kernicterus, infection, administration of ototoxic medications, or exposure to excessive noise. Sensorineural hearing loss results in distortion of sound and difficulties with sound discrimination. Although the child hears some of everything going on around them, the sounds are distorted, severely affecting discrimination and comprehension.

Mixed (conductive-sensorineural) **hearing loss** results from interference with the transmission of sound in the middle ear and along neural pathways. It frequently results from recurrent otitis media and its complications.

Central auditory imperception (**central hearing loss**) includes all hearing losses that are not linked to defects in the conductive or sensorineural structures. They are usually divided into organic or functional losses. In the organic type of central auditory imperception, the defect involves the reception of auditory stimuli along the central pathways and the expression of the message into meaningful communication. Examples are *aphasia*, the inability to express ideas in any form, either written or verbal; *agnosia*, the inability to interpret sound correctly; and *dysacusis*, difficulty in processing details or discriminating among sounds. In the functional type of hearing loss, no organic lesion exists to explain a central auditory loss. Examples of functional hearing loss are conversion hysteria (an unconscious withdrawal from hearing to block remembrance of a traumatic event), infantile autism, and childhood schizophrenia.

Symptom severity. Hearing impairment is expressed in terms of sound intensity in decibels (dB), a unit of loudness; hearing is measured at various frequencies, such as 500, 1 000, and 2 000 cycles/sec, the critical listening speech range (Table 42.1). Hearing impairment can be classified according to hearing threshold level (the measurement of an individual's hearing threshold by means of an audiometer) and the degree of symptom severity as it affects speech (Table 42.2). These classifications offer only general guidelines regarding the effect of the impairment on any individual child, since children differ greatly in their ability to use residual hearing.

Therapeutic Management

Conductive hearing loss. Treatment of hearing loss depends on the cause and type of hearing impairment. Many conductive hearing defects respond to medical or surgical treatment, such as antibiotic therapy for acute otitis media or insertion of tympanostomy tubes for chronic otitis media. When the conductive loss is permanent, hearing can be improved with the use of a hearing aid to amplify sound.

The nurse should be familiar with the types, basic care, and handling of hearing aids, especially when the child is hospitalized (see Additional Resources at the end of this chapter). Types of aids include those worn in or behind the ear, models incorporated into an eyeglass frame, or types worn on the body with a wire connection to the ear (Figure 42.5). One of the most common issues with a hearing aid is acoustic feedback, an annoying whistling sound usually caused by improper fit of the ear mould. Sometimes the whistling may be at a frequency that the child cannot hear but that is annoying to others. In this case, if children are old enough, they can be told of the noise and asked to readjust the aid.

! NURSING ALERT

To reduce or eliminate whistling from a hearing aid, try removing and reinserting the aid, making certain that no hair is caught between the ear mould and the ear canal; cleaning the ear mould or ear; or lowering the volume of the aid.

As children grow older, they may become self-conscious about the device. Every effort should be made to make the aid inconspicuous if this is a concern, such as having an appropriate hairstyle to cover behind-the-ear or in-the-ear models; wearing attractive frames for glasses; and placing the on-the-body type where it is not seen, such as under a shirt or sweater. Children should be given responsibility for the care of the device as soon as they are able, since fostering independence is a primary goal of rehabilitation.

TABLE 42.1 Intensity of Sounds Expressed in Decibels

Decibels	Representative Sound
0	Softest sound normal ear can hear
10	Heartbeat, rustling of leaves
20	Whisper at 1.5 m (5 feet)
30 to 45	Normal conversation
60	Noise in average restaurant
70 to 80	Street noises
80	Loud radio in home
90 to 100	Train
120	Thunder, loud music
140	Jet plane during departure
>140	Pain threshold

TABLE 42.2 Classification of Hearing Impairment Based on Symptom Severity

Hearing Level (dB)	Effect
Slight—16–25	Has difficulty hearing faint or distant speech Usually is unaware of hearing difficulty Likely to achieve in school but may have difficulties No speech defects
Mild to moderate—26–55	May have speech difficulties Understands face-to-face conversational speech at 0.9–1.5 m
Moderately severe—56–70 (hard of hearing)	Unable to understand conversational speech unless loud Considerable difficulty with group or classroom discussion Requires special speech training
Severe—71–90 (deaf)	May hear a loud voice if nearby May be able to identify loud environmental noises Can distinguish vowels but not most consonants Requires speech training
Profound—91 (deaf)	May hear only loud sounds Requires extensive speech training

! NURSING ALERT

Stress to parents the importance of storing batteries for hearing aids in a safe location out of reach of children and of teaching children not to remove the battery from the hearing aid (or supervising young children when they do so). Battery ingestion requires immediate emergency management.

Sensorineural hearing loss. Treatment for sensorineural hearing loss is much less satisfactory. Because the impairment is not one of intensity of sound, hearing aids are of less value. The use of cochlear implants (a surgically implanted prosthetic device) provides a sensation of hearing for individuals who have severe or profound hearing loss (see

Fig. 42.5 On-the-body hearing aids are convenient for young children, such as this child with severe bilateral hearing loss. Note eye patching for strabismus.

Additional Resources at the end of this chapter). Children with sensorineural hearing loss have lost or damaged some or all of their hair cells or auditory nerve fibres. Often these children cannot benefit from conventional hearing aids because they only amplify sound that cannot be processed by a damaged inner ear. A cochlear implant bypasses the hair cells to directly stimulate surviving auditory nerve fibres so that they can send signals to the brain. These signals can be interpreted by the brain to produce sound and sensations (Haddad et al., 2020).

The multichannel implant is a sophisticated device that stimulates the auditory nerve at a number of locations with differently processed signals. This type of stimulation allows a person to use the pitch information present in speech signals, leading to better understanding of speech. The trend is toward early use of cochlear implants, usually by 12 months of age, to give the child maximum opportunity to develop listening, language, and speaking skills. These implants have been used with children under 12 months of age with success. Electroacoustic cochlear implants or hybrids are being developed that may offer hope for children using hearing aids but who struggle with noise in the classroom or in social contexts (Haddad et al., 2020). Unilateral implants, across all age groups, have been reported to provide sustained benefits in recipients overall as well as improved quality of life (Crowson et al., 2017).

Nursing Care. Assessment of children for hearing impairment is a critical nursing responsibility. Early detection of hearing loss, preferably within the first 3 to 6 months of life, is essential to improve the language and educational outcomes of those with hearing impairments. Without early intervention, children with hearing impairment have irreversible deficits in communication and in psychosocial skills, cognition, and literacy (Patel et al., 2011/2018). Usually the screening is done as a newborn before discharge from the hospital (see Chapter 26). The CPS strongly recommends that universal newborn hearing screening be done across Canada (Patel et al., 2011/2018). According to the Early Hearing Detection and Intervention (EHDI) Report Card (Speech-Language and Audiology Canada, 2019), the provinces and territories that have sufficient hearing screening programs are British Columbia, Alberta, Northwest Territories, Yukon, Ontario, and Nova Scotia. The rest of Canada has insufficient screening programs.

At birth the nurse can observe the newborn's response to auditory stimuli, as evidenced by the startle reflex, head turning, eye blinking, and cessation of body movement. The newborn may vary in the intensity of the response, depending on the state of alertness. However, a consistent absence of a reaction should lead to suspicion of hearing impairment. Box 42.6 summarizes other clinical manifestations of hearing impairment.

Children who are profoundly deaf are much more likely to be diagnosed during infancy than the those who are less severely affected. If the defect is not detected during early childhood, it likely will become evident during entry into school, when the child has difficulty learning. Unfortunately, some of these children are mistakenly placed in special classes for students with learning disabilities or ID. Therefore, it is essential that the nurse consider a hearing impairment in any child who demonstrates the behaviours listed in Box 42.6.

Of primary importance is the effect of hearing impairment on speech development. A child with a mild conductive hearing loss may speak fairly clearly but in a loud, monotone voice. A child with a sensorineural defect usually has difficulty with articulation. For example, inability to hear higher frequencies may result in the word *spoon* being pronounced "poon." Children having difficulty with articulation need to have their hearing tested.

As children learn to compensate for their lack of hearing, they become extremely perceptive to visual and vibratory changes. They often know when another person wants to talk to them because the person walks close by but does not pass them. They learn to be alert to other people approaching them by seeing their shadows or feeling the vibrations of their footsteps. They are acutely aware of facial

BOX 42.6 Clinical Manifestations of Hearing Impairment

Infants

Lack of startle or blink reflex to a loud sound
Failure to be awakened by loud environmental noises
Failure to localize a source of sound by 6 months of age
Absence of babble or voice inflections by age 7 months
Lack of response to the spoken word; failure to follow verbal directions
Response to loud noises as opposed to the voice

Children

Use of gestures rather than verbalization to express desires
Failure to develop intelligible speech by age 24 months
Monotone and unintelligible speech; lessened laughter
Vocal play, head banging, or foot stamping for vibratory sensation
Yelling or screeching to express pleasure, needs, or annoyance (tantrum)
Asking to have statements repeated or answering them incorrectly
Greater response to facial expression and gestures than to verbal explanation
Avoidance of social interaction; preference for playing alone
Inquiring, sometimes confused facial expression
Suspicious alertness alternating with cooperation
Frequent stubbornness because of lack of comprehension
Irritability at not making themselves understood
Shy, timid, and withdrawn behaviour
Frequently appearing "dreamy," "in a world of their own," or exhibiting inattentiveness

expressions and may comprehend unspoken messages more quickly than the spoken word.

NURSING ALERT

When parents express concern about their child's hearing and speech development, refer the child for a hearing evaluation. Absence of well-formed syllables (da, na, yaya) by 11 months of age should result in immediate referral.

Lipreading. Even though the child may become an expert at lipreading, only about 40% of the spoken word is understood, and less is understood if the speaker has an accent, a moustache, or a beard. Exaggerating pronunciation or speaking in an altered rhythm further reduces comprehension. Parents can help their child understand the spoken word by using the suggestions in the Guidelines box: Facilitating Lipreading. The child learns to supplement the spoken word with sensitivity to visual cues, primarily body language and facial expression (e.g., tightening the lips, muscle tension, eye contact).

GUIDELINES

Facilitating Lipreading

- Attract the child's attention before speaking; use light touch to signal the speaker's presence.
- Stand close to the child.
- Face the child directly or move to a 45-degree angle.
- Stand still; do not walk back and forth or turn away to point or look elsewhere.
- Establish eye contact and show interest.
- Speak at eye level and with good lighting on the speaker's face and no light at the back of the speaker's head.
- Be certain nothing interferes with speech patterns, such as chewing food or gum.
- Speak clearly and at a slow and even rate.
- Use facial expression to assist in conveying messages.
- Keep sentences short.
- Rephrase the message if the child does not understand the words.

Cued speech. The cued speech method of communication is an adjunct to straight lipreading. Hand signals are used to help the child with a hearing impairment distinguish between words that look alike when formed by the lips (e.g., *mat, bat*). It is most often used by children with hearing impairments who are using speech, rather than those who are nonverbal.

Sign language. Sign language, such as American Sign Language (ASL) or British Sign Language (BSL), is a visual gestural language in which hand signals roughly correspond to specific words and concepts in the English language. Family members are encouraged to learn signing because using or watching hands requires much less concentration than lipreading or talking. Also, a symbol method enables some children to learn more and to learn faster.

Speech language therapy. The most formidable task in the education of a child who is profoundly hearing impaired is learning to speak. Speech is learned through a multisensory approach, using visual, tactile, kinesthetic, and auditory stimulation. Parents should be encouraged to participate fully in the learning process. One form of speech training involves the skills of a speech language pathologist, who can provide evaluation and treatment of the language difficulties experienced by children who have some form of ID or hearing impairment. The speech language pathologist can work closely with schools, the family, and the health care team to implement effective programs to help children with ID or hearing impairment develop stronger communication skills (see Additional Resources at the end of this chapter).

Additional aids. Everyday activities can present challenges for older children with hearing impairment. For example, they may not be able to hear the telephone, doorbell, or alarm clock. Several commercial devices are available to help them adjust to these dilemmas. A new visual fire alarm is now available as an additional safety device. Flashing lights can be attached to a telephone or doorbell to signal its ringing, and cellular phones can be set on vibrate. Trained hearing ear dogs can provide assistance because they alert the person to sounds, such as someone approaching, a moving car, a signal to wake up, or a child's cry. Special teletypewriters or telecommunications devices for the deaf (TDD or TTY) help people with impaired hearing communicate with each other over the telephone; the typed message is conveyed via the telephone line and displayed on a small screen. Information on available electronic aids and new equipment is available on the Canadian Hearing Society website (see Additional Resources). Cellular phones and smartphones also offer means of sending text and visual messages.

Any audiovisual medium presents challenges for these children, who can see the picture but cannot hear the message. With closed captioning, a special decoding device is attached to the television, and the audio portion of a program is translated into subtitles that appear on the screen. It is also a common feature available on video streaming services. Closed-caption applications are available for smartphones and software for computers for closed captioning with video games and online streaming.

Socialization. Socialization is extremely important to the child's development. If children attend a special school for the hearing impaired, they are able to socialize with peers in that setting. Classmates become a potential source of close friendships because they communicate more easily among themselves. Parents should be encouraged to promote these relationships whenever possible.

Children with a hearing impairment may need help with school or social activities. For children wearing hearing aids, background noise should be kept to a minimum. Because many of these children are able to attend regular classes, the teacher may need assistance in adapting methods of teaching for the child's benefit. The nurse is often in an optimal position to emphasize methods of facilitated communication, such as lipreading (see Guidelines box: Facilitating Lipreading). Because group projects and audiovisual teaching aids may hinder the child's learning, these educational methods should be carefully evaluated.

In a group setting, it is helpful for the other class members to sit in a semicircle in front of the child. Because one of the difficulties in following a group discussion is that the child is unaware of who will speak next, someone should point out each speaker. Speakers can also be given numbers, or their names can be written down as each person talks. If one person writes down the main topic of the discussion, the child is able to follow lipreading more closely. Such suggestions can increase the child's ability to participate in sports, organizations such as Scouts, and group projects.

Supporting the child and family. After the diagnosis of hearing impairment is made, parents may need extensive support to adjust to learning about their child's disability and an opportunity to realize the extent of the hearing impairment. If the hearing loss occurs during childhood, the child also requires sensitive, supportive care during the long and often difficult adjustment to this sensory impairment. Early rehabilitation is one of the best strategies for fostering adjustment. However, progress in learning communication may not always coincide with emotional adjustment. Depression or anger is common, and such feelings are a normal part of the grieving process.

For older children with hearing impairment, the Canadian Hearing Society offers a youth transition program to support career planning (see Additional Resources).

Caring for the child during hospitalization. The needs of the hospitalized child with impaired hearing are the same as those of any other child, but the disability presents special challenges to the nurse (see Clinical Reasoning Case Study). For example, verbal explanations must be supplemented by tactile and visual aids, such as books or actual demonstration and practice. Children's understanding of the explanation needs to be constantly reassessed. If their verbal skills are poorly developed, they can answer questions through drawing, writing, or gesturing. For example, if the nurse is attempting to clarify where a spinal tap is done, the child is asked to point to where the procedure will be done on the body. Because these children often need more time to grasp the full meaning of an explanation, the nurse needs to be patient, allowing ample time for understanding.

CLINICAL REASONING CASE STUDY

Hearing Impairment

Four-year-old Jamel has a severe congenital hearing impairment. Jamel has been admitted to the outpatient surgery, postanaesthetic care unit (PACU) after a herniorrhaphy and regional block. As he emerges from anaesthesia, he becomes more and more agitated.

Questions

1. What evidence should you consider regarding what is happening?
2. What additional information is required at this time?
3. List the nursing intervention(s) that have the highest priority.
4. Identify important patient-centred outcomes with reference to your nursing interventions.

When communicating with the child, the nurse should use the same principles as those outlined for facilitating lipreading. The child's hearing aid should be checked to ensure that it is working properly. If it is necessary to awaken the child at night, the nurse can gently shake the child or turn on the hearing aid before arousing the child. The nurse should always make certain that the child can see them before any procedures, even routine ones such as changing a diaper or regulating an infusion. It is important to remember that the child may not be aware of one's presence until alerted through visual or tactile cues.

Ideally, parents should be encouraged to room-in with the child. However, it must be conveyed to them that this is not to serve as a convenience to the nurse but as a benefit to the child. Although the parents' aid can be enlisted in familiarizing the child with the hospital and explaining procedures, the nurse also needs to talk directly to the youngster, encouraging expression of feelings about the experience. If the child's speech is difficult to understand, the nurse should make an effort to become familiar with their pronunciation of words. Parents often can be helpful by explaining the child's usual speech habits. Nonverbal communication devices that employ pictures or words that the child can point to are also available. Such boards can be made by drawing pictures or writing the words of common needs on cardboard, such as *parent*, *food*, *water*, or *toilet*.

The nurse has a special role as child advocate and is in a strategic position to alert other health care team members and other patients to the child's special needs regarding communication. For example, the nurse should accompany other practitioners on visits to the child's room to ensure that they speak to the child and that the child understands what is said. Caregivers sometimes forget that the child has the ability to perceive and learn despite a hearing impairment and, consequently, they communicate only with the parents. As a result, the child's needs and feelings remain unrecognized and unmet.

Because children with impaired hearing may have difficulty forming social relationships with other children, the child should be introduced to roommates and encouraged to engage in play activities. The hospital setting can provide growth-promoting opportunities for social relationships. With the assistance of a child life specialist, the child can learn new recreational activities, experiment with group games, and engage in therapeutic play. The use of puppets, dollhouses, role playing with dress-up clothes, building with a hammer and nails, finger painting, and water play can help the child express feelings that previously were suppressed.

Assisting in measures to prevent hearing impairment. A primary nursing role is to prevent hearing impairment. Because the most common cause of impaired hearing is chronic otitis media, it is essential that appropriate measures be instituted to treat existing infections and prevent recurrences. Children with a history of ear or respiratory tract infections or any other condition known to increase the risk of hearing impairment should receive periodic auditory testing.

To prevent the causes of hearing impairment that begin prenatally and perinatally, pregnant patients need counselling regarding the necessity of early prenatal care, including genetic counselling for known familial disorders; avoidance of all ototoxic medications, especially during the first trimester; tests to rule out syphilis, rubella, or blood incompatibility; medical management of maternal diabetes; abstinence of alcohol intake; adequate dietary intake; and avoidance of smoke exposure. The necessity of routine immunization during childhood to eliminate the possibility of acquired sensorineural hearing loss from rubella, mumps, or measles (encephalitis) should be stressed.

Excessive noise pollution is a well-established cause of sensorineural hearing loss. The nurse should routinely assess the possibility of environmental noise pollution and advise children and parents of the potential danger. When individuals engage in activities associated with high-intensity noise, such as flying model airplanes, target shooting, or snowmobiling, they should wear ear protection such as earmuffs or earplugs. Even common household equipment, such as lawn mowers, vacuum cleaners, and cordless telephones and cell phones, may cause noise-induced hearing impairment. Children should ensure that when using headphones to listen to music the noise should not be heard outside of the headset as this increases the risk of hearing deficits.

NURSING ALERT

Suspect hazardous noise if the listener experiences (1) difficulty in communication while hearing the sound, (2) ringing in the ears (tinnitus) after exposure to the sound, or (3) muffled hearing after leaving the sound.

Visual Impairment

Visual impairment is a common concern during childhood. Vision impairment such as refractive error, strabismus, and **amblyopia** occurs in 5 to 10% of all preschoolers, who are usually identified through vision screening programs. If left untreated, the impairment may interfere with the proper development of visual acuity (Amit & CPS, Community Paediatrics Committee, 2009/2018). The nurse's role is

one of early assessment and detection, prevention, referral, and, in some instances, rehabilitation.

Definition and Classification. *Visual impairment* is a general term that encompasses both partial sight and legal blindness. Partial sight or partial visual impairment is defined as a visual acuity between 20/70 and 20/200. The child can generally use normal-sized print because near vision is almost always better than distance vision. *Legal blindness or* severe permanent visual impairment is defined as visual acuity of 20/200 or lower or a visual field of 20 degrees or less in the better eye. It is important to keep in mind that legal blindness is not a medical diagnosis but a legal definition. It allows special considerations with regard to taxes, entrance into special schools, eligibility for aid, and other benefits.

Etiology. Visual impairment can be caused by a number of genetic and prenatal or postnatal conditions. These include perinatal infections (herpes, chlamydia, gonococci, rubella, syphilis, toxoplasmosis); retinopathy of prematurity; trauma; postnatal infections (meningitis); and conditions such as sickle cell disease, juvenile rheumatoid arthritis, Tay-Sachs disease, albinism, and retinoblastoma. In many instances, such as with **refractive errors**, the cause of the defect is unknown.

Refractive errors are the most common types of visual disorders in children. The term *refraction* means bending and refers to the bending of light rays as they pass through the lens of the eye. Normally, light rays enter the lens and fall directly on the retina. However, in refractive disorders the light rays either fall in front of the retina (**myopia**) or beyond it (**hyperopia**). Other eye conditions, such as **strabismus**, may or may not include refractive errors, but they are important because, if untreated, they result in severe permanent visual impairment from amblyopia. These, along with other less frequent visual disorders, are summarized in Box 42.7. In addition to these disorders, other visual conditions can be a result of **infection** or **trauma**.

Trauma. Trauma is a common cause of visual impairment in children. Injuries to the eyeball and adnexa (supporting or accessory structures, such as eyelids, conjunctiva, or lacrimal glands) can be classified as penetrating or nonpenetrating. Penetrating wounds are most often a result of sharp instruments, such as sticks, knives, or scissors; propulsive objects, such as firecrackers, bullets from guns, arrows, or rocks from slingshots; or a powerful contusion by a blunt object, which may occur during a fight or from a serious car accident. Nonpenetrating injuries may be a result of foreign objects in the eyes, lacerations, a blow from a blunt object such as a ball (from baseball, softball, basketball, or racquet sports) or fist, or thermal or chemical burns.

BOX 42.7 Types of Visual Impairment

Refractive Errors

Myopia

Nearsightedness—Ability to see objects clearly at close range but not at a distance

Pathophysiology

Results from eyeball that is too long, causing image to fall in front of retina

Clinical Manifestations

Excessive eye rubbing
Head tilt or forward head thrusts
Difficulty in reading or in doing other close work
Headaches
Dizziness
Clumsiness; walking into objects
Blinking more than usual or irritability when doing close work
Inability to see objects clearly
Poor school performance, especially in subjects that require demonstration, such as math

Treatment

Corrected with biconcave lenses that focus rays on retina
May be corrected with laser surgery

Hyperopia

Farsightedness—Ability to see objects at a distance

Pathophysiology

Results from eyeball that is too short, causing image to focus beyond retina

Clinical Manifestations

Because of accommodative ability, usually an ability to see objects at all ranges
Most children are normally hyperopic until about 7 years of age

Treatment

When required, corrected with convex lenses that focus rays on retina
May be corrected with laser surgery

Astigmatism

Unequal curvatures in refractive apparatus

Pathophysiology

Results from unequal curvatures in cornea or lens that cause light rays to bend in different directions

Clinical Manifestations

Depend on severity of refractive error in each eye
Possible clinical manifestations of myopia

Treatment

Corrected with special lenses that compensate for refractive errors
May be corrected with laser surgery

Anisometropia

Different refractive strength in each eye

Pathophysiology

May develop amblyopia as weaker eye is used less

Clinical Manifestations

Depend on severity of refractive error in each eye
Possible clinical manifestations of myopia

Treatment

Treated with corrective lenses, preferably contact lenses, to improve vision in each eye so the eyes work as a unit
May be corrected with laser surgery

Continued

BOX 42.7 Types of Visual Impairment—cont'd

Amblyopia

Lazy eye—Reduced visual acuity in one eye

Pathophysiology

Results when one eye does not receive sufficient stimulation
Each retina receives different images, resulting in diplopia (double vision)
Brain accommodates by suppressing less intense image
Visual cortex eventually does not respond to visual stimulation in that eye, with resultant loss of vision

Clinical Manifestations

Poor vision in affected eye

Treatment

Preventable if treatment of primary visual defect, such as anisometropia or strabismus, begins before 6 years of age

Strabismus

"Squint" or cross-eye—Malalignment of eyes
Estropia—Inward deviation of eye
Exotropia—Outward deviation of eye

Pathophysiology

May result from muscle imbalance or paralysis, poor vision, or congenital defect
Because visual axes are not parallel, brain receives two images, and amblyopia can result

Clinical Manifestations

Squints eyelids together or frowns
Has difficulty focusing from one distance to another
Inaccurate judgement in picking up objects
Unable to see print or moving objects clearly
Closes one eye to see
Tilts head to one side
If combined with refractive errors, may see any of the manifestations listed for refractive errors
Diplopia
Photophobia
Dizziness
Headaches

Treatment

Depends on cause of strabismus
May involve occlusion therapy (patching stronger eye) or surgery to increase visual stimulation to weaker eye
Early diagnosis essential to prevent vision impairment

Cataracts

Opacity of crystalline lens

Pathophysiology

Prevents light rays from entering eye and refracting on retina

Clinical Manifestations

Gradual decrease in ability to see objects clearly
Possible loss of peripheral vision
Nystagmus (with severe permanent visual impairment)
Grey opacities of lens
Strabismus
Absence of red reflex

Treatment

Requires surgery to remove cloudy lens and replace lens (with intraocular lens implant, removable contact lens, prescription glasses)
Must be treated early to prevent severe permanent visual impairment from amblyopia

Glaucoma

Increased intraocular pressure

Pathophysiology

Congenital type results from defective development of some component related to flow of aqueous humour
Increased pressure on optic nerve causes eventual atrophy and severe permanent visual impairment

Clinical Manifestations

Loss of peripheral vision—mostly seen in acquired types
Possible bumping into objects
Perception of halos around objects
Possible pain or discomfort (pain, nausea, or vomiting if sudden rise in pressure)
Eye redness
Excessive tearing (epiphora)
Photophobia
Spasmodic winking (blepharospasm)
Corneal haziness
Enlargement of eyeball (buphthalmos)

Treatment

Requires surgical treatment (goniotomy) to open outflow tracts
May require more than one procedure

Treatment is aimed at preventing further ocular damage and is primarily the responsibility of the ophthalmologist. It involves adequate examination of the injured eye (with the child sedated or anaesthetized in severe injuries); appropriate immediate intervention, such as removal of the foreign body or suturing of the laceration; and prevention of complications, such as administration of antibiotics or steroids and complete bed rest to allow the eye to heal and blood to reabsorb (see Emergency box: Eye Injuries). The prognosis varies according to the type of injury. It is usually guarded in all cases of penetrating wounds because of the high risk of serious complications.

EMERGENCY

Eye Injuries

Foreign Object

Examine eye for presence of a foreign body (evert upper lid to examine upper eye).
Remove a freely movable object with the pointed corner of a gauze pad lightly moistened with water.
Do not irrigate the eye or attempt to remove a penetrating object (see following section).
Caution child against rubbing the eye.

Chemical Burns

Irrigate the eye copiously with tap water for 20 minutes.
Evert upper lid to flush thoroughly.
Hold the child's head with the eye under tap of running lukewarm water.
Take child to emergency department.
Have child rest with eyes closed.
Keep the room darkened.

Ultraviolet Burns

If skin is burned, patch both eyes (make certain lids are completely closed); secure dressing with Kling bandages wrapped around the head rather than tape.
Have child rest with eyes closed.
Refer to an ophthalmologist.

Hematoma ("Black Eye")

Use a flashlight to check for gross hyphema (hemorrhage into anterior chamber; visible fluid meniscus across iris; more easily seen in light-coloured than in brown eyes).
Apply ice for the first 24 hours to reduce swelling if no hyphema is present.
Refer to an ophthalmologist immediately if hyphema is present.
Have child rest with eyes closed.

Penetrating Injuries

Take child to emergency department.
Never remove an object that has penetrated the eye.
Follow strict aseptic technique in examining the eye.
Observe for the following:

- Aqueous or vitreous leaks (fluid leaking from point of penetration)
- Hyphema
- Shape and equality of pupils, reaction to light, prolapsed iris (not perfectly circular)

Apply a Fox shield if available (not a regular eye patch) and apply a patch over the unaffected eye to prevent bilateral movement.
Maintain bed rest with child in 30-degree Fowler's position.
Caution child against rubbing the eye.
Refer to an ophthalmologist.

Infections. Infections of the adnexa and structures of the eyeball or globe may occur in children. The most common eye infection is conjunctivitis. Treatment is usually with ophthalmic antibiotics. Severe infections may require systemic antibiotic therapy. Steroids are used with caution because they exacerbate viral infections such as herpes simplex, increasing the risk of damage to the involved structures.

Nursing Care. Assessment of children for visual impairment is a critical nursing responsibility. Discovery of a visual impairment as early as possible is essential to prevent social, physical, and psychological harm to the child. Assessment involves (1) identifying those children who by virtue of their history are at risk, (2) observing for behaviours that indicate a vision impairment, and (3) screening all children for visual acuity and signs of other ocular disorders such as strabismus. The discussion here focuses on clinical manifestations of various types of visual issues (see Box 42.7). Vision testing is discussed in Chapter 33.

Infancy. At birth, the nurse should observe the newborn's response to visual stimuli, such as following a light or object and cessation of body movement. The newborn may vary in the intensity of the response, depending on the state of alertness. By 4 weeks of age an infant should follow faces.

Of special importance in detecting visual impairment during infancy are the parents' concerns regarding visual responsiveness in their child. Their concerns, such as lack of eye contact from the infant, must be taken seriously. During infancy the child should be tested for strabismus. Lack of binocularity after 4 months of age is considered abnormal and must be treated to prevent amblyopia.

! NURSING ALERT

Suspect visual impairment in an infant who does not react to light and in a child of any age if the parents express concern.

Childhood. Because the most common visual impairment during childhood is refractive errors, testing for visual acuity is essential. The community health nurse usually assumes major responsibility for vision testing in schoolchildren, but only some provinces and territories have these vision programs in place. Preschool vision screening is important for early detection of amblyopia and to prevent long-term major eye damage, including severe permanent visual impairment from this condition. The Public Health Association of Canada recommends universal preschool screening across Canada (Mema et al., 2012). In addition to refractive errors, the nurse should be aware of signs and symptoms that indicate other ocular issues. Visual acuity is measurable with a chart by 42 months of age.

Early screening has been associated with a decrease in the prevalence of amblyopia, which is reduced vision in one eye (lazy eye), and has improved acuity by 60%. Screening before 3 years of age is associated with a 70% lower prevalence of amblyopia after treatment (Amit & CPS, 2009/2018). The single and most effective test for amblyopia is determination of visual acuity by using noninvasive screening.

Learning that their child is visually impaired may precipitate a crisis for families. The family is encouraged to investigate appropriate stimulation and educational programs for their child as soon as possible. Sources of information include local schools for children with visual impairments and the CNIB Foundation (see Additional Resources).

Promoting parent–child attachment. A crucial time in the life of infants with visual impairment is when they and their parents are getting acquainted with each other. Pleasurable patterns of interaction between the infant and parents may be lacking if there is not enough reciprocity. For example, if the parent gazes fondly at the infant's face and seeks eye contact but the infant fails to respond because they cannot see the parent, a troubled cycle of responses may occur. The nurse can help parents learn to look for other cues that indicate the infant is responding to them, such as whether the eyelids blink; whether the activity level accelerates or slows; whether respiratory patterns change, such as faster or slower breathing, when the parents come near; and whether the infant makes throaty sounds when the parents speak to the infant. In time, parents learn that the infant has unique ways of relating to them. They should be encouraged to show affection using nonvisual methods, such as talking or reading, cuddling, and walking with the child.

Promoting the child's optimum development. Promoting the child's optimum development requires rehabilitation in a number of important areas, including learning self-help skills and appropriate communication techniques to become independent. Although nurses

may not be directly involved in such programs, they can provide direction and guidance to families regarding the availability of programs and the need to promote these activities in their child.

Development and independence. Motor development depends on sight almost as much as verbal communication depends on hearing. From earliest infancy, parents are encouraged to expose the infant to as many visual-motor experiences as possible, such as sitting supported in an infant seat or swing and being given opportunities for holding up the head, sitting unsupported, reaching for objects, and crawling.

Despite visual impairment, the child can become independent in all aspects of self-care. The same principles used for promoting independence in sighted children apply, with additional emphasis on nonvisual cues. For example, the child may need help in dressing, such as special arrangement of clothing for style coordination and braille tags to distinguish colours and prints.

The permanently visually impaired child also must learn to become independent in navigational skills. The two main techniques are the tapping method (use of a cane to survey the environment for direction and to avoid obstacles) and guides, such as a sighted human guide or a dog guide, such as a seeing eye dog. Children who are partially sighted may benefit from ocular aids, such as a monocular telescope.

Play and socialization. Children with severe permanent visual impairment do not learn to play automatically. Because they cannot imitate others or actively explore the environment as sighted children do, they depend much more on others to stimulate and teach them how to play. Parents need help in selecting appropriate play materials, especially those that encourage fine and gross motor development and stimulate the senses of hearing, touch, and smell. Toys with educational value such as dolls with various clothing closures are especially useful.

Children with severe permanent visual impairment have the same needs for socialization as sighted children. Because they have little difficulty in learning verbal skills, they are able to communicate with agemates and participate in suitable activities. The nurse should discuss with parents opportunities for socialization outside the home, especially regular preschools. The current trend is to include these children with sighted children to help them adjust to the outside world for eventual independence.

To compensate for inadequate stimulation, these children may develop self-stimulatory activities, such as body rocking, finger flicking, or arm twirling. Such habits restrict the child's social acceptance and are discouraged. Behaviour modification is often successful in reducing or eliminating self-stimulatory activities.

Education. The main difference from sighted children in the child's learning is the child's total dependence on nonvisual cues. Although the child can learn via verbal lecturing, they are unable to read the written word or to write without special education. Therefore, the child must rely on braille, a system that uses raised dots to represent letters and numbers. The child can then read the braille with the fingers and can write a message using a braille writer. However, unless others read braille, this system is not useful for communicating with others. A more portable system for written communication is the use of a braille slate and stylus, or an iPod or smartphone with a recording device app. A recorder is especially helpful for leaving messages for others and taking notes during classroom lectures. For mathematical calculations, portable calculators with voice synthesizers are available.

Audio books, other recordings, and even CDs are significant sources of reading material other than braille books, which are large and cumbersome. The CNIB Foundation has the Library for the Blind and provides audio books, e-books, and braille books online, or they will mail the materials. Many local libraries also provide audio and e-books (see Additional Resources). Various talking watches and clocks are also available. For written communication children can use a computer or tablet with a voice synthesizer, which "speaks" each letter or word that has been typed.

The child with partial sight can benefit from specialized visual aids that produce a magnified retinal image. The basic devices are accommodation (e.g., bringing the object closer), special plus lenses, handheld and stand magnifiers, telescopes, video projection systems, and large print. E-readers and computer tablets can be easily adjusted to increase the font size. Special equipment is also available to enlarge print.

Children with diminished vision often prefer to do close work without their glasses and compensate by bringing the object very near to their eyes. This practice should be allowed. The exception is the child with vision in only one eye, who should always wear glasses for protection.

Caring for the child during hospitalization. Because nurses are more likely to care for children who are hospitalized for procedures that involve temporary loss of vision than for children who have severe permanent visual impairment, the following discussion concentrates primarily on the needs of such children. The nursing care objectives in either situation are to (1) reassure the child and family throughout every phase of treatment, (2) orient the child to the surroundings, (3) provide a safe environment, and (4) encourage independence. Whenever possible, the same nurse should care for the child to ensure consistency in the approach.

When sighted children temporarily lose their vision, almost every aspect of the environment becomes bewildering and frightening. They are forced to rely on nonvisual senses for help in adjusting to the visual impairment without the benefit of any special training. Nurses have a major role in minimizing the effects of temporary loss of vision. They need to talk to the child about everything that is occurring, emphasizing aspects of procedures that are felt or heard. They should approach the child by always identifying themselves as soon as they enter the room. Because unfamiliar sounds are especially frightening, these should be explained. Parents should be encouraged to room with their child and participate in the care. Familiar objects, such as a teddy bear or doll, should be brought from home to help lessen the strangeness of the hospital. As soon as the child is able to be out of bed, they can be oriented to the immediate surroundings. If the child is able to see on admission, significant aspects of the room should be pointed out. The child needs to be encouraged to practise ambulation with the eyes closed to become accustomed to this experience.

The room should be arranged with safety in mind. For example, a stool or chair can be placed next to the bed to help the child climb in and out of bed. The furniture should always be placed in the same position to prevent collisions. Cleaning personnel need to be reminded to keep the room in the same order. If the child has difficulty navigating by feeling the walls, a rope can be attached from the bed to the point of destination, such as the bathroom. Attention to details such as well-fitting slippers or robes that do not drag on the floor is important in order to prevent tripping. Unlike children who have permanent visual impairments, children with temporary vision loss are not familiar with navigating with a cane.

The child should be encouraged to be independent in self-care activities, especially if the visual impairment may be prolonged or potentially permanent. For example, during bathing the nurse can set up all the equipment and encourage the child to participate. At mealtime the nurse should explain where each food item is on the tray, open any special containers, prepare cereal or toast, and encourage the child in self-feeding. Favourite finger foods, such as sandwiches, hamburgers, hot dogs, or pizza, may be good selections. The child needs to be praised for their efforts at working together and being independent. Any improvements made in self-care, no matter how small, should be stressed.

Appropriate recreational activities should be provided, and if a child life specialist is available, such planning can be done jointly. Because children with temporary visual impairment have a wide variety of play experiences to draw on, they should be encouraged to select activities. For example, if they like to read, they may enjoy being read to. If they prefer manual activity, they may appreciate playing with clay or building blocks or feeling different textures and naming them. If they need an outlet for aggression, activities such as pounding or banging on a drum can be helpful. Simple board and card games can be played with a "seeing partner" or an opponent who helps with the game. They should have familiar toys from home to play with, since familiar items are more easily manipulated than new ones. If parents want to bring presents, they should be objects that stimulate hearing and touch, such as a radio, music box, or stuffed animal.

Occasionally, children who are visually impaired come to the hospital for procedures to restore their vision. Although this is an extremely happy time, it also requires intervention to help them adjust to sight. They need an opportunity to take in all that they see. They should not be bombarded with visual stimuli. They may need to concentrate on people's faces or their own to become accustomed to this experience. They often need to talk about what they see and to compare the visual images with their mental ones. The children may also go through a period of depression, which must be respected and supported. The nurse or parents should encourage the child to discuss how it feels to see, especially in terms of seeing themselves.

Newly sighted children also need time to adjust to the ability to engage in activities that were impossible before. For example, they may prefer to use braille to read, rather than learning a new "visual approach," because of familiarity with the touch system. Eventually, as they learn to recognize letters and numbers, they will integrate these new skills into reading and writing. However, parents and teachers must be careful not to push them before they are ready. This applies to social relationships and physical activities as well as learning situations.

Assisting in measures to prevent visual impairment. An essential nursing goal regarding sight in children is to prevent visual impairment. This involves many of the same interventions discussed under hearing impairments:

- Prenatal screening for pregnant patients at risk, such as those with rubella or syphilis infection and family histories of genetic disorders associated with vision impairment
- Adequate prenatal and perinatal care to prevent prematurity
- Periodic screening of all children, especially newborns through preschoolers, for congenital and acquired visual impairments caused by refractive errors, strabismus, and other disorders
- Rubella immunization of all children
- Safety counselling regarding the common causes of ocular trauma and safe practices when working with, playing with, or carrying objects such as scissors, knives, and balls

! NURSING ALERT

A helmet with a face mask should be required for children playing football, hockey, baseball, and lacrosse.

After detection of eye conditions, the nurse has a responsibility to prevent further ocular damage by ensuring that corrective treatment is used. For the child with strabismus, occlusion patching of the stronger eye is often needed. Compliance with the procedure is greatest during the early preschool years. It is more difficult to encourage school-age children to wear the occlusive patch because the poor visual acuity of the uncovered weaker eye interferes with schoolwork and the patch sets them apart from their peers. In school they benefit from being positioned favourably (closer to the board or other visual media) and allowed extra time to read or complete an assignment. If treatment of the eye disorder requires instillation of ophthalmic medication, the family should be taught the correct procedure (see Chapter 44).

The nurse can help children with refractive errors adjust to wearing glasses. Young children who often pull glasses off benefit from temporal pieces that wrap around the ears or an elastic strap attached to the frames and around the back of the head to hold the glasses on securely. After children appreciate the value of clear vision, they are more likely to wear the corrective lenses.

Glasses should not interfere with any activity. Special protective guards are available during contact sports to prevent accidental injury, and all corrective lenses should be made from safety glass, which is shatterproof. Often, corrective lenses improve visual acuity so dramatically that children are able to compete more effectively in sports. This in itself is an inducement to continue wearing glasses.

Contact lenses are a popular alternative, especially for adolescents. Several types are available, such as hard lenses, including gas-permeable ones, and soft lenses, which may be designed for daily or extended wear. Contact lenses offer several advantages over glasses, such as greater visual acuity, total corrected field of vision, convenience (especially with the extended-wear type), and optimal cosmetic benefit. Unfortunately, they are usually more expensive and require much more care than glasses, including considerable practice to learn techniques for insertion and removal. If they are prescribed, the nurse can be helpful in teaching parents or older children how to care for the lenses.

Because trauma is the leading cause of visual impairment in children, the nurse has major responsibility in preventing further eye injury until specific treatment is instituted. The major principles to follow when caring for an eye injury are outlined in the Emergency box earlier in the chapter. Because patients with a serious eye injury fear visual impairment, the nurse should stay with the child and family to provide support and reassurance.

Hearing–Visual Impairment

The most traumatic sensory impairment is loss of both vision and hearing, which may have profound effects on the child's development. Such impairment interferes with the usual sequence of physical, intellectual, and psychosocial growth. Although these children often achieve the usual motor milestones, their rate of development is slower and they learn communication only with specialized training. Finger spelling is one desirable method often taught to these children. Some children with hearing–visual impairment, especially those with residual hearing or sight, can learn to speak. Whenever possible, speech is encouraged because it allows communication with other individuals.

The future prospects for children with hearing–visual impairment are, at best, unpredictable. Congenital hearing–visual impairment may be accompanied by other physical or neurological challenges, which further diminish the child's learning potential. The most favourable prognosis is for children who have acquired hearing–visual impairment, as these children tend to have few, if any, associated disabilities. Their learning capacity is greatly potentiated by their developmental progress before the sensory impairments. Although total independence, including gainful vocational training, is the goal, some children with hearing–visual impairment are unable to develop to this level. The nurse working with such families can help them address future goals for the child, including possible alternatives to home care during the parents' advancing years.

Retinoblastoma

Retinoblastoma, which arises from the retina, is the most common congenital malignant intraocular tumour of childhood. In Canada, the most recent incidence statistics for retinoblastoma in children aged 0 to 14 years are from 2012 to 2016, when 80 Canadian children were diagnosed with retinoblastoma, and 2013 to 2017, when 4 children died from retinoblastoma (Canadian Cancer Society, 2019). The average age of the child at the time of diagnosis is 2 years of age, and bilateral and hereditary disease is diagnosed earlier than unilateral and nonhereditary disease (Tarek & Herzog, 2020).

Retinoblastoma is caused by a mutation in a gene and may occur sporadically or be inherited (Tarek & Herzog, 2020). Retinoblastoma develops when the mutated gene is unable to produce the natural signals to stop the growth of retinal cells. The majority of cases are nonhereditary and unilateral, with the remainder divided between hereditary and unilateral, and hereditary and bilateral. Hereditary retinoblastomas are transmitted with few exceptions as an autosomal dominant trait with high but incomplete penetrance (Tarek & Herzog, 2020).

Clinical Manifestations. Retinoblastoma has few grossly obvious signs. Typically the parents are the first to detect a whitish "glow" in the child's pupil, known as the *cat's eye reflex,* or *leukocoria* (Figure 42.6). The reflex represents visualization of the tumour as the light momentarily falls on the mass. When a tumour arises in the macular region (which is the area directly at the back of the retina when the eye is focused straight ahead), a white reflex may be visible when the tumour is small. It is best observed when a bright light is shining toward the child as the child looks forward. Sometimes parents accidentally discover it when taking a photograph of their child using a flash setting.

When the tumour arises in the periphery of the retina, it must grow to a considerable size before light can strike it sufficiently to produce the cat's eye reflex. In this situation, it is visible only when the child looks in certain directions (sideways) or if the observer stands at an oblique angle to the child's face as the child looks straight ahead. The fleeting nature of the reflex often results in a delayed diagnosis because health care providers fail to appreciate the ominous significance of the parents' findings.

Fig. 42.6 Leukocoria (cat's eye reflex). Whitish appearance of lens is produced as light falls on tumour mass in left eye.

The next most common sign is strabismus resulting from poor fixation of the visually impaired eye, particularly if the tumour develops in the macula, the area of sharpest visual acuity. Blindness is usually a late sign, but it frequently is not obvious unless the parent consciously observes for behaviours indicating loss of sight, such as bumping into objects, slowed motor development, or turning of the head to see objects lateral to the affected eye. Other signs and symptoms include heterochromia (different colour of the iris), glaucoma, and pain.

Diagnostic Evaluation. A detailed family history and recording of eye symptoms are essential. Children suspected of having this disorder are referred to an ophthalmologist; the diagnosis is usually based on indirect ophthalmoscopy, ultrasound, computed tomography (CT), and magnetic resonance imaging (MRI) scans.

Metastatic disease at the time of retinoblastoma diagnosis is rare (Tarek & Herzog, 2020); therefore, staging procedures such as bone marrow aspiration, bone scan, and lumbar puncture are not routinely performed.

Prognosis. The overall prognosis for retinoblastoma is favourable, with a survival rate of nearly 95% for both unilateral and bilateral tumours. Retinoblastoma is one of the tumours that may spontaneously regress. Of major concern in long-term survivors is the development of decreased visual acuity; facial disfiguration; and secondary tumours, especially osteogenic sarcoma, other sarcomas, and melanoma. Children with bilateral disease (hereditary form) are more likely to develop secondary cancers than are children with unilateral disease. It is thought that these individuals are predisposed to developing cancer and that radiation increases their risk.

Therapeutic Management. Treatment of retinoblastoma is complex. Enucleation may be used to treat advanced disease with optic nerve invasion in which there is no hope for salvage of vision. Irradiation can be used when there is vitreous seeding. Chemotherapy has been used to decrease the tumour size to allow treatment with local therapies, such as plaque brachytherapy (surgical implantation of an iodine-125 applicator on the sclera until the maximum radiation dose has been delivered to the tumour), photocoagulation (use of a laser beam to destroy retinal blood vessels that supply nutrition to the tumour), and cryotherapy (freezing of the tumour, which destroys the microcirculation to the tumour and the cells themselves through microcrystal formation) (Tarek & Herzog, 2020).

Nursing Care.

Preparing the family for diagnostic and therapeutic procedures and home care. One of the most important nursing goals is to have a high index of suspicion for this rare malignancy. If parents report noticing a strange light in the eye or expression, these concerns must be taken seriously. Families with a history of retinoblastoma require follow-up; the nurse can be instrumental in reminding parents of appointments and the importance of genetic counselling.

Because the tumour is usually diagnosed in infants or very young children, most of the preparation for diagnostic tests and treatment involves parents. Once the disease is staged, the health care provider confers with the parents regarding treatment. In most cases, enucleation can be avoided. In the event that an enucleation is performed, the parents must be taught about the procedure and the benefits of a prosthesis. Showing parents pictures of another child with an artificial eye may help them adjust to the procedure. Although the loss of vision is distressing, most parents realize that there is no alternative.

Emphasizing that the unaffected eye retains normal vision and that the affected eye is probably already blind is particularly helpful in promoting acceptance of the imposed impairment.

After surgery, the parents should be prepared for the child's facial appearance. An eye patch is in place, and the child's face may be edematous or ecchymotic. Parents often fear seeing the surgical site because they imagine a cavity in the skull. A surgically implanted sphere maintains the shape of the eyeball, and the implant is covered with conjunctiva. When the lids are open, the exposed area resembles the mucosal lining of the mouth. After the child is fitted for a prosthesis, usually within 3 weeks, the facial appearance returns to normal.

After an uneventful recovery from enucleation, plans can be made for discharge from the hospital, usually within 3 to 4 days postoperatively. Parents need instruction in care of the surgical site and preparation for any additional therapy. They should be given the opportunity to see the socket as soon after surgery as possible. A good time to do this without unduly pressuring them is during dressing changes. They should then be encouraged to participate in the dressing changes.

Care of the socket is minimal and easily accomplished. The wound itself is clean and has little or no drainage. If an antibiotic ointment is prescribed, it is applied in a thin line on the surface of the tissues of the socket. The dressing consists of an eye pad changed daily. Once the socket has healed completely, a dressing is no longer necessary, although there are several reasons for having the child continue to wear an eye patch. Infants and toddlers explore their environment with their hands, and without an eye patch in place, the socket is available to exploring fingers. Although there is little danger of the child injuring the socket, parents may feel more secure with the socket covered. This also helps prevent infection.

The ocularist, who fits and manufactures the prosthesis, gives initial instructions for care of the device. Once in place, the prosthesis need not be removed unless cleaning is necessary, in which case it is taken out by gently pulling down on the lower lid, which frees the lower edge of the prosthesis, and applying pressure to the upper lid. The prosthesis is cleaned by placing it in hot water and soaking it for several minutes. Reinsertion is easier if the prosthesis remains wet. To reinsert the prosthesis, the lids are separated, and with the prosthesis held in the correct position (it should be marked to indicate the nasal side), it is pushed up under the upper lid, allowing the lower lid to cover its lower edge.

Safety is a major concern to prevent damage to the unaffected eye. Safety measures should be practised at all times, and children should avoid playing rough contact sports or wear protective eyewear.

Supporting the family. The diagnosis of retinoblastoma presents some special concerns in addition to those raised by any type of cancer. Families with a history of the disorder may feel guilt for transmitting the defect to their offspring, especially if they knowingly "played the odds" and parented an affected child. In families with no history of retinoblastoma, the diagnosis is a shock, frequently complicated by guilt for not having discovered it sooner. Each of these situations need to be considered while offering supportive care to the family.

KEY POINTS

- *Intellectual disabilities* (ID) refers to the challenges that some people face in learning and in communication that are usually present from the time they are born or from an early age.
- Causes of severe ID are primarily genetic, biochemical, and infectious. Mild ID is associated primarily with familial, social, and environmental causes, whereas severe ID is more likely to be associated with specific syndromes.
- Education of children with ID emphasizes sensory and verbal discrimination, improvement of short-term memory, motivation, and technological support.
- Optimum development for the child with ID may be promoted through family guidance regarding play, communication, discipline, socialization, and sexuality.
- Prevention of ID focuses on support for preterm newborns and other high-risk newborns, rubella immunization, genetic counselling, and maternal education regarding the risks of chemical use (e.g., alcohol ingestion) and the importance of adequate nutrition.
- Down syndrome, a chromosomal abnormality, is characterized by mild to moderate ID, physical characteristics, slowed language development, congenital anomalies, sensory issues, and diminished growth and sexual development.
- Fragile X syndrome is characterized by ID and phenotypic findings in affected males. It is considered the most common hereditary cause and the second leading chromosomal cause of ID after Down syndrome.
- Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder of brain function accompanied by a broad range and severity of intellectual and behavioural deficits.
- Hearing disorders may be classified according to the location of the impairment: conductive, sensorineural, mixed conductive-sensorineural, and central auditory imperception.
- Rehabilitation for hearing impairment involves parent education and support, hearing aids, lipreading, sign language, speech therapy, and promotion of socialization.
- Prevention of hearing impairment includes treatment of infection, universal newborn screening and child auditory testing, immunization, pregnancy and genetic counselling, and reduction of noise pollution.
- Common visual impairments in childhood include refractive errors, amblyopia, strabismus, cataracts, and glaucoma, with trauma and infections being common causes of visual impairment.
- Prevention of visual impairment focuses on prenatal screening, prenatal and perinatal care, periodic vision screening, immunization, and safety counselling.
- Nursing goals in visual rehabilitation include helping the family and child adjust to the child's visual impairment, promoting parent–child attachment, fostering optimum development and independence, providing for play and socialization, and being aware of educational facilities.
- For the child undergoing ocular surgery, nursing care is aimed at reassuring the child and family throughout treatment, orienting the child to their surroundings, providing a safe environment, and encouraging independence.
- Retinoblastoma is a rare congenital malignant tumour; its most common clinical manifestations are white pupil reflex and strabismus.

Family-Centred Care of the Child During Illness and Hospitalization

Cheryl Sams and
Originating US chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the stressors of illness and hospitalization for children during each developmental stage.
2. List essential priorities of nursing care for a child on admission to the hospital.
3. Review nursing interventions that prevent or minimize the stress of separation during hospitalization.
4. Discuss nursing interventions that minimize the stress of loss of control during hospitalization.
5. Describe nursing interventions that minimize the fear of bodily injury during hospitalization.
6. Outline nursing interventions that support parents, siblings, and other family members during a child's illness and hospitalization.
7. Describe nursing interventions needed when children are admitted to special units such as the emergency department.

STRESSORS OF HOSPITALIZATION AND CHILDREN'S REACTIONS

For many children, illness and hospitalization can be the first crises they face. Especially during the early years, children are particularly vulnerable to these stressors because (1) stress represents a change from the usual state of health and environmental routine, and (2) children have a limited number of coping mechanisms to resolve stressors. Major stressors of hospitalization include separation, loss of control, fear of bodily injury, and **pain**. Children's reactions to these stressors are influenced by their **developmental age**; their cognitive level; their cultural background; their previous experience with illness, separation, or hospitalization; their innate and acquired coping skills; the seriousness of the diagnosis; the support system available; and their preparation for hospitalization. The parent's reaction to the child's condition and hospitalization also has a significant effect. Children may also express fears caused by the unfamiliar environment or lack of information, child–staff relations, and the physical, social, and symbolic environment.

Separation Anxiety

The major stress from middle infancy throughout the preschool years, especially for children ages 6 to 30 months, is **separation anxiety**, also called *anaclitic depression*. This peaks at 18 months of age. The principal behavioural responses to this stressor during early childhood are summarized in Box 43.1. During the stages of *protest*, children react aggressively to separation from the parent. They cry and scream for their parents, refuse the attention of anyone else, and are inconsolable in their grief (Figure 43.1). In contrast, through the stage of *despair*, the crying stops and depression is evident. The child is much less active, is uninterested in play or food, and withdraws from others (Figure 43.2).

The third stage is *detachment*, also called **denial**. Superficially it appears that the child has finally adjusted to the loss. The child becomes more interested in the surroundings, plays with others, and seems to form new relationships. However, this behaviour is the result of resignation and is not a sign of contentment. The child detaches from the parent in an effort to escape the emotional pain of desiring the parent's presence and copes by forming shallow relationships with others, becoming increasingly self-centred, and attaching primary importance to material objects. This is the most serious stage in that reversal of the potential adverse effects is less likely to occur after detachment is established. However, in most situations, the temporary separations imposed by hospitalization do not cause such prolonged parental absences that the child enters into detachment. In addition, considerable evidence suggests that even with stressors such as separation, children are remarkably adaptable, and permanent ill effects are rare.

BOX 43.1 Manifestations of Separation Anxiety in Young Children

Stage of Protest

Behaviours observed during later infancy include the following:

- Crying
- Screaming
- Searching for parent with eyes
- Clinging to parent
- Avoiding and rejecting contact with strangers

Additional behaviours observed during toddlerhood include the following:

- Verbally attacking strangers, such as saying "Go away"
- Physically attacking strangers, such as kicking, biting, hitting, pinching
- Attempting to escape to find parent
- Attempting to physically force parent to stay

Behaviours may last from hours to days.

Protest, such as crying, may be continuous, ceasing only with physical exhaustion.

Approach of a stranger may precipitate increased protest.

Stage of Despair

Observed behaviours include the following:

- Being inactive
- Withdrawing from others
- Being depressed, sad
- Lacking interest in environment
- Being uncommunicative
- Regressing to earlier behaviour, such as thumb sucking, bed-wetting, use of pacifier, use of bottle

Behaviours may last for a variable length of time.

The child's physical condition may deteriorate from refusal to eat, drink, or move.

Stage of Detachment (Denial)

Observed behaviours include the following:

- Showing increased interest in surroundings
- Interacting with strangers or familiar caregivers
- Forming new but superficial relationships
- Appearing happy

Detachment usually occurs after prolonged separation from the parent; it is rarely seen in hospitalized children.

Behaviours represent a superficial adjustment to loss.

Fig. 43.1 In the protest phase of separation anxiety, children cry loudly and are inconsolable in their grief for the parent. (© Christina Kennedy/Alamy Stock Photo.)

Fig. 43.2 During the despair phase of separation anxiety, children are sad, lonely, and uninterested in food and play. (iStock.com/PraewBlackWhile)

Although progression to the stage of detachment is uncommon, the initial stages are frequently observed even with brief separations from either parent. Unless health care team members understand the meaning of each stage of behaviour, they may erroneously label the behaviours as positive or negative. For example, they may see the loud crying of the protest phase as "bad" behaviour. Because the protests increase when a stranger approaches the child, they may interpret that reaction as meaning they should stay away. During the quiet, withdrawn phase of despair, health care team members may think that the child is finally "settling in" to the new surroundings, and they may see the detachment behaviours as proof of a "good adjustment." The faster this stage is reached, the more likely it is that the child will be regarded as the "ideal patient."

Because children seem to react "negatively" to visits by their parents, uninformed observers feel justified in restricting parental visiting privileges. For example, during the protest stage, children outwardly do not appear happy to see their parents (Figure 43.3). In fact, they may even cry louder. If they are depressed, they may reject their parents or begin to protest again. Often they cling to their parents in an effort to ensure their continued presence. Consequently, such reactions may be regarded as "disturbing" the child's adjustment to the new surroundings. If the separation has progressed to the phase of detachment, children will respond no differently to their parents than they would to any other person.

Such reactions are distressing to parents, who are unaware of their meaning. If parents are regarded as intruders, they will see their absence as "beneficial" to the child's adjustment and recovery. They may respond to the child's behaviour by staying for only short periods, visiting less frequently, or deceiving the child when it is time to leave. The result is a destructive cycle of misunderstanding and unmet needs.

Early Childhood. Separation anxiety is the greatest stress imposed by hospitalization during early childhood. If separation is avoided, young children have a tremendous capacity to withstand any other stress. During this period, the typical reactions just described are seen. However, children in the toddler stage demonstrate more goal-directed

Fig. 43.3 In the protest phase of separation anxiety, young children may appear withdrawn and sad even in the presence of a parent. (Courtesy E. Jacob, Texas Children's Hospital.)

behaviours. For example, they may plead with the parents to stay and physically try to keep the parents with them or try to find parents who have left. They may demonstrate displeasure on the parents' return or departure by having temper tantrums; refusing to follow with the usual routines of mealtime, bedtime, or toileting; or regressing to earlier levels of development. However, temper tantrums, bed-wetting, or other behaviours may also be expressions of anger, a physiological response to stress, or symptoms of illness.

Because preschoolers are more secure interpersonally than toddlers, they can tolerate brief periods of separation from their parents and are more inclined to develop substitute trust in other significant adults. However, the stress of illness usually renders preschoolers less able to cope with separation; as a result, they manifest many of the stage behaviours of separation anxiety, although in general the protest behaviours are more subtle and passive than those seen in younger children. Preschoolers may demonstrate separation anxiety by refusing to eat, experiencing difficulty sleeping, crying quietly for their parents, continually asking when the parents will visit, or withdrawing from others. They may express anger indirectly by breaking their toys, hitting other children, or refusing to cooperate during usual self-care activities. Nurses need to be sensitive to these less obvious signs of separation anxiety in order to intervene appropriately.

Later Childhood and Adolescence. Previous research, usually based on adult recollections, indicated that the family does not play as important a role for school-age children as it does during the toddler and preschool years. However, in a qualitative study of children ages 5 to 9 years, children described hospitalizations in stories that focused on being alone and feeling afraid, sad, or angry. These children also described the need for protection and companionship while hospitalized (Wilson et al., 2010). Creating a care plan and involving parents to engage in the decision-making process can help parents feel more in control in managing the generally high level of fear regarding their children's illness and hospitalization (Petit-Steeghs et al., 2019). Researchers also discovered that parents worry about their child being in an unfamiliar environment, receiving investigations or treatments, and losing self-determination or choices (Coyne & Kirwan, 2012).

Although school-age children are better able to cope with separation in general, the stress and often accompanying **regression** imposed by illness or hospitalization may increase their need for parental security and guidance. This is particularly true for young school-age children, who have only recently left the safety of the home and are struggling with the crisis of school adjustment. Middle and late school-age children may react more to the separation from their usual activities and peers than to the absence of their parents. These children have a high level of physical and mental activity that frequently finds no suitable outlets in the hospital environment, and even when they dislike school, they admit to missing its routine and worry that they will not be able to compete or "fit in" with their classmates when they return. Feelings of loneliness, boredom, isolation, and depression are common. Such reactions may occur more as a result of separation than of concern over the illness, treatment, or hospital setting.

School-age children may need and desire parental guidance or support from other adult figures but may be unable or unwilling to ask for it. Because the goal of attaining independence is so important, they are reluctant to seek help directly, fearing that they will appear weak, childish, or dependent. Cultural expectations to "act like a man" or to "be brave and strong" weigh heavily on these children, especially boys, who tend to react to stress with stoicism, withdrawal, or passive acceptance. Often the need to express hostile, angry, or other negative feelings finds outlets in alternative ways, such as irritability and aggression toward parents, withdrawal from hospital personnel, inability to relate to peers, rejection of siblings, or subsequent behavioural issues in school.

For adolescents, separation from home and parents may produce varied emotions, ranging from difficulty coping to welcoming the event. However, loss of peer-group contact may pose a severe emotional threat because of loss of group status, inability to exert group control or leadership, and loss of group acceptance. Deviations within peer groups tend to be poorly tolerated, and although group members may express concern for the adolescent's illness or need for hospitalization, they will continue their group activities, quickly filling the gap of the absent member. During the temporary separation from their usual group, ill adolescents may benefit from group associations with other hospitalized teens.

Loss of Control

One of the factors influencing the amount of stress imposed by hospitalization is the amount of control that people perceive themselves as having. Lack of control increases the perception of threat and can affect children's coping skills. Many hospital situations decrease the amount of control a child feels. Although the usual sensory stimulations are lacking, the additional hospital stimuli of sight, sound, and smell may be overwhelming. Without insight into the type of environment conducive to children's optimal growth, the hospital experience can at best temporarily slow development and at worst permanently restrict it.

Effects of Hospitalization on the Child

Children may react to the stresses of hospitalization before admission, during hospitalization, and after discharge (Box 43.2). A child's concept of illness is even more important than age and intellectual maturity when it comes to hospitalization. This may or may not be affected

BOX 43.2 Posthospital Behaviours in Children

Young Children

Show initial aloofness toward parents; this may last from a few minutes (most common) to a few days. This is frequently followed by dependency behaviours:

- Tendency to cling to parents and demand attention from parents
- Vigorous opposition to any separation, such as staying at preschool or with a babysitter

Other negative behaviours include the following:

- New fears, such as nightmares
- Resistance to going to bed, night waking
- Withdrawal and shyness
- Hyperactivity
- Temper tantrums
- Food peculiarities
- Attachment to a blanket or toy
- Regression in newly learned skills such as self-toileting

Older Children

Negative behaviours include the following:

- Emotional coldness, followed by intense, demanding dependence on parents
- Anger toward parents
- Jealousy toward others, such as siblings

by the duration of the condition or prior hospitalizations; therefore, nurses should avoid overestimating the concepts of illness in children who have prior medical experience.

Individual Risk Factors. A number of risk factors make certain children more vulnerable than others to the stresses of hospitalization (Box 43.3). Because separation is such an important issue surrounding hospitalization for young children, children who are active and strong-willed tend to fare better when hospitalized than youngsters who are passive. Consequently, nurses should be alert to children who passively accept all changes and requests; these children may need more support than the "oppositional" child.

The stressors of hospitalization may cause young children to experience short- and long-term negative outcomes; stressors may be related to the length and number of admissions, multiple invasive procedures, and the parents' anxiety. Common responses include regression, separation anxiety, apathy, fears, and sleep disturbances, especially for children younger than 7 years of age. Supportive practices, such as family-centred care and frequent family visiting, may lessen the detrimental effects. Nurses should attempt to identify those children at risk for poor coping strategies. In a study of health care providers' perceptions of children's stress level in health care settings, the data indicated that one third of the participating health care providers were unaware or did not think that their health care setting could cause stress for pediatric patients. It is essential that pediatric health care providers know how to minimize stress for children and their parents (Al-Yateem et al., 2015). Recommended practices to minimize stress for children and parents include providing focused information for both children and health care providers, adapting the environment and systems to fit children's needs, and improving the interpersonal skills and attitudes of health care providers (Al-Yateem et al., 2015).

BOX 43.3 Risk Factors That Increase Children's Vulnerability to Stresses of Hospitalization

- "Difficult" temperament
- Lack of bonding between child and parent
- Age (especially between 6 months and 5 years)
- Male gender
- Developmental delays
- Multiple and continuing stresses (e.g., frequent hospitalizations)

Changes in the Pediatric Population. With a growing trend toward shortened hospital stays and outpatient surgery, a greater percentage of the children hospitalized today have more serious and complex conditions than those hospitalized in the past. Many of these children are fragile newborns and children with severe injuries or complex conditions who have survived because of major technological advances, yet have been left with chronic or disabling conditions that require frequent and lengthy hospital stays. The nature of their conditions increases the likelihood that they will experience more invasive and traumatic procedures while they are hospitalized. These factors make them more vulnerable to the emotional consequences of hospitalization and result in their needs being significantly different from those of the short-term patients of the past (see Chapter 41 for further discussion on children with special needs). Most of these children are infants and toddlers, the age group most vulnerable to the effects of hospitalization.

Concern has focused on the increasing length of hospitalization due to complex medical and nursing care, elusive diagnoses, and complicated psychosocial issues. Without special attention devoted to meeting the child's psychosocial and developmental needs in the hospital environment, the detrimental consequences of prolonged hospitalization may be severe.

Beneficial Effects of Hospitalization. Although hospitalization usually is stressful for children, it can also be beneficial. The most obvious benefit is the recovery from illness, but hospitalization also can present an opportunity for children to master stress and feel competent in their coping abilities. The hospital environment can provide children with new socialization experiences that can broaden their interpersonal relationships. The psychological benefits need to be considered and maximized during hospitalization. Appropriate nursing strategies to achieve this goal are presented later in the chapter.

Parents and caregivers can often experience burnout when caring for a chronically ill child in the home setting. Hospitalization of the child can be perceived as beneficial to the parent or caregiver as an opportunity for nurses and social workers to help with meals, rooming-in, and providing respite from caregiving.

STRESSORS AND REACTIONS OF THE FAMILY OF THE HOSPITALIZED CHILD

Parental Reactions

The crisis of childhood illness and hospitalization affects every member of the family. Parents' reactions to illness in their child depend on a variety of factors. Although one cannot predict which factors are most likely to influence their response, a number of possible variables have been identified (Box 43.4).

Parents whose children have been hospitalized may feel an overall sense of helplessness, question the skills of staff, need to have information explained in simple language, be dealing with fear and guilt, have to

BOX 43.4 Factors Affecting Parents' Reactions to Their Child's Illness

- Seriousness of the threat to the child
- Previous experience with illness or hospitalization
- Medical procedures involved in diagnosis and treatment
- Available support systems
- Personal ego strengths
- Previous coping abilities
- Additional stresses on the family system
- Cultural and religious beliefs
- Communication patterns among family members

cope with uncertainty, and seek reassurance from caregivers. Reassurance from the health care team can be in the form of collaboration, information sharing, preparation for procedures, ensuring formal and informal support for the family, and providing information in an unbiased and culturally sensitive manner (Eichner & Johnson, 2012).

When considering both nurses' and parents' self-perceived roles in the caring for hospitalized children it is important to clarify what nurses and parents consider to be their respective roles. Negotiation of these roles may be necessary, and how successful this negotiation is depends on the family's background, life experiences, and circumstances. Poor communication and failure to provide information may be obstacles to negotiating these roles (Bedells & Bevan, 2016). Other factors that may influence parental reactions to hospitalization are their insecurities, often caused by an unpredictable disease course. These insecurities can be exacerbated by limited specialized knowledge of long-term consequences, logistical issues, and nontransparent communication (Petit-Steeghs et al., 2019). Providing security through a clear care plan and engaging parents in the decision-making process can enhance their feelings of control (Bedells & Bevan, 2016). Additional strategies nurses can use to build relationships and encourage shared parent–nurse communication include expressing trust and respect for each other's expertise, having a caring attitude, and being an advocate for the child (Giambra et al., 2014).

Sibling Reactions

Siblings' reactions to a sister's or brother's illness or hospitalization are discussed in Chapter 41. These reactions differ little from those when a child becomes temporarily ill; siblings experience loneliness, fear, and worry, as well as anger, resentment, jealousy, and guilt. Illness may also result in a sibling's loss of status within their family or social group. Various factors have been identified that influence the effects of the child's hospitalization on siblings. In one study, parents of siblings of children with chronic illness tended to rate sibling health–related quality of life better than the siblings' self-reports. Greater disease severity of the sick child and older sibling age may be risk factors for impaired well-sibling quality of life (Limbers & Skipper, 2014).

Risk factors found to predict poor sibling adjustment include inadequate social support, poor family functioning, low income, and short time since diagnosis, but the findings are inconsistent. Siblings' maturity, compassion, and autonomy may contribute to adjusting well to the hospitalization. Siblings who do not adjust well may have strong negative emotions and face uncertainty, family disruptions, limited parental support, difficulties in school, altered friendships, as well as unmet needs (Long et al., 2018).

Parents are often unaware of the number of effects that siblings experience during the sick child's hospitalization and the benefit of simple interventions to minimize such effects, such as giving explicit explanations about the illness and providing for adequate care for siblings to remain at home. Sibling visitation is usually beneficial to the patient and sibling, as the visit may allow the child to see that their fears are unfounded. Siblings should be prepared for the visit with developmentally appropriate information and be given the opportunity to ask questions.

CARING FOR THE CHILD WHO IS HOSPITALIZED

Preparation for Hospitalization

Children and families require individualized care to minimize the potential negative effects of hospitalization. One action that can decrease negative feelings and fear in children is preparing them for hospitalization. The rationale for preparing children for the hospital experience and related procedures is based on the principle that fear of the unknown (fantasy) exceeds fear of the known. When children do not have paralyzing fear to cope with, they are better able to direct their energies toward dealing with the other, unavoidable stresses of hospitalization.

Although preparation of children for hospitalization is a common practice, there is no universal standard or program for all settings. The preparation process may be elaborate with tours, puppet shows, and playtime with miniature hospital equipment; it may involve the use of books, videos, or films; or it may be limited to a brief description of the major aspects of any hospital stay. No consensus exists on the timing of preparation. Some authorities recommend preparing children 4 to 7 years of age about 1 week in advance (when possible) so that they can assimilate the information and ask questions. For older children the time may be longer. However, for young children, who may begin to fantasize about what they observed, 1 or 2 days before admission is sufficient time for anticipatory preparation. The length of the session should be tailored to the children's attention span—the younger the child, the shorter the program. The optimal approach is one that is individualized for each child and family.

It is also essential for families to prepare for the hospitalization. Parents who are unsure or anxious about the hospital will transmit those emotions to the child. Nurses play an important role in helping children and families understand the reason for the hospitalization and what to expect during the admission.

Regardless of the specific type of program, all children, even those who have been hospitalized before, benefit from an introduction to the environment and routine of the unit. Sometimes it is not possible to prepare the child, as in the event of sudden, acute illness or an accident. However, care should be taken to orient the child and family to hospital routines, establish expectations, and allow for questions.

! NURSING ALERT

In many hospitals, child life specialists—health care providers with extensive knowledge of child growth and development and of the special psychosocial needs of children who are hospitalized and their families—help prepare children for hospitalization, surgery, and procedures. Although the structure of a program may vary, depending on the size of the pediatric facility, the patient population, and the availability of ancillary services, the two primary program objectives for child life are consistent: (1) to reduce the stress and anxiety related to the hospitalization or health care–related experiences, and (2) to promote normal growth and development in the health care setting and at home (Thompson, 2018).

A collaborative effort between the nurse, child life specialist, and other members of the child's health care team can help ensure the best possible hospital experience for the child and family.

Preparing the Child for Admission

The preparation that children require on the day of admission depends on the kind of prehospital counselling they have received. If they have been prepared in a formalized program, they will usually know what to expect in terms of initial medical procedures, inpatient facilities, and nursing staff. However, prehospital counselling does not preclude the need for support during procedures such as obtaining blood specimens, X-ray tests, or physical examinations. For example, undressing young children before they feel comfortable in their new surroundings can be upsetting to them. Causing needless anxiety and fear during admission may adversely affect the nurse's establishment of trust with these children. Nursing assistance during the admission procedure is vital, regardless of how well prepared any child is for the experience of hospitalization. In addition, spending this time with the child gives the nurse an opportunity to evaluate the child's understanding of subsequent procedures (Figure 43.4). Ideally, a primary nurse is assigned whenever possible to allow for individualized care and provide a substitute support person for the child.

When a child is admitted, nurses need to follow admission procedures (see Guidelines box: Hospital Admission). One particularly important decision is room assignment. The minimum considerations for room assignment are age, sex, and nature of the illness, including type of infectious precautions required. No absolute rules govern room selection, but, in general, placing children of the same age group and with similar types of illness in the same room is both psychologically and medically advantageous. However, there are many exceptions. For example, a child in traction may be therapeutic for another child confined to bed because of a serious illness. A child who is independent despite physical disabilities may help another child with similar or different limitations, and the parents of the child with disabilities may achieve deeper insight and acceptance of their child's disorder.

Age-grouping is especially important for adolescents. Many hospitals make an effort to place teenagers on their own unit or in a separate, designated section of the pediatric or general unit whenever possible.

GUIDELINES

Hospital Admission

Preadmission

Assign a room based on developmental age, seriousness of diagnosis, communicability of illness, and projected length of stay.

Prepare roommate(s) for the arrival of a new patient; when children are too young to benefit from this consideration, prepare parents.

Prepare room for the child and family, with admission forms and equipment nearby to eliminate need to leave the child.

Admission

Introduce the primary nurse to the child and family.

Orient the child and family to inpatient facilities, especially to the assigned room and unit; emphasize positive areas of the pediatric unit.

- Room—Explain call light, bed controls, television, bathroom, telephone, etc.
- Unit—Direct to playroom, desk, dining area, or other areas.

Introduce family to the child's roommate and their parents.

Apply identification band to the child's wrist, ankle, or both (if not already done).

Explain hospital guidelines and schedules, such as visiting hours, mealtimes, bedtime, and limitations (give written information and website if available).

Perform nursing admission history (see Box 43.5).

Take vital signs, blood pressure, height, and weight.

Obtain specimens as needed and order needed laboratory work.

Support child and assist practitioner with physical examination (for purposes of nursing assessment).

Fig. 43.4 The initial admission procedures give the nurse an opportunity to get to know the child and to assess the child's understanding of the hospital experience. (iStock.com/FatCamera)

Admission Assessment. The *nursing admission history* refers to a systematic collection of data about the child and family that enables the nurse to plan individualized care. The nursing admission history is presented in Box 43.5. The questions are directed to both the child and the child's parents or other primary caregivers. One of the main purposes of the history is to assess the child's usual health habits at home in order to promote a more normal environment in the hospital. Therefore, questions related to activities of daily living in the nutrition–metabolic, elimination, sleep–rest, and activity–exercise patterns are a major part of the assessment. The questions found under the health perception–health management pattern are directed toward evaluation of the child's preparation for hospitalization and are key factors in determining whether additional preparation is needed. The questions included in the self-perception–self-concept and role–relationship patterns address the child's potential reaction to hospitalization, especially in terms of separation.

The nurse should also inquire about the use of any medications at home, including complementary and alternative medicine (CAM) (see Chapter 35, Complementary and Alternative Medicine). Many Canadians take natural health products such as vitamins and minerals, herbal products, and homeopathic medicines on a regular basis. It is also important that the use of any herbal or complementary therapy be noted in a preoperative assessment because of possible **anaesthesia** or surgical complications related to use of herbal products. See Nursing Skills on Evolve: Admitting a Child to the Health Care System.

Besides completing the nursing admission history, nurses should also perform a physical assessment (see Chapter 33) before planning care. At the very least, the nurse's physical assessment of the child should include observation of the body for any impairments or physical limitations. The nurse should also listen to the heart and lungs to assess overall physical status to provide baseline data. It is important for nurses to be on alert for any signs of maltreatment, such as bruises or signs of neglect, which must be reported to child authorities.

Nursing Care

Preventing or Minimizing Separation. A primary nursing goal is to prevent separation anxiety, particularly in children younger than 5 years of age. Family-centred care started in pediatrics with the increased recognition of trauma related to child and family separation in the inpatient setting. Thus, in family-centred care the integral role of the family in a child's life is recognized and the family is seen as an

BOX 43.5 Nursing Admission History

Health Perception—Health Management

Why has your child been admitted?
How has your child's general health been?
What does your child know about this hospitalization?
- Ask the child why they came to the hospital.
- If the answer is "For an operation or for tests," ask the child to tell you about what will happen before, during, and after the operation or tests.

Has your child ever been in the hospital before?
- How was that hospital experience?
- What things were important to you and your child during that hospitalization? How can we be most helpful now?

What medications does your child take at home?
- Why are they given?
- When are they given?
- How are they given (if a liquid, with a spoon; if a tablet, swallowed with water; or other)?
- Does your child have any difficulty taking medication? If so, what helps?
- Is your child allergic to any medications?

What, if any, forms of complementary medicine practices are being used?

Nutrition

What are the family's usual mealtimes?
What are your child's favourite foods, beverages, and snacks?
- Average amounts consumed or usual size of portions
- Special cultural practices, such as family eating certain foods particular to their culture

What foods and beverages does your child dislike?
What are your child's feeding habits (bottle, cup, spoon, eating by self, needing assistance, any special devices)?
How does your child like the food served (warmed, cold, one item at a time)?
How would you describe your child's usual appetite (hearty eater, picky eater)?
- Has being sick affected your child's appetite? In what ways?

Are there any known or suspected food allergies?
Is your child on a special diet?
Are there any feeding issues (excessive fussiness, spitting up, colic); any dental or gum conditions that affect feeding?
- What do you do for these conditions?

Elimination

What are your child's toilet habits (diaper, uses toilet—day only or day and night, use of word to communicate urination or defecation, potty chair, regular toilet, other routines)?
What is your child's usual pattern of elimination (bowel movements)?
Do you have any concerns about elimination (bed-wetting, constipation, diarrhea)?
- What do you do for these concerns?

Have you ever noticed that your child sweats a lot?

Sleep

What is your child's usual hour of sleep and awakening?
What is your child's type of bed and schedule for naps; length of naps?
Is there a special routine before sleeping (bottle, drink of water, bedtime story, nightlight, favourite blanket or toy, prayers)?
Is there a special routine during sleep time, such as waking to go to the bathroom?
In which type of bed does your child sleep?
Does your child have a separate room or share a room; if shares, with whom?
Does your child sleep with someone or alone (sibling, parent, other person)?
What is your child's favourite sleeping position?
Are there any sleeping issues (falling asleep, waking during night, nightmares, sleep walking)?
Are there any difficulties in awakening and getting ready in the morning?
- What do you do for these issues?

Activity and Exercise

What is your child's schedule during the day (preschool, day care centre, regular school, extracurricular activities)?
What are your child's favourite activities or toys (both active and quiet interests)?
What are your child's usual television-viewing schedule and restrictions? Favourite programs at home?
Are there any television restrictions?
Does your child have any illness or disabilities that limit activity? If so, how?
What are your child's usual habits and schedule for bathing (bath in tub or shower, sponge bath, shampoo)?
What are your child's dental habits (brushing, flossing, fluoride supplements or rinses, favourite toothpaste); schedule of daily dental care?
Does your child need help with dressing or grooming, such as hair combing?
Are there any difficulties with any hygiene activities (dislike of or refusal to bathe, shampoo hair, or brush teeth) and how do you manage them?
Are there special devices that your child requires help in managing (eyeglasses, contact lenses, hearing aid, orthodontic appliances, artificial elimination appliances, orthopedic devices)?

Cognition and Perception

Does your child have any hearing difficulty?
- Does your child use a hearing aid?
- Have "tubes" been placed in your child's ears?

Does your child have any vision impairment?
- Does your child wear glasses or contact lenses?

Does your child have any learning difficulties?
- What is the child's grade in school?

Self-Concept

How would you describe your child (e.g., takes time to adjust, settles in easily, shy, friendly, quiet, talkative, serious, playful, stubborn, easygoing)?
What makes your child angry, annoyed, anxious, or sad? What helps when your child feels this way?
How does your child act when annoyed or upset?
What have been your child's experiences with and reactions to temporary separation from you (parent) and their reactions to it?
Does your child have any fears (places, objects, animals, people, situations)?
- How do you handle them?

Do you think your child's illness has changed the way they think about themselves, such as being more shy, embarrassed about appearance, or less competitive with friends, or staying at home more?

Relationships

Does your child have a favourite nickname?
What are the names of other family members or others who live in the home (relatives, friends, pets)?
Who usually takes care of your child during the day and night (especially if other than parent, such as babysitter, relative)?
What are the parents' occupations and work schedules?
Are there any special family considerations (adoption, foster child, step-parent, divorce, lone parent)?
Have any major changes in the family occurred lately (death, divorce, separation, birth of a sibling, loss of a job, financial strain, parent beginning a career, other)? Describe the child's reaction.

Continued

BOX 43.5 Nursing Admission History—cont'd

Who are your child's play companions or social groups (peers, younger or older children, adults, prefers to be alone)?
Do things generally go well for your child in school or with friends?
Does your child have "security" objects at home (pacifier, bottle, blanket, stuffed animal, or doll)? Did you bring any of these to the hospital?
How do you handle discipline issues at home? Are these methods usually effective?
Does your child have any condition that interferes with communication? If so, what are your suggestions for communicating with your child?
Will your child's hospitalization affect the family's financial support or care of other family members?
What concerns do you have about your child's illness and hospitalization?
Will anyone be staying with your child while hospitalized?
How can we contact you or another close family member outside the hospital?

Sexuality

(Questions to parent: Answer questions that apply to your child's age group.)
Has your child begun puberty (developing physical sexual characteristics, menstruation)? Have you or your child had any concerns?
How have you approached topics of sexuality with your child?
Do you think you might need some help with some topics?
Has your child's illness affected the way they feel about being a boy or a girl? If so, how?
Do you have any concerns about behaviours of your child, such as masturbation, asking many questions or talking about sex, not respecting others' privacy, or wanting too much privacy?
(Questions to adolescent: Answer questions about sexual concerns that apply to you.)
Who are your closest friends? (If one friend is identified, the nurse could ask more about that relationship, such as how much time they spend together, how serious they are about each other, if the relationship is going the way the teenager hoped.)
What are your views on sexuality education, living together, "hooking up," having an intimate friend or partner, or premarital sex? (The nurse should use the terms *friends* or *partners* rather than *girlfriend* or *boyfriend*.)
Which friends would you like to have visit in the hospital?

Coping and Stress

(Questions to parent: Answer questions that apply to your child's age group.)
What does your child do when tired or upset?
- If upset, does your child want a special person or object?
- If so, explain.

If your child has temper tantrums, what causes them and how do you handle them?
To whom does your child talk when worried about something?
How does your child usually handle difficulties or disappointments?
Have there been any big changes or difficulties in your family recently? If so, how have you handled them?
Has your child ever used drugs or alcohol or tried to commit suicide?
Do you think your child is "accident prone"? If so, explain.

Values and Beliefs

Is religion important to you? If so, what is your religion?
Is religion or faith important in your child's life? If so, how?
What, if any, religious practices would you like continued in the hospital (e.g., prayers before meals or bedtime; visit by minister, priest, rabbi, or other spiritual leader; prayer group)?

essential part of the child's care and illness experience. The family is considered a partner in the child's care. Family-centred care also supports the family by respecting the individual needs of the child and the family and establishing priorities based on the needs and values of the family unit. Efforts to collaborate with families and encourage their involvement in the patient's care include optimizing family visitation, family-centred rounding, family presence during procedures or interventions, and opportunities for formal and informal family conferences (Meert et al., 2013).

At the very least, most hospitals welcome parents at any time. Many hospitals provide facilities such as a chair or bed for at least one person per child, a unit kitchen, and other amenities that create a welcoming atmosphere for parents. Additionally, many units have a communication board outlining special activities or upcoming events for the families, as well as personal communication boards for each room. However, not all hospitals provide such amenities, and parents' own schedules may prevent rooming-in. In such instances, strategies to minimize the effects of separation must be implemented. There are out-of-hospital supports across Canada for families of seriously ill children receiving ongoing hospital care, such as Ronald McDonald House Charities Canada, which create a home-away-from-home atmosphere as well as the ability to make connections with and receive support from other families in similar situations (see Additional Resources).

Nurses need to have an appreciation of the child's separation behaviours. As discussed earlier, the phases of protest and despair are normal. The child should be allowed to cry. Even if the child rejects strangers, the nurse can provide support through physical presence. *Presence* is defined as spending time being physically close to the child while using a quiet tone of voice, appropriate choice of words, eye contact, and touch in ways that establish rapport and communicate empathy. If detachment behaviours are evident, the nurse can help maintain the child's contact with the parents by talking about them frequently with the child, encouraging the child to remember them, and stressing to the parents the significance of their visits, telephone calls, or letters. The use of cellular phones and personal tablets can increase the contact between the hospitalized child and parents or other significant family members and friends. In one Canadian study that evaluated the use of videophones among families with limited access to visit their hospitalized child because of being geographically separated, the videophones connected the children with their families and decreased feelings of isolation and anxiety and increased feelings of connection between family members (Nicholas et al., 2011). Another research study, which assessed use of both virtual reality and videoconferencing combinations, found that the technology allowed children to feel that they were at home rather than in the hospital. The disadvantages of this system are technical abilities required, physical side effects, and complexity of use. However, the children enthusiastically welcomed this experience (Bakker et al., 2018).

Separation may be equally difficult for parents, especially when they do not understand the behaviours of separation anxiety. To avoid the child's immediate protest, parents may sneak out or lie to the child about leaving. As a result, instead of learning that absence is associated with a guaranteed return, the child learns that absence means loss of parents. Helping parents recognize that separation behaviours are normal and expected can decrease the parents' anxiety and may ease their fears about leaving their child. Explaining to parents how the child reacts after they leave may also be helpful. Many parents imagine that

the child cries for hours after they leave, whereas in reality the child may cry for a few minutes but settle down when comforted by someone else.

Toddlers and preschoolers have a limited concept of time. Time is measured in associations, such as eating dinner "when Daddy comes home." Therefore, when helping parents with children's fears of separation, nurses need to suggest ways of explaining leaving and returning. For example, if parents must leave to go to work or make meals for other family members, they should tell the child the reason for leaving. They also need to convey the expected time of return in terms of anticipated events. For example, if the parents will return in the morning, they can say to the child, "We'll see you after the sun comes up" or "We'll come back when [a favourite program] is on television."

The young child's ability to tolerate parental absence is limited. Thus parental visits should be frequent, such as visiting three times a day for short periods rather than once a day for an extended time. This may mean that each parent visits at different times in order to lessen the length of separation. When parents cannot visit, the presence of other significant people can be most comforting for the child.

Older children who know how to tell time may find it helpful to have a clock or watch. However, these children have the same need for honesty from their parents regarding visiting schedules. For adolescents, peer groups are important, thus they often appreciate planning visiting hours with their parents to ensure that they have some private time for friends.

Familiar surroundings also increase the child's adjustment to separation. If parents cannot stay with the child, they should leave favourite articles from home with the child, such as a blanket, toy, bottle, feeding utensil, or article of clothing. Because young children associate such inanimate objects with significant people, they gain comfort and reassurance from these possessions. They make the association that if the parents left this, the parents will surely return. Placing an identification band on the toy lessens the chances of its being misplaced and provides a symbol that the toy is experiencing the same needs as the child. Other reminders of home include photographs, audio or video recordings, or live video online streaming of family members reading a story, singing a song, saying prayers before bedtime, relating events at home, or taking a "talking walk" through the home. The recordings can be played at lonely times, such as on awakening or before sleeping. Some units allow pets to visit, which can have therapeutic benefits for a child. Older children also appreciate familiar articles from home, particularly photographs, a smartphone or tablet, a favourite toy or game, and their own pajamas. Often the importance of treasured objects to school-age children is overlooked or criticized. However, many school-age children have a special object to which they formed an attachment in early childhood. Such treasured or transitional objects can help even older children feel more comfortable in a strange environment.

The strange sights, smells, and sounds in the hospital that are commonplace for the nurse can be frightening and confusing for children. It is important for the nurse to try to evaluate stimuli in the environment from the child's point of view (considering also what the child may see or hear happening to other patients) and to make every effort to protect the child from frightening and unfamiliar sights, sounds, and equipment. The nurse should offer explanations or prepare the child for those experiences that are unavoidable. Combining familiar or comforting sights with the unfamiliar can relieve much of the harshness of medical equipment.

Helping children maintain their usual contacts also minimizes the effects of separation imposed by hospitalization. This includes continuing school lessons during the illness and confinement, visiting with friends either directly or through email, text messaging, or telephone calls, and participating in stimulating projects whenever possible (Figure 43.5). For extended hospitalizations, youngsters enjoy personalizing the hospital room to make it "home" by decorating the walls with posters and cards, rearranging the furniture (when possible), and displaying a collection or hobby.

Fig. 43.5 For extended hospitalizations children enjoy having projects with other patients to occupy time. (© Image Source/Alamy Stock Photo.)

Minimizing Loss of Control. Feelings of loss of control result from separation, physical restriction, changed routines, enforced dependency, and magical thinking. Although some of these cannot be prevented, most can be minimized through individualized planning of nursing care.

Promoting freedom of movement. Younger children react most strenuously to any type of physical restriction or immobilization. Although temporary immobilization may be necessary for some interventions, such as maintaining an intravenous line, most physical restriction can be prevented if the nurse and child work together.

For young children, particularly infants and toddlers, preserving parent–child contact is the best means of decreasing the need for or stress of restraint. For example, almost the entire physical examination can be done with the child in a parent's lap, with the parent hugging the child for procedures such as otoscopy. For painful procedures, the nurse should assess the parents' preferences for assisting, observing, or waiting outside the room.

Environmental factors may also restrict movement. Keeping children in cribs or playpens may not represent immobilization in a concrete sense, but it certainly limits sensory stimulation. Increasing mobility by transporting children in carriages, wheelchairs, carts, or wagons provides them with a sense of freedom.

In some cases, physical restraint or isolation is necessary because of the child's medical diagnosis. In these cases, the environment can be altered to increase sensory freedom, such as moving the bed toward the window, opening window shades, or providing musical, visual, or tactile activities.

Maintaining the child's routine. Altered daily schedules and loss of rituals are particularly stressful for toddlers and early preschoolers and may increase the stress of separation. The nursing admission history will provide a baseline for planning care around the child's usual home activities. A frequently neglected aspect of altered routines is the change in the child's daily activities. A typical child's day, especially during the school years, is structured with specific times for eating, dressing, going to school, playing, and sleeping. However, this time structure vanishes when the child is hospitalized. Although nurses have a set schedule, the child is frequently unaware of it, and the new schedules that are imposed may be rigid. For example, some units have uniform nap times and bedtimes for all children, whereas others allow children to stay up

Eric's Daily Schedule

7:30 AM	– Breakfast, morning bath	3:00 PM	– Tutor (M, W, F)
			– Study time (T, Th)
9:00	– Medications, dressing change	4:00	– Physical therapy
		5:30	– Dinner
11:00	– Physical therapy	9:00	– Medications, dressing change
12:00 PM	– Lunch		
		9:15	– Bedtime

Fig. 43.6 Time structuring is an effective strategy for normalizing the hospital environment and increasing the child's sense of control.

late at night. Many children obtain significantly less sleep in the hospital than at home; the primary causes are delay in sleep onset and early termination of sleep because of hospital routines. Not only are hours of sleep disrupted, but waking hours are spent in passive activities. For example, few institutions impose any limits on the amount of time the child spends watching television or using a handheld device. This may lead to the child being less "tired" at bedtime and can delay the onset of sleep.

One technique that can minimize the disruption in the child's routine is establishing a daily schedule. This approach is most suitable for the non–critically ill school-age child or adolescent who has mastered the concept of time. It involves scheduling the child's day to include all those activities that are important to the child and nurse, such as treatment procedures, schoolwork, exercise, television, playroom, and hobbies. Together, the nurse, parent, and child can then plan a daily schedule with times and activities written down (Figure 43.6) and left in the child's room, with a clock or watch. Whenever possible, a calendar should also be constructed with special events marked, such as favourite television programs, visits by friends or relatives, events in the playroom, and holidays or birthdays. If specific changes in treatment are expected, such as "beginning physiotherapy in 2 days," these can be added.

Encouraging independence. The dependent role of the hospitalized patient can instill tremendous feelings of loss in older children. Principal interventions should focus on respect for individuality and the opportunity for decision making. Although these sound simple to carry out, their efficacy lies with nurses who are flexible and tolerant. It is also important for the nurse to empower the patient while not feeling threatened by a sense of lessened control.

Enabling children's sense of control involves helping them maintain independence and promoting the concept of self-care. *Self-care* refers to the practice of activities that individuals personally initiate and perform on their own behalf in maintaining life, health, and well-being. Although self-care is limited by the child's age and physical condition, most children beyond infancy can perform some activities with little or no help in the hospital. Other approaches include jointly planning care, time structuring, having the child wear street clothes and make choices in food selections and bedtime, continuing school activities, and placing the child in a room with an appropriate age-mate.

Promoting understanding. A sense of loss of control can occur from feelings of having too little influence on one's destiny or from sensing overwhelming control or power over one's fate. Although preschoolers' cognitive abilities predispose them most to magical thinking and delusions of power, all children are vulnerable to misinterpreting causes for stresses such as illness and hospitalization.

Most children feel more in control when they know what to expect, since the element of fear is reduced. Anticipatory preparation and provision of information can help to lessen stress and increase understanding (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44).

Informing children of their rights while they are hospitalized fosters greater understanding and may relieve some of the feelings of powerlessness they typically experience. Hospitals providing services to children should have a hospital-wide policy on the rights and responsibilities of these patients and of their parents or guardians. An example of hospital rights is provided in Box 43.6.

Preventing or Minimizing Fear of Bodily Injury. Beyond early infancy, all children fear bodily injury from mutilation, bodily intrusion, body-image change, disability, or death. In general, preparation of children for painful procedures decreases their fears and increases the child's ability to assist. Modifying procedural techniques for children in each age group also minimizes the fear of bodily injury. For example, toddlers and young preschoolers are traumatized by insertion of a rectal thermometer, thus axillary or tympanic temperatures can effectively be substituted. Whenever procedures are performed on young children, the most supportive intervention is to do the procedure as quickly as possible while maintaining parent–child contact.

BOX 43.6 IWK Health Centre—Family-Centred Care and Rights

Patient- and family-centred care involves the patient and their family in making decisions about their care and much more:

It is honouring a family's cultural and social background and religious beliefs.

It is making sure directional signs are helpful and make sense to families trying to use them.

It is connecting patients with their families sooner after a surgical procedure, and communicating with the family often.

It is teaching families to advocate for the patient, the patient to advocate for themselves, and staff advocating for them when they are unable to.

While health care providers are the experts on health and disease, family members are experts on the patient. Family is also a patient's primary strength and support. Information from patients and families can be helpful to staff, improve care, and help the health care team design better programs and friendlier systems.

Everyone's role is important, and what health care providers and the family do together is greater than what either can do separately to achieve the best health for loved ones.

Therefore, care is based on partnerships with families, health care providers, and community supports. Families are encouraged to become an active partner in their and their loved one's health care.

Everyone (patients, families, staff, physicians, learners, researchers, and volunteers) has the RIGHT to . . .

- Be treated with respect
- Be listened to and be heard
- Be in a place that is safe (physically, emotionally, psychologically, and spiritually)
- Be active partners in care
- Be given information that is needed to provide or receive the best care

Source: IWK Health Centre. (2020). *Family-centred care*. http://www.iwk.nshealth.ca/pfcc.

Because of toddlers' and preschool children's poorly defined body boundaries, the use of bandages may be particularly helpful. For example, telling children that the bleeding will stop after the needle is removed does little to relieve their fears, whereas applying a small Band-Aid usually reassures them. The size of bandages is also significant to children in this age group; the larger the bandage, the more importance is attached to the wound. Watching their surgical dressings become successively smaller is one way young children can measure healing and improvement. Prematurely removing a dressing may cause these children considerable concern for their well-being.

For children who fear mutilation of body parts, it is essential that the nurse repeatedly stress the reason for a procedure and evaluate their understanding. For example, explaining cast removal to preschoolers may seem simple enough, but children's comprehension of the details may vary considerably. Asking them to draw a picture of what they think will happen can present substantial evidence of how they perceive events.

Children may fear bodily injury from a great variety of sources. Imaging machines, strange equipment used for examination, unfamiliar rooms, or awkward positions can be perceived as potentially hazardous. In addition, thoughts and actions can be imagined sources of bodily damage. Therefore, it is important to investigate imagined reasons, particularly of a sexual nature, for illness. Because children may fear revealing such thoughts, using techniques such as drawing or doll play may elicit previously undisclosed misconceptions.

Older children fear bodily injury of both internal and external origins. For example, school-age children are aware of the significance of the heart and may fear the actual operation as much as the pain, the stitches, and the possible scar. Adolescents may express concern about the actual procedure but be much more anxious over the resulting scar.

Children can grasp information only if it is presented on or close to their level of cognitive development. This requires an awareness of the words used to describe events or processes. For example, young children told that they are going to have a CAT (i.e., CT, computed tomography) scan may wonder, "Will there be cats? Or something that scratches?" It is clearer to describe the procedure in simple terms and explain what the letters of the common name stand for. Therefore, to prevent or alleviate fears, nurses must be keenly aware of the medical terminology and vocabulary that they use every day.

When children are upset about their illness, their perception can be changed by (1) providing a somewhat different and less negative account of the disease or (2) offering an explanation that is characteristic of the next stage of cognitive development. An example of the first strategy is reassuring a preschooler who fears that, after a tonsillectomy, another sore throat means a second operation. Explaining that after tonsils are "fixed" they do not need fixing again can help relieve the fear. An example of the latter strategy is to explain that germs made the tonsils sick, and even though germs can cause another sore throat, they cannot cause the tonsils to ever be sick again. This higher-level explanation is based on the school-age child's concept of germs as a cause of disease.

Providing Developmentally Appropriate Activities. A primary goal of nursing care for the child who is hospitalized is to minimize threats to the child's development. Children who experience prolonged or repeated hospitalization are at greater risk for developmental delays or regression. The nurse who provides opportunities for the child to participate in developmentally appropriate activities further normalizes the child's environment and helps reduce interference with the child's ongoing development.

Interference with normal development may have long-term implications for the infant and toddler. The nurse can play a primary role in identifying children at risk and helping to plan, implement, and evaluate developmental interventions.

School is an integral part of the school-age child's and adolescent's development. A key factor in accreditation for hospitals serving children is whether the hospital provides access to appropriate educational services when a child's treatment requires a significant absence from school (Accreditation Canada, 2020). For example, BC Children's Hospital provides provincial school services to school-age children and youth (kindergarten to grade 12) while they or their siblings are staying in the hospital (BC Children's Hospital, 2021). The nurse can encourage children to resume schoolwork as their condition permits, help them schedule time for studies, and help the family coordinate hospital educational services with their children's schools. Children should have the opportunity to continue art and music classes as well as their academic subjects.

To meet the unique developmental needs of adolescents, special units may be designated that provide both privacy and increased socialization and appropriate activities. Teenagers should not share space with younger children, who are often perceived as a threat to their maturity.

In caring for the adolescent patient, it is essential to provide flexible routines and activities, such as more group activity, wearing of street clothes, and access to the items so critical to adolescents—cell phones, laptops, personal tablets, video games, and televisions. Because adolescents' food habits are rarely limited to the three traditional meals a day, a ready supply of snacks should be available. However, the most important benefit of these units is increased socialization with peers. In addition, staff members usually enjoy working with this age group and are able to establish the trust that is so essential for communication.

! NURSING ALERT

When adolescents must share a common activity room with younger patients, referring to the area as the "activity room" rather than the "playroom" may entice them to visit the room and participate in activities.

Although regression is expected and normal for all age groups, nurses have the responsibility to foster the child's growth and development. Hospitalization can become a significant opportunity for learning and advancing. Extended hospitalizations for long-term chronic illness or situations of failure to thrive, abuse, or neglect represent instances in which regression must be seen as an adjustment period, to be followed by plans for promoting appropriate developmental skills.

Providing Opportunities for Play and Expressive Activities. Play is one of the most important aspects of a child's life and is an effective tool for managing stress. Because illness and hospitalization constitute crises in a child's life and often involve overwhelming stresses, children need to act out their fears and anxieties as a means of coping with these stresses. Play is essential to children's mental, emotional, and social well-being; it does not stop when children are ill or in the hospital. On the contrary, play in the hospital serves many functions, including to promote well-being (Box 43.7). Of all hospital facilities, no room alleviates the stressors of hospitalization more than the playroom (or activity room). In the playroom, children temporarily distance themselves from their illness, hospitalization, and the associated stressors. This room should be a safe haven for children, free from medical or nursing procedures, strange faces, and probing questions. The playroom then becomes a sanctuary in an otherwise frightening environment.

Engaging in play activities also gives children a sense of control. In the hospital environment, most decisions are made for the child; play

BOX 43.7 Functions of Play in the Hospital

- Provides diversion and brings about relaxation
- Helps child feel more secure in a strange environment
- Lessens the stress of separation and the feeling of homesickness
- Provides a means for release of tension and expression of feelings
- Encourages interaction and development of positive attitudes toward others
- Provides an expressive outlet for creative ideas and interests
- Provides a means for accomplishing therapeutic goals (see Use of Play in Procedures, Chapter 44)
- Places child in active role and provides an opportunity to make choices and be in control

and other expressive activities offer the child opportunities to make choices for themselves. Even if a child chooses not to participate in a particular activity, the nurse has offered the child a choice, perhaps one of only a few real choices the child has had that day.

The hospitalized child typically has lower energy levels than those of healthy children of the same age. Hospitalized children may not appear engaged and enthusiastic about an activity, even though they are enjoying the experience. Activities may need to be adjusted or limited according to the child's age, endurance, and special needs.

Diversional activities. Almost any form of play can be used for diversion and recreation, but the activity should be selected on the basis of the child's age, interests, and limitations (Figure 43.7). Children do not necessarily need special direction for using play materials. Small children enjoy a variety of small, colourful toys that they can play with in bed or in their room, or more elaborate play equipment, such as playhouses, sandboxes, rhythm instruments, or large boxes and blocks, that may be a part of the hospital playroom.

Fig. 43.7 Play materials for children in the hospital need to be appropriate for their age, interests, and limitations. (© BSIP SA/Alamy Stock Photo.)

Games that can be played alone or with another child or an adult are popular with older children, as are puzzles; reading material; quiet, individual activities, such as sewing, stringing beads, and weaving; and Lego blocks and other building materials. Assembling models is an excellent pastime, but one should make certain that all pieces and necessary materials are included in the package so the child is not disappointed and becomes frustrated.

Well-selected books are of infinite value to the child. Children never tire of stories; having someone read aloud to them gives them much pleasure and is of special value to the child who has limited energy to expend in play. A radio, tablet, computer, electronic games, and television are useful tools for entertaining a child. Computers or tablets with access to the Internet can provide diversion, educational opportunities, and online support groups.

When supervising play for ill or convalescent children, it is best to select activities that are simpler than would normally be chosen for the child's specific developmental level. These children usually do not have the energy to cope with more challenging activities. Other limitations may also influence the type of activities. Special consideration must be given to the child who is confined in movement, has a restricted extremity, or is isolated. Toys for isolated children must be disposable or need to be disinfected after every use.

Toys. Parents of hospitalized children often ask nurses about the types of toys that would be best to bring for their child. Although they want to buy new toys for the hospitalized child to offer cheer and comfort, it is often better to wait to bring new things, especially for younger children. Small children need the comfort and reassurance of familiar things, such as the stuffed animal the child hugs for comfort and takes to bed at night. All toys brought into the hospital should be assessed for safety.

Children who are hospitalized for an extended time benefit from changes in toys. Rather than a confusing accumulation of toys, older toys should be replaced periodically as interest wanes.

A highly successful diversion for a child who is hospitalized is having the parents bring a box with several small, inexpensive, brightly wrapped items with a different day of the week printed on the outside of each package. The child will eagerly anticipate the time for opening each one. If the parents know when their next visit will be, they can provide the number of packages that corresponds to the time between visits. In this way the child knows that the diminishing packages also represent the anticipated visit from the parent.

Expressive activities. Play and other expressive activities provide one of the best opportunities for encouraging emotional expression, including the safe release of anger and hostility. Nondirective play that allows children freedom for expression can be tremendously therapeutic. However, **therapeutic play** should not be confused with play therapy, a psychological technique reserved for use by trained and qualified therapists as an interpretative method with emotionally disturbed children. On the other hand, therapeutic play is an effective, nondirective modality for helping children manage their concerns and fears; at the same time it often helps the nurse gain insights into children's needs and feelings. See Nursing Skills on Evolve: Assisting with Therapeutic Play.

Tension release can be facilitated through almost any activity; with younger ambulatory children, large-muscle activity through use of tricycles and wagons is beneficial. Much aggression can be safely directed into games or activities that involve pounding and throwing. Beanbags are often thrown at a target or open receptacle with surprising vigour and hostility. A pounding board can be a favourite item for young children; clay and play dough are beneficial for use at any age.

Fig. 43.8 Drawing and painting are excellent media for expression.

Creative expression. Although all children derive physical, social, emotional, and cognitive benefits from engaging in art or other creative activities, children's need for such activities is intensified when they are hospitalized. Drawing and painting are excellent media for expression (Figure 43.8). Children are often more at ease expressing their thoughts and feelings through art, since humans think first in images and later learn to translate these images into words. Children can work individually or work together on a group project, such as a mural painted on a long piece of paper.

Although interpretation of children's drawing requires special training, observing changes in a series of the child's drawings over time can be helpful in assessing psychosocial adjustment and coping. The nurse can use children's drawings, stories, poetry, and other products of creative expression as a springboard for discussion of thoughts, fears, and understanding of concepts or events (see Communication Techniques, Chapter 30). For example, a child's drawing before surgery may reveal unvoiced concerns about mutilation, body changes, and loss of self-control.

Nurses can incorporate opportunities for musical expression into routine nursing care. For example, simple musical instruments, such as bracelets with bells, can be placed on infants' legs for them to shake to accompany mealtime music or dressing changes. The nurse can suggest dance or movement to encourage a child to ambulate.

Dramatic play. **Dramatic play** is a well-recognized technique for emotional release, allowing children to re-enact frightening or puzzling hospital experiences. Through the use of puppets, replicas of hospital equipment, or some actual hospital equipment, children can act out the situations that are a part of their hospital experience. Dramatic play enables children to learn about procedures and events that concern them and to assume the roles of the adults in the hospital environment.

Puppets are universally effective for communicating with children. Most children see them as peers and readily communicate with them. Children will tell the puppet feelings that they hesitate to express to adults. Puppets can share children's own experiences and help them find solutions to their problems. Puppets dressed to represent figures in the child's environment—for example, a physician, nurse, child patient, therapist, and members of the child's own family—are especially useful. Small, appropriately attired dolls are equally effective in encouraging the child to play out situations, although puppets are usually best for direct conversation.

When choosing play for a child, medical needs must be considered, but at times a procedure can be postponed briefly to allow the child to complete a special activity (see Clinical Reasoning Case Study: Playroom and Hospital Procedures). In addition, any limitations imposed by the child's condition need to be taken into account. For example, small children may eat paste and other creative media; therefore, a child who is allergic to wheat should not be given finger paint made from wallpaper paste or modelling dough made with flour. A child on a restricted salt intake should not play with modelling dough because salt is one of its major constituents. Play can be satisfactorily incorporated into the child's care if the nurse and others involved allow some flexibility and use creativity in planning for play.

CLINICAL REASONING CASE STUDY

Playroom and Hospital Procedures

Hannah, a 7-year-old with cystic fibrosis, has been hospitalized numerous times with complications from the condition. She is playing a board game with her brother, sister, and several other children in the playroom on the pediatric unit. A pediatric phlebotomist enters the playroom and says, "Hannah, I need to take some blood. I can see that you are playing a game, so I'll just do it while you play. It will just take a minute." Hannah nods her head indicating that she agrees to let the phlebotomist draw the blood at this time. The playroom is usually off-limits for invasive procedures. As Hannah's nurse, you are aware that the pediatric health care provider wants the results of the laboratory studies as soon as possible to make a decision about her course of therapy.

Questions

1. What are the functions of play in a hospitalized child?
2. What is the priority in this situation?
3. What are the implications of performing the venipuncture in the playroom?
4. What nursing intervention(s) should be implemented and which ones have the highest priority?
5. Identify important patient-centred outcomes with reference to your nursing interventions.

Maximizing Potential Benefits of Hospitalization. Although hospitalization generally represents a stressful time for children and families, it also represents an opportunity for facilitating positive change within the child and among family members. For some families the stress of a child's illness, hospitalization, or both can lead to strengthening of family coping behaviours and the emergence of new coping strategies.

Fostering parent–child relationships. The crisis of illness or hospitalization can mobilize parents into more acute awareness of their child's needs. For example, hospitalization provides opportunities for parents to learn more about their children's growth and development. When parents are helped to understand children's usual reactions to stress, such as regression or aggression, they are not only better able to support the child through the hospital experience but also may extend their insights into child-rearing practices after discharge.

Difficulties in parent–child relationships that existed before hospitalization that are characterized by feeding issues, negative behaviour, and sleep disturbances may decrease during hospitalization. The temporary cessation of such issues sometimes alerts parents to the role they may be playing in promoting the negative behaviour. With help from

health care providers, parents can restructure ways of relating to their children to foster more positive behaviour.

Hospitalization may also represent a temporary reprieve or refuge from a disturbed home. Typically, maltreated or neglected children's dramatic physical and social improvement during hospitalization is proof of the benefits and potential growth that can occur during such times. These children temporarily are able to seek support, reassurance, and security from new relationships, particularly with nurses and hospitalized peers.

Providing educational opportunities. Illness and hospitalization represent excellent opportunities for children and other family members to learn more about their bodies, each other, and the health professions. For example, during a hospital admission for a diabetic crisis, the child may learn about the disease; the parents may learn about the child's needs for independence, normalcy, and appropriate limits; and each of them may find a new support system in the hospital staff.

Promoting self-mastery. The experience of facing a crisis such as illness or hospitalization, coping successfully with it, and maturing as a result of it constitutes an opportunity for self-mastery. Younger children have the chance to test fantasy-versus-reality fears. They realize that they were not abandoned, mutilated, or punished. In fact, they were loved, cared for, and treated with respect for their individual concerns. It is not unusual for children who have undergone hospitalization or surgery to tell others that "it was nothing" or to display proudly their scars or bandages. For older children, hospitalization may represent an opportunity for decision making, independence, and self-reliance. They are proud of having survived the experience and may feel a genuine self-respect for their achievements. Nurses can facilitate such feelings of self-mastery by emphasizing aspects of personal competence in the child and not focusing on negative behaviour.

Providing socialization. Hospitalization may offer children a special opportunity for social acceptance. Lonely, asocial, and even children with behavioural issues find a sympathetic environment in the hospital. Children with a physical disability or who are in some other way "different" from their age-mates may find an accepting social peer group (Figure 43.9). Although this does not always spontaneously occur, nurses can structure the environment to foster a supportive child group. For example, selection of a compatible roommate can help children gain a new friend and learn more about themselves. Forming relationships with significant members of the health care team, such as the physician, nurse, child life specialist, or social worker, can greatly enhance children's adjustment in many areas of life.

Parents may also encounter a new social group in other parents who face similar challenges. The waiting room or hallway "support" groups are inherent to every institution. Parents meet while in the hospital or clinic and discuss their children's illnesses and treatments. Nurses can capitalize on this informal gathering by encouraging parents to discuss collectively their concerns and feelings. Nurses can also refer parents to organized parent groups or can use the help and support of parents of recovered hospitalized patients. It is important that nurses emphasize to families that each child responds differently to disease, treatments, and care. Questions raised during group discussions can be clarified with a nurse or health care provider.

Providing Support for the Family. Although it is not possible to predict exactly which factors are most likely to have an effect on the family's reactions, important variables are (1) the seriousness of the child's illness, (2) the family's previous experience with hospitalization, and (3) the medical procedures involved in the diagnosis and treatment. Important information is also obtained in the nursing admission history (see Box 43.5).

Fig. 43.9 Placing children of the same age group with similar illnesses near each other on the unit is both psychologically and medically supportive. (Courtesy E. Jacob, Texas Children's Hospital.)

Support for family members involves the willingness to stay and listen to parents' verbal and nonverbal messages. Sometimes the nurse does not give this support directly. For example, the nurse may offer to stay with the child to allow the parents time alone or may discuss with other family members the parents' need for extra relief. Often relatives and friends want to help but do not know how. Suggesting ways to be of assistance, such as babysitting, preparing meals, doing laundry, or transporting the siblings to school, can prompt others to help reduce responsibilities that burden parents.

Parents with religious beliefs may appreciate the counsel of a clergy member, but because of stress they may not have sufficient time and energy to initiate the contact. Nurses can be supportive by arranging for clergy to visit.

Support also involves accepting cultural and ethnic values. Health and illness are defined differently by various ethnic groups. For some, a disorder that has few outward manifestations of illness, such as diabetes, hypertension, or cardiac conditions, is not a sickness. Consequently, following a prescribed treatment may be seen as unnecessary. Nurses who appreciate the influences of culture are more likely to intervene therapeutically (see also Chapter 31, Social, Cultural, and Religious Factors That Impact Health).

Parents may need help in accepting their own feelings toward the ill child. If given the opportunity, parents often disclose their feelings of loss of control, anger, and guilt. They often resist admitting to such feelings because they expect others to disapprove of behaviour that is less than perfect. Unfortunately, health personnel, including nurses, sometimes exercise little tolerance for deviation from the expected norm. This only increases the psychological impact of a child's illness on family members. Helping parents identify the specific reasons for such feelings and emphasizing that each is a normal and healthy response to

stress may reduce the parents' emotional burden. Often a social worker, who may become involved early on in the hospital experience, can provide families with links to community resources and organizations that provide financial help and other supports. They can also help the child and family members talk through personal issues related to the hospitalization.

The needs of siblings should also be addressed. Support may involve preparing siblings for hospital visits, assessing their adjustment, and providing appropriate interventions or referrals when needed. The Family-Centred Care box: Supporting Siblings During Hospitalization suggests ways that parents can support siblings during hospitalization.

FAMILY-CENTRED CARE

Supporting Siblings During Hospitalization

Trade off staying at the hospital with your partner or have a surrogate who knows the siblings well stay in the home.

Offer information about the child's condition to siblings; respect the sibling who avoids information as a means of coping with the situation.

Arrange for children to visit their brother or sister in the hospital if possible.

Encourage phone visits, mail, email, and text messages between brothers and sisters; provide children with phone numbers, email addresses, writing supplies, and stamps.

Help each sibling identify an extended family member or friend to be their support person and provide extra attention during parental absence.

Make or buy inexpensive toys or trinkets for siblings, one gift for each day the child will be hospitalized.

- Wrap each gift separately and place it in a basket, box, or other container at each child's bedside.
- Instruct siblings to open one gift each night at bedtime and to remember that they are in the parent's thoughts.

If the child's condition is stable and distance is not prohibitive, plan a special time at home with the siblings or have your partner or another relative or friend bring the children to meet you at a restaurant or other location near the hospital.

- Have extended family members or friends schedule a visit by siblings to the child in the hospital during parental absence.
- Arrange a pass for the child to leave the hospital to join the family if the child's condition permits.

Perceived changes in siblings of hospitalized children: A comparison of sibling and parent reports. *Child Health Care, 18*(1), 42–48. https://doi.org/10.1207/s15326888chc1801_6; Rollins, J. (1992). *Brothers and sisters: A discussion guide for families*. Epilepsy Foundation of America.

Providing Information. One of the most important nursing interventions is providing information about (1) the disease, its treatment, the prognosis, and home care; (2) the child's emotional and physical reactions to illness and hospitalization; and (3) the probable emotional reactions of family members to the crisis.

For many families the child's illness is the first contact they have with the hospital experience. Often parents are not prepared for the child's behavioural reactions to hospitalization, such as separation behaviours, regression, aggression, and hostility. Providing parents with information about these normal and expected behavioural responses can lessen the parents' anxiety during the hospitalization. The family is equally unfamiliar with hospital routines and policies, which often compounds their confusion and anxiety. Thus, the family needs clear explanations about what to expect and what is expected of them.

Parents also need to be aware of the effects of illness on the family and of strategies to prevent negative changes. Specifically, parents should keep the family well informed and communicate with everyone as much as possible. They should try to treat all the children equally and in the same way as before the illness occurred. Discipline, which initially may be lessened for the ill child, should be continued, to provide a measure of security and predictability. When ill children know that their parents expect certain standards of conduct from them, they feel certain that they will recover. Conversely, when all limits are removed, they fear that something catastrophic will happen.

Helping parents understand the meaning of posthospitalization behaviours of the sick child can help them tolerate and support such behaviours. In addition, parents should be forewarned of common reactions following discharge (see Box 43.2). Parents who do not expect such reactions may misinterpret them as evidence of the child's "being spoiled" and demand perfect behaviour at a time when the child is still reacting to the stress of illness and hospitalization. If the behaviours, especially the demand for attention, are dealt with in a supportive manner, most children are able to relinquish them and assume precrisis levels of functioning.

Nurses should also prepare parents for the reactions of siblings—particularly anger, jealousy, and resentment. Older siblings may deny such reactions because they provoke feelings of guilt. However, everyone needs outlets for emotions, and the repressed feelings may surface as difficulties in school or with age-mates, as psychosomatic illnesses, or in untoward behaviour.

Probably one of the most neglected areas of communication involves giving information to siblings. Frequently, age becomes the only factor that leads to an awareness of this issue because older children may begin to ask questions or request explanations. Even in this situation, however, the information may be seriously inadequate. Children in every age group deserve some explanation of the sibling's illness or hospitalization. In addition, nurses can minimize a sibling's fear of also getting sick or having caused the illness.

Encouraging Parent Participation. Preventing or minimizing separation is a key nursing goal for the child who is hospitalized, but maintaining parent–child contact is also beneficial for the family. One of the best approaches is encouraging parents to stay with their child and to participate in the care whenever possible (Figure 43.10). Although some health facilities provide special accommodations for parents, the concept of rooming-in can be instituted anywhere. The first

Fig. 43.10 Parental presence during hospitalization provides emotional support for the child and increases the parent's sense of empowerment in the caregiver role. (Courtesy E. Jacob, Texas Children's Hospital.)

requirement is the staff's positive attitude toward parents. A negative attitude toward parent participation can create barriers to collaborative working relationships.

When hospital staff members genuinely appreciate the importance of continued parent–child attachment, they foster an environment that encourages parents to stay. When parents are included in the care planning and understand that they are contributing to the child's recovery, they are more inclined to remain with their child and have more emotional reserves to support themselves and the child through the crisis. In an empowerment model of helping, the nurse focuses on parents' strengths and seeks ways to promote growth and family functioning so that the parents can gain more confidence in caring for their child. Strategies such as bedside reporting that allow parents to be involved in the discussion of the child's current status are moving health care settings closer to family-centred care (Uhl et al., 2013).

Not all parents feel equally comfortable assuming responsibility for their child's care. Some may be under such great emotional stress that they need a temporary reprieve from total participation in caregiving activities. Others may feel insecure in participating in specialized areas of care, such as bathing the child after surgery. On the other hand, some parents may feel a great need to control their child's care. Individual assessment of each parent's preferred involvement is necessary to prevent the effects of separation while supporting parents in their needs.

With lifestyles and gender roles changing, the nonmaternal parent may assume all or some of the usual "mothering" roles in the household, and it may be this relationship that requires preservation. All parents need to be included in the care plan and respected for their roles. For some parents the child's hospitalization may represent an opportunity to alter their usual caregiving roles and increase their involvement. In lone-parent families the caregiver may not be a parent but an extended family member, such as a grandparent or aunt.

One of the potential concerns with continuous parent involvement is neglect of the parent's need for sleep, nutrition, and relaxation. Often the sleeping accommodations are limited to a chair, and sleep is disrupted by nursing procedures. Encouraging the parents to leave for brief periods, arranging for sleeping quarters on the unit but outside the child's room, and planning a schedule of alternating visits with another family member can minimize the stresses for the parent.

All too often, nurses respond to parent participation by abandoning their patient responsibilities. Nurses need to restructure their roles to complement and augment the parents' caregiving functions. Even in units structured to provide care by parents, parents frequently feel anxiety in their caregiving responsibilities. Therefore, 24-hour responsibility may be too much for some parents. Assistance and relief by nursing personnel should always be available to these families, and nurses may need to work to establish the strong bond of trust that some parents need in order to take advantage of these opportunities.

Preparing for Discharge and Home Care. Most hospitalizations require some type of discharge preparation. Often this involves education of the family regarding continued care and follow-up in the home. Depending on the diagnosis, this may be relatively simple or highly complex. Preparing the family for home care demands a high degree of competence in planning and implementing discharge instructions.

Nurses are often key individuals in initiating and carrying out the discharge process. They collaborate with others in the planning and implementation phases to ensure appropriate care after hospitalization. Throughout the hospitalization the nurse should be aware of the need for discharge planning and those assessment factors that affect the family's ability to provide home care. A thorough assessment of the family and home environment should be performed to ensure that the family's emotional and physical resources are sufficient to manage the tasks of home care. In addition to adequate family resources, an investigation of community services, including respite care, is needed to ensure that appropriate support agencies are available, such as emergency facilities, home health agencies, and equipment vendors. Financial resources are also a consideration. To coordinate the immense task of assessment and to plan implementation, a care coordinator or manager should be appointed early in the discharge process.

The preparation for hospital discharge and home care begins during the admission assessment. Short- and long-term goals are established to meet the child's physical and psychosocial needs. For children with complex care needs, discharge planning focuses on obtaining appropriate equipment and health care personnel for the home. Discharge planning is also concerned with treatments that parents or children are expected to continue at home. In planning appropriate teaching, nurses need to assess (1) the actual and perceived complexity of the skill, (2) the parents' or child's ability to learn the skill, and (3) the parents' or child's previous or present experience with such procedures.

The teaching plan incorporates levels of learning, such as observing, participating with assistance, and finally acting without help or guidance. The skill is divided into discrete steps, and each step is taught to the family member until it is learned. Return demonstration of the skill is requested before new skills are introduced. A record of teaching and performance provides an efficient checklist for evaluation. All families need to receive detailed *written* instructions about home care, with telephone numbers for assistance, before they leave the hospital. Communication between the nurse performing discharge planning and home health care is essential for ensuring a smooth transition for the child and family (see Chapter 41, General Concepts of Home Care).

After the family feels competent in performing the skill, they are given responsibility for the care. When possible, the family should have a transition or trial period to assume care with minimal health care supervision. This may be arranged on the unit; during a home pass; or in a facility, such as a motel, near the hospital. Such transitions provide a safe practice period for the family, with assistance readily available when needed, and are especially valuable when the family lives far from the hospital.

In many instances, parents need only simple instructions and understanding of follow-up care. However, the often overwhelming care assumed by some families, coupled with other stressors that they may be experiencing, necessitates continued professional support after discharge. A follow-up home visit or telephone call gives the nurse an opportunity to individualize care and provide information in perhaps a less stressful learning environment than the hospital. Appropriate referrals and resources may include visiting nurse or home health agencies, private nurse services, the school system, a physiotherapist, a mental health counselor, a social worker, and any number of community agencies. Sharing the important issues surrounding the child's and family's needs is essential. Referral summaries should be concise, specific, and factual. When numerous support services are required, periodic collaboration among the professionals involved and the family is an excellent strategy to ensure efficient usage and comprehensive delivery of services.

CARE OF THE CHILD AND FAMILY IN SPECIAL HOSPITAL SITUATIONS

In addition to a general pediatric unit, children may be admitted to special facilities such as an ambulatory or outpatient setting, an isolation room, or critical care.

Ambulatory or Outpatient Setting

The ambulatory or outpatient setting provides needed medical services for the child while eliminating the necessity of overnight admission. The benefits of ambulatory care are (1) minimized stressors of hospitalization, especially separation from the family; (2) reduced chances of infection; and (3) increased cost savings. Admission to the ambulatory or outpatient hospital setting usually is for surgical or diagnostic procedures, such as insertion of tympanostomy tubes, hernia repair, adenoidectomy, tonsillectomy, cystoscopy, or bronchoscopy.

In the ambulatory or outpatient setting, adequate preparation is particularly challenging. Ideally, the child and parents should receive preadmission preparation, including a tour of the facility and a review of the day's events. Parents need information in advance to help prepare the child and themselves for surgery and enable them to care for the child at home after the procedure. Parents also appreciate suggestions for items to bring to the hospital, such as blankets or stuffed animals. When preadmission preparation is not possible, time should be allowed on the day of the procedure for children to become acquainted with their surroundings and for nurses to assess, plan, and implement appropriate teaching.

Explicit discharge instructions are important after outpatient surgery (see Family-Centred Care box: Discharge From Ambulatory Settings, and Preparing for Discharge and Home Care, above). Parents need guidelines on when to call their provider regarding a change in the child's condition. A follow-up telephone call enables nurses to check on the child's progress within 48 to 72 hours after discharge. It also provides an opportunity for the nurse to review discharge information and answer questions.

Isolation

Admission to an isolation room increases all of the stressors typically associated with hospitalization. There is further separation from familiar persons; additional loss of control; and added environmental changes, such as sensory deprivation and the strange appearance of visitors. Orientation to time and place is affected. These stressors are compounded by children's limited understanding of isolation. Preschool children have difficulty understanding the rationale for isolation because they cannot comprehend the cause-and-effect relationship between germs and illness. They are likely to view isolation as punishment. Older children understand the causality better but still require information to decrease fantasizing or misinterpretation.

When a child is placed in isolation, preparation is essential for the child to feel in control. With young children the best approach is a simple explanation, such as "You need to be in this room to help you get better. This is a special place to make all the germs go away. The germs made you sick, and you could not help that."

All children, but especially younger ones, need preparation in terms of what they will see, hear, or feel in isolation. They should be shown the mask, gloves, and gown and be encouraged to "dress up" in them. Playing with the strange apparel lessens the fear of seeing "ghostlike" people walk into the room. Before entering the room, nurses and other health personnel should introduce themselves and let the child see their face before donning a mask. In this way, the child associates them with significant experiences and gains a sense of familiarity in an otherwise strange and lonely environment.

When the child's condition improves, appropriate play activities should be provided to minimize boredom, stimulate the senses, provide

FAMILY-CENTRED CARE

Discharge From Ambulatory Settings

Before beginning the discharge, explain that all instructions will also be presented in writing for the family to refer to later.

Provide an overview of the typical trajectory (expected pattern) of recovery.

Discuss expected progression of the child's activity level during the postdischarge period, such as "Sophia will probably sleep for the rest of the day, feel kind of tired most of tomorrow, but be back to her usual activities the next day."

Explain which activities the child is allowed to do and what is not permitted (e.g., bed rest, bathing).

Discuss dietary restrictions, being very specific and giving examples of "clear fluids" or what is meant by a "full liquid diet."

Discuss nausea and vomiting, if applicable, explaining how much is "normal" and what to do if more occurs, such as "Juan may be sick to his stomach and vomit. This is normal. However, if he vomits more than three times, please call us at this number right away."

Discuss fever and appropriate comfort measures, explaining how much fever is considered "normal" and specifically what to do if the child goes beyond the range.

Explain the amount, location, and kind of pain or discomfort the child may experience.

- Send an age-appropriate pain scale home with the family.
- Explain how much pain and discomfort is "normal" and what to do if the child surpasses that level or if pain management interventions are unsuccessful.
- Discuss pain management, including dosages for pain medications and details on how to administer them.
- Describe appropriate nonpharmacological comfort measures, such as holding, or rocking. Give any prescribed medication before leaving the facility.

Provide information about each medication that the child will be taking at home.

- Review the details, including dose and route.
- Demonstrate how to administer medications, if necessary (e.g., how to take wrapping off suppositories, how to insert).
- Discuss guidelines for requesting other medications.
- Request that all prescriptions be filled and given to the family before discharge.

Make certain the family has all of the equipment and supplies (e.g., gauze and tape for dressing changes) they will need at home.

Discuss complications that may occur and the steps to take if they do.

Ensure that appropriate measures are in place for safe transport home.

- Remind the family to use a seat belt or car seat for the child.
- Determine whether there will be one person whose sole responsibility is helping to ensure the child's safety and comfort during transport.
- Discuss measures the driver may need to take if this is impossible (e.g., be certain a basin is within the child's reach should vomiting occur; take a route that permits slower traffic and has places along the roadside to stop, if necessary).
- Determine the availability of a blanket, pillow, and cup with a lid and straw for the child's use in the car.
- Provide a basin or plastic bag in case of vomiting.

Provide emergency phone numbers for the family to call with any concerns.

Explain that the family will be contacted (give an approximate time) to follow up on the child but that they should not hesitate to call if concerns arise before then.

Ask the family and child, if appropriate, if they have any questions, and problem solve with family members to meet their unique needs.

a real or perceived sense of movement, orient the child to time and place, provide social interaction, and reduce depersonalization. For example, the environment can be manipulated to increase sensory freedom by moving the bed toward the door or window. Opening window shades; providing musical, visual, or tactile toys; and increasing interpersonal contact can substitute mental mobility for the limitations of physical movement. Rather than dwelling on the negative aspects of isolation, the child can be encouraged to view this experience as challenging and positive. For example, the nurse can help the child look at isolation as a method of keeping others out and letting only special people in. Children often think of intriguing signs for their doors, such as "Enter at your own risk." These signs also encourage people "on the outside" to talk with the child about the ominous greeting.

Emergency Admission

One of the most traumatic hospital experiences for the child and parents is an **emergency** admission. The sudden onset of an illness or the occurrence of an injury leaves little time for preparation and explanation. Sometimes the emergency admission is compounded by admission to a critical care unit (CCU) or the need for immediate surgery. However, even in those instances requiring only outpatient treatment, the child is exposed to a strange, frightening environment and to experiences that may elicit fear or cause pain.

There is a wide discrepancy between what constitutes a medically defined emergency and a patient-defined emergency. A growing concern is the use of major emergency departments for routine primary care health visits. To offset overcrowding in emergency departments, many facilities have minor emergency units or pediatric minor emergency units for after-hours health care. Telephone triage for minor illnesses for patients is also emerging as a health care delivery mode to differentiate illnesses such as a common cold from true life-threatening conditions that require immediate practitioner attention and intervention. Other factors contributing to the overuse of emergency departments (as opposed to the primary practitioner's office) include the increasing number of households in which both parents work full time and cannot afford to take time off during the daytime to take the sick child to a practitioner.

In pediatric populations most visits to an emergency department are for respiratory infections. The most common reason parents give for bringing the child to the emergency department is concern about the illness worsening. However, practitioners may not think that the progressive symptoms necessitate immediate or emergency care. One of the nurse's primary goals is to assess the parents' perception of the event and their reasons for considering it serious or life-threatening.

Lengthy preparatory admission procedures are often inappropriate for emergency situations. In such instances, nurses must focus their nursing interventions on the essential components of admission counselling (Box 43.8) and complete the process as soon as the child's condition has stabilized.

Unless an emergency is life-threatening, children need to participate in their care to maintain a sense of control. Because emergency departments are frequently hectic, there is a tendency to rush through procedures to save time. However, the extra few minutes needed to allow children to participate may save many more minutes of resistance during subsequent procedures. Other supportive measures include ensuring privacy, accepting various emotional responses to fear or pain, preserving parent–child contact, explaining all events before or as they occur, and remaining calm.

At times, because of the child's physical condition, little or no preparatory counselling for emergency hospitalization can be done. In such situations counselling subsequent to the event has therapeutic value. Counselling should focus on evaluating children's thoughts regarding admission and related procedures. It is similar to precounselling techniques; however, instead of supplying information, the nurse listens to the explanations offered by the child. Projective techniques such as drawing, doll play, or storytelling are especially effective. The nurse can then base additional information on what has already been understood.

Critical Care Unit

Admission to a CCU can be traumatic for both the child and parents. The nature and severity of the illness and the circumstances surrounding the admission are major factors, especially for parents. Parents experience significantly more stress when the admission is unexpected rather than expected. Canadian researchers have identified that parents of children in pediatric CCUs that experience significant psychological stress including severe anxiety, major depression, and decisional conflict. These parents are at risk for developing post-traumatic stress syndrome. For all psychological outcomes, higher levels of social support are protective. Inconsistency in sleep schedule and sleep location affect psychological outcomes as well. Screening for those at risk and implementing interventions to promote coping strategies and reduce decisional conflict may be helpful. Pediatric nurses have a critical role in assessing parents' psychological distress and promoting family health during a child's hospitalization (Stremler et al., 2017).

Stressors for the child and parent are described in Box 43.9. The most effective strategy to assist with overcoming parental stress levels may be to simply ask parents what is stressful and implement interventions that will enhance their ability to cope. Assessment should be repeated periodically to account for changes in perceptions over time. In one study, writing daily patient goals on a whiteboard was successful in improving communication among health care providers caring for children in the CCU (Justice et al., 2016; Rehder et al., 2012). By clearly defining daily patient care goals, health care providers believed that care was improved.

The family's emotional needs are paramount, and family-centred care is needed when a child is admitted to a CCU. A major stressor for parents of a child in the CCU is the child's appearance (Latour et al., 2011). Although the same interventions discussed earlier for the stressors of separation and loss of control apply here, additional interventions may also benefit the family and child (see Box 43.9). Nurse behaviours that show caring and affection may help decrease stress. Another research study evaluated parental concerns when their children were admitted to a CCU. The parents experienced a variety of stressors, including trauma, anxiety about where the child was, post-traumatic stress symptoms, and transfer to the ward, but admission to the unit and discharge from the unit created the most anxiety (Oxley, 2015). It is important that visiting hours be liberal and flexible enough to accommodate parental needs and involvement.

Critically ill children become the focus of the parents' lives, and parents' most pressing need is for information. They want to know if their child will live and, if so, whether the child will be the same as before. They need to know why various interventions are being done for the child, that the child is being treated for pain or is comfortable, and that the child may be able to hear them even though not awake. Ideally, the nurse should answer any questions.

Despite the stresses normally associated with CCU admission, a special security develops from being carefully monitored and receiving individualized care. Therefore, planning for transition to the regular unit is essential and should include the following:

- Assignment of a primary nurse on the regular unit
- Continued visits by the CCU staff to assess the child's and parents' adjustment and to act as a temporary liaison with the nursing staff
- Explanation of the differences between the two units and the rationale for the change to less intense monitoring of the child's physical condition
- Selection of an appropriate room, such as one that is close to the nursing station, and a compatible roommate

BOX 43.8 Guidelines for Special Hospital Admission

Emergency Admission

Focus assessment on airway, breathing, and circulation; weigh child whenever possible for calculation of medication dosages.

Unless an emergency is life-threatening, children need to participate in their care to maintain a sense of control.

Focus on essential components of admission counselling:

- Appropriate introduction to the family
- Use of child's name, not terms such as "honey" or "dear"
- Determination of child's age and some judgement about developmental age (If the child is of school age, asking about the grade level will offer some evidence of intellectual ability.)
- Information about child's general state of health, any conditions that may interfere with medical treatment (e.g., allergies), and previous experience with hospital facilities
- Information about the chief concern, from both the parents and the child

Admission to Critical Care Unit (CCU)

Prepare child and parents for elective CCU admission, such as for postoperative care after cardiac surgery.

Prepare child and parents for unanticipated CCU admission by focusing primarily on the sensory aspects of the experience and on the usual family concerns (e.g., persons in charge of child's care, visiting guidelines, area where family can stay).

Prepare parents for child's appearance and behaviour when they first visit their child in the CCU.

Accompany family to bedside to provide emotional support and answer questions.

Prepare siblings for their visit; plan length of time for sibling visit; monitor siblings' reactions during visit to prevent them from becoming overwhelmed.

Encourage parents to stay with their child:

- If visiting hours are limited, allow flexibility in the schedule to accommodate parental needs.
- Give family members a written schedule of visiting guidelines.
- If visiting hours are liberal, be aware of family members' needs and suggest periodic respites.
- Assure family that they can call the unit at any time.

Prepare parents for expected role changes and identify ways for parents to participate in the child's care without overwhelming them with responsibilities:

- Help with bath or feeding.
- Touch and talk to the child.
- Help with procedures.

Provide information about the child's condition in understandable language:

- Repeat information often.
- Seek clarification of understanding.
- During bedside conferences, interpret information for family members and the child or, if appropriate, conduct report outside the room.

Prepare child for procedures, even if this involves explanation while the procedure is performed.

Assess and manage pain; recognize that a child who cannot talk, such as an infant or child in a coma or on mechanical ventilation, can be in pain.

Establish a routine that maintains some similarity to daily events in the child's life whenever possible:

- Organize care during normal waking hours.
- Keep regular bedtime schedules, including quiet times when television or radio volume is lowered or turned off.
- Provide uninterrupted sleep cycles (60 minutes for infant, 90 minutes for older child).
- Close and open drapes and dim lights to establish day–night pattern.
- Place curtain around bed for privacy.
- Orient child to day and time; have clocks or calendars in easy view for older children.

Schedule a time when the child is left undisturbed (e.g., during naps, visits with family, playtime, or favourite programs).

Provide opportunities for play.

Reduce stimulation in environment:

- Refrain from loud talking or laughing.
- Keep equipment noise to a minimum:
  - —Turn alarms to as low as safely possible.
  - —Perform treatments requiring equipment at one time.
  - —Turn off bedside equipment that is not in use, such as suction and oxygen.
- Avoid loud, abrupt noises.

BOX 43.9 Neonatal or Pediatric Critical Care Unit Stressors for the Child and Family

Physical Stressors

Pain and discomfort (e.g., injections, intubation, suctioning, dressing changes, other invasive procedures)

Immobility (e.g., use of restraints, bed rest)

Sleep deprivation

Inability to eat or drink

Changes in elimination habits

Environmental Stressors

Unfamiliar surroundings (e.g., crowding)

Unfamiliar sounds

- Equipment noise (e.g., monitors, telephone, suctioning, computer printout)
- Human sounds (e.g., talking, laughing, crying, coughing, moaning, retching, walking)

Unfamiliar people (e.g., health care providers, patients, visitors)

Unfamiliar and unpleasant smells (e.g., alcohol, adhesive remover, body odours)

Constant lights (disturb day–night rhythms)

Activity related to other patients

Sense of urgency among staff

Unkind or thoughtless comments from staff

Psychological Stressors

Lack of privacy

Inability to communicate (if intubated)

Inadequate knowledge and understanding of situation

Severity of illness

Parental behaviour (expression of concern)

Social Stressors

Disrupted relationships (especially with family and friends)

Concern with missing school or work

Play deprivation

Data primarily from Shudy, M., de Almeida, M. L., Ly, S., et al. (2006). Impact of pediatric critical illness and injury on families: A systematic literature review. *Pediatrics, 118*(3), 203–218.

KEY POINTS

- Children are particularly vulnerable to the stressors of illness and hospitalization because stress represents a change from the usual state of health and routine and because they possess limited coping mechanisms for handling stress.
- The major stressors of hospitalization for children include fear of separation, loss of control, bodily injury, and pain.
- The three phases of separation anxiety are protest, despair, and detachment.
- Feelings of loss of control are caused by unfamiliar environmental stimuli, physical restriction, altered routine, and dependency.
- Because of their separation from significant people, children who are hospitalized may lack the opportunity to form new attachments in the strange environment of the hospital and exhibit negative behaviours after discharge.
- Nursing care of the child in the hospital is aimed at preventing or minimizing separation, decreasing loss of control, minimizing fear of bodily injury, using play or expressive activities to lessen stress, and maximizing the potential benefits of hospitalization.
- The nurse can maximize potential benefits of hospitalization by fostering parent–child relations, providing educational opportunities, promoting self-mastery, and encouraging socialization.
- Family reactions are influenced by the seriousness of the illness, experience with illness or hospitalization and diagnostic or therapeutic procedures, available support systems, personal ego strengths, coping abilities, presence of additional stressors, cultural and religious beliefs, and family communication patterns.
- Siblings' fear of contracting illness, their younger age, a close relationship with the ill sibling, substitute child care, minimal explanation of the illness, and perceived changes in parenting all increase the deleterious effects of a brother's or sister's illness and hospitalization on siblings.
- Nursing care of the family involves listening to parents' verbal and nonverbal messages; providing clergy support; accepting cultural and ethnic values; giving information to families and siblings; and preparing them for discharge and home care.
- Admission to an outpatient setting, emergency department, isolation room, or CCU requires additional intervention strategies to meet the child's and family's needs.

Pediatric Variations of Nursing Interventions

Monping Chiang
With contributions from *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify those instances in which informed consent is required from parents or legal guardians and when minors can provide their own informed consent.
2. Formulate general guidelines for preparing children for procedures, including surgery.
3. Use play in therapeutic procedures for children.
4. List general strategies for ensuring that children and families make informed choices regarding a treatment plan and are able to follow it.
5. Outline general hygiene and care procedures for hospitalized children.
6. Implement feeding techniques that encourage a child's food and fluid intake.
7. Describe methods of reducing the temperature of a child with fever or hyperthermia.
8. Describe the body's systems that can be used for infection control.
9. Describe safe methods of administering oral, parenteral, rectal, optic, otic, and nasal medications to children.
10. Identify nursing responsibilities in maintaining fluid balance in pediatric patients.
11. Demonstrate correct procedures for administering oxygen, postural drainage, and tracheostomy care in children.
12. Describe the procedures involved in providing nutrition via gavage, gastrostomy, and parenteral routes.
13. Describe the procedures involved in administering an enema and ostomy care to children.
14. Describe the procedure required to obtain a laboratory specimen from a child.

GENERAL CONCEPTS RELATED TO PEDIATRIC PROCEDURES

Informed Consent

Before undergoing any invasive procedure, the patient, the patient's legal surrogate, or both must receive sufficient information on which to make an informed health care decision. All decisions should be based on a combination of known facts and personal values. In health care, treatment decisions relate to medical information and personal evaluation of this information. In order to make appropriate decisions, individuals and families must have pertinent information, be able to understand how it applies to themselves or their children, and then make a voluntary decision. The following guidelines of medical decision making define the three hallmarks of informed choice (Coughlin, & Canadian Paediatric Society [CPS], Bioethics Committee, 2018):

1. **Appropriate information:** Appropriate decisions can only be made with sufficient information.
2. **Decision-making capacity:** The person with decision-making capacity must have more than the simple ability to understand. They must be able to realize the purpose of the intervention, the consequences of consent or refusal, the alternatives, and the magnitude and probabilities of harm and benefit.
3. **Voluntariness:** The decision maker should not be manipulated or coerced, and the option to change one's mind should always be available.

The patient or legal guardian has the right to accept or refuse any health care. If a patient is treated without consent, the hospital or health care provider may be charged with battery. *Battery* is defined as any intentional physical contact with a person without that person's consent, which can create a situation in which the patient or legal guardian could sue the health care provider or hospital. The contact can be harmful to the patient and cause an injury, or it can be considered to be offensive to the patient's personal dignity (Shapiro, 2019). *Assault* is conduct (such as a physical or verbal threat) that creates in another

person apprehension or fear of imminent harmful or offensive contact. No actual contact is necessary in order for damages for assault to be awarded to the patient or legal guardian and held liable for damages in a lawsuit (Shapiro, 2019).

Requirements for Obtaining Informed Consent. Written **informed consent** is usually required for medical or surgical treatment, including many diagnostic procedures. One universal consent for all procedures is not sufficient. Separate informed permissions must be obtained for each surgical or diagnostic procedure, including the following:

- Major surgery
- Minor surgery (e.g., cutdown, biopsy, dental extraction, suturing a laceration [especially one that may have a cosmetic effect], removal of a cyst, closed reduction of a fracture)
- Diagnostic tests with an element of risk (e.g., bronchoscopy, angiography, lumbar puncture, cardiac catheterization, bone marrow aspiration)
- Medical treatments with an element of risk (e.g., blood transfusion, thoracentesis or paracentesis, radiotherapy)

Other situations that require patient or parental consent include the following:

- Photographs for medical, educational, or public use
- Removal of the child from the health care institution against medical advice
- Postmortem examination, except in unexplained deaths, such as sudden infant death, violent death, or suspected suicide
- Release of medical information

Children who have partial skills to make decisions should be recognized as having some authority over their own health care. This can be achieved through the concept of *assent*, whereby children are given both information that they can understand and some appropriate choice in their treatment. Assent should include the following elements:

- Helping the patient achieve a developmentally appropriate awareness of the nature of their condition
- Telling the patient what they can expect
- Making a clinical assessment of the patient's understanding
- Soliciting an expression of the patient's willingness to accept the proposed procedure of care

Multiple methods should be used to provide information, including age-appropriate resources such as videos, Internet sources, peer discussion, diagrams, and written materials.

Eligibility for Giving Informed Consent.

Informed consent for minors. In most parts of Canada, there is no specific legal age for medical consent; instead, the patient's ability to understand and make decisions regarding their own condition, the treatment, and its consequences is more important than their **chronological age**. Québec is the only exception to this practice and stipulates an age of consent (14 years) (Evans, 2021). It is important for the nurse to be aware of the procedures and laws that govern informed consent for the province or territory and institution in which they work. Generally, when the minor patient lacks the necessary capacity, the parents or guardian are authorized to consent to treatment on the minor's behalf. In doing so, the parents or guardian must be guided by what is in the best interests of the minor (Evans, 2021).

Evidence of consent. In obtaining informed consent, it is the health care provider's responsibility to explain the procedure, risks, benefits, and alternatives to the parents or legal guardians and to the child, if the child is able to understand this information. This information needs to be conveyed in a way that is fitting to their personal circumstances and ensures their understanding of the treatment and alternatives, including associated risks and benefits. A health care provider witnesses the patient's, parent's, or legal guardian's signature on the signed consent and the nurse may reinforce what the patient and parents have been told. A signed *consent form* is the legal document that signifies that the process of informed consent has occurred. If parents are unavailable to sign consent forms, verbal consent may be obtained via telephone by a health care provider and the nurse can sign as the witness. When the nurse signs a consent form as a witness, the nurse is not legally assuming the responsibility of informed consent, only that the patient or guardian signature is authentic and that the patient or guardian appears to be competent to give consent.

Emancipated minors. *Emancipated minors* are those who are no longer dependent on their parents or legal guardians. They may be supporting themselves or living independently from their families.

Emergency treatment without consent. An emergency exists if the patient is apparently experiencing severe suffering or is at risk of suffering serious bodily harm if treatment is not administered promptly. In cases of emergency when the patient is unable to consent and a substitute decision maker (guardian) is not readily available, a health care provider must do what is immediately necessary without consent.

Conflicts in decision making for children. In some situations, conflict may arise if the values and beliefs of the parents differ from those of the health care team or even from each other. Open communication is often key to resolving such issues. Participants should clearly identify the values contributing to conflict and discuss the goals of the proposed treatment. Early discussion around the expectations, limitations, and uncertainties of treatment options and outcomes may help establish mutually agreeable treatment plans (Coughlin & CPS, Bioethics Committee, 2018). Although most conflicts involve a remediable breakdown in communication, sometimes a genuine clash in values exists. In these complex situations consultation with a spiritual care leader, social worker, patient relations expert, bioethicist or a bioethics committee, or institutional or personal legal counsel is often a useful step. If the young patient's life is at risk, child welfare or child protection legislation mandates reporting in most jurisdictions. In such cases, consent will be given or withheld by a court. In the event of a true emergency, where time does not permit the health care provider to access the options described, the ethical principles of beneficence and nonmaleficence, as well as laws under the emergency doctrine, permit the provision of emergent life-sustaining interventions (Coughlin & CPS, Bioethics Committee, 2018).

Consent and confidentiality. The *Personal Health Information Protection Act* of 2004 (PHIPA) was passed to help protect and safeguard the security and confidentiality of a person's health information. A capable individual, regardless of age, can consent to the collection, use, or disclosure of their own personal health information. If a child is incapable of consenting, a parent or legal guardian may do so on their behalf.

Consent for health research in children. Pediatric health research involves some special challenges. The researcher must take into consideration the vulnerability of the population and needs to mitigate any potential risks (see Chapter 1, Ethical Guidelines for Nursing Research). There must not be any conflict of interest. A fully informed consent and assent must be signed by the parent or legal guardian or the child, if capable of consent. The Canadian Paediatric Society (CPS) has developed ethical guidelines for research in children. Attaining an informed consent is the responsibility of the researchers and must follow the same principles as obtaining a medical consent (Fernandez & CPS, Bioethics Committee, 2008/2018). It is also important that the researchers take into consideration the cultural and community differences in various groups and populations, such as with Indigenous participants.

Preparation for Diagnostic and Therapeutic Procedures

Technological advances and changes in health care delivery have resulted in more pediatric procedures being performed in a variety

of settings. Many of these procedures are both stressful and painful experiences. Others, such as routine procedures like measuring blood pressure and administering oral medication, may simply be of concern to some children. For most procedures the focus of care is on psychological preparation of the child and family. See Nursing Skills on Evolve: Preparing the Child for Procedures.

Psychological Preparation. Preparing children for procedures decreases their anxiety, promoting their assistance, supporting their coping skills, and facilitating a feeling of mastery in experiencing a potentially stressful event. Many institutions have developed preadmission teaching programs designed to educate children and their families by offering hands-on experience with hospital equipment, information about the procedure to be performed, and an overview of departments they may visit. Most preparation strategies used by nurses are informal, focus on providing information about the experience, and are directed at the child undergoing stressful or painful procedures. The most effective preparation is to provide sensory-procedural information and help the child develop coping skills, such as imagery, distraction, or relaxation.

Many pediatric hospitals offer a preoperative preparation program for children and families. A child life specialist and preanaesthesia nurse may be present to help prepare the child for the operative experience. There is often a tour of the operating room area, and children are able to play with medical equipment. Hospitals recommend that, if possible, any child requiring these services come to the tour about 1 to 2 weeks before the surgery. If for travel or medical reasons the family cannot make the tour in person, virtual tours are often available online. For example, the SickKids website has a video tour of the hospital and the operative suite as well as helpful tips for families on how to verbally prepare their child. See Additional Resources at the end of this chapter for more information.

General guidelines for preparing children for procedures are described in the Guidelines box: Preparing Children for Procedures. Age-specific preparation that takes into account children's developmental needs and cognitive abilities is presented in Box 44.1. In addition to these guidelines, nurses should consider the child's temperament, existing coping strategies, and previous experiences in individualizing the preparatory process. Children who are distractible and highly active, as well as those who need more time to adapt, may need individualized sessions that are shorter for the active child or more slowly paced for the shy child. Whereas children who tend to cope well may need more emphasis on using their present skills, those who appear to cope less adequately can benefit from more time devoted to simple coping strategies, such as relaxing, breathing, counting, squeezing a hand, or singing. Children with previous health-related experiences still need preparation for repeat or new procedures; the nurse must assess what they know, correct their misconceptions, supply new information, and introduce new coping skills as indicated by their previous reactions.

Children differ in their "information-seeking dimension." Some actively ask for information about the intended procedure, while others characteristically avoid it. Parents can often guide nurses in deciding how much information is enough for their child, because they know whether the child is typically inquisitive or satisfied with short answers. Asking older children their preferences about the amount of explanation is also important.

The exact timing of the preparation for a procedure varies with the child's age and type of procedure. While no exact guidelines govern timing, in general, the younger the child, the closer the explanation should be to the actual procedure, to prevent undue fantasizing and worrying. With complex procedures, more time may be needed for assimilation of information, especially with older children. For example, the explanation for an injection can immediately precede the procedure for all ages, whereas preparation for surgery may begin the day before for young children and a few days before for older children (although older children's preferences should be elicited).

GUIDELINES

Preparing Children for Procedures

- Determine details of exact procedure to be performed.
- Review parents' and child's current understanding.
- Base teaching on developmental age and existing knowledge.
- Incorporate parents in the teaching if they desire, especially if they plan to participate in care.
- Inform parents of their supportive role during the procedure, such as standing near the child's head or in the child's line of vision and talking softly to the child.
- Allow for ample discussion to prevent information overload and ensure adequate feedback.
- Use concrete, not abstract, terms and visual aids to describe the procedure. For example, use a simple line drawing of a boy or girl and mark the body part that will be involved in the procedure. Use nonthreatening but realistic models.
- Emphasize that no other body part will be involved.
- If the body part is associated with a specific function, stress the change in or noninvolvement of that ability, such as after tonsillectomy, the child can still speak.
- Use words appropriate to the child's level of understanding. (Rule of thumb: the number of words in a child's sentence is equal to their age in years plus 1.)
- Avoid words and phrases with dual meanings unless the child understands such words.
- Clarify all unfamiliar words, such as "Anaesthesia is a special sleep."
- Emphasize sensory aspects of the procedure—what the child will feel, see, hear, smell, and touch and what the child can do during the procedure, such as lie still, count out loud, squeeze a hand, hug a doll.
- Allow the child to practise procedures that require some assistance (e.g., turning, deep breathing, incentive spirometry).
- Introduce anxiety-laden information last, such as starting an intravenous line.
- Be honest with the child about unpleasant aspects of a procedure but avoid creating undue concern. When discussing that a procedure may be uncomfortable, state that it feels differently to different people.
- Emphasize the end of the procedure and any pleasurable events afterward (e.g., going home, seeing parents).
- Stress positive benefits of the procedure, such as "After your tonsils are fixed, you won't have as many sore throats."
- Provide a positive ending, praising efforts at being helpful and coping.

Establish trust and provide support. The nurse who has spent time with and established a positive relationship with a child will usually find it easier to work together with the child. If the relationship is based on trust, the child will associate the nurse with caregiving activities that provide comfort and pleasure most of the time, rather than discomfort and stress. If the nurse does not know the child, it is best to be introduced by another staff person whom the child trusts. The first visit with the child should not include any painful procedure and ideally should focus on the child first, then on the explanation of the procedure.

Parental presence and support. Children need support during procedures, and for young children the greatest source of support is the parents. They represent security, safety, protection, and comfort. Research has found that children who had their parents present during invasive procedures had lowered respirations and heart rate levels, felt

BOX 44.1 Age-Specific Preparation of Children for Procedures, Based on Developmental Characteristics

Infant: Developing a Sense of Trust and Sensorimotor Thought

Attachment to Parent

Involve parent in procedure, if desired.*
Keep parent in infant's line of vision.
If parent is unable to be with infant, place a familiar object with infant (e.g., stuffed toy).

Stranger Anxiety

Have usual caregivers perform or assist with procedure.*
Make advances slowly and in a nonthreatening manner.
Limit number of strangers entering the room during procedure.*

Sensorimotor Phase of Learning

During procedure, use sensory soothing measures such as stroking skin, talking softly, giving pacifier.
Use analgesics, such as topical anaesthetic, intravenous opioid, to control discomfort.*
Cuddle and hug infant after stressful procedure; encourage parent to comfort infant.

Increased Muscle Control

Expect an older infant to resist.
Restrain only as required.
Keep harmful objects out of reach.

Memory for Past Experiences

Realize that older infants may associate objects, places, or persons with prior painful experiences and will cry and resist at the sight of them.
Keep frightening objects out of view.*
Perform painful procedures in a separate room, not in crib (or bed).*
Use nonintrusive procedures whenever possible, such as axillary temperatures, oral medications.*

Imitation of Gestures

Model desired behaviour, such as opening mouth.

Toddler: Developing a Sense of Autonomy and Sensorimotor to Preoperational Thought

Use the same approaches as for an infant, plus the following.

Egocentric Thought

Explain procedure in relation to what the child will see, hear, taste, smell, and feel.
Emphasize those aspects of procedure that require cooperation, such as lying still.
Tell the child it is okay to cry, yell, or use other means to express discomfort verbally.
Designate one health care provider to speak during procedures. Hearing more than one can be confusing for the child.*

Negative Behaviour

Expect treatments to be resisted; the child may try to run away.
Use a firm, direct approach.
Ignore temper tantrums.
Use distraction techniques, such as singing a song with the child.
Restrain only as required.

Animism

Keep frightening objects out of view (young children believe objects have lifelike qualities and can harm them).

Limited Language Skills

Communicate using gestures or demonstrations.
Use a few simple terms familiar to the child.
Give the child one direction at a time, such as "Lie down," then "Hold my hand."
Use small replicas of equipment; allow the child to handle equipment.
Use play; demonstrate on a doll but avoid using the child's favourite doll, since the child may think that the doll is really "feeling" the procedure.
Prepare parents separately to avoid child's misinterpreting of words.

Limited Concept of Time

Prepare the child shortly or immediately before procedure.
Keep teaching sessions short (about 5 to 10 minutes).
Have preparations completed before involving child in procedure.
Have extra equipment nearby, such as alcohol swabs, new needle, adhesive bandages, to avoid delays.
Tell the child when the procedure is completed.

Striving for Independence

Allow choices whenever possible; the child may still be resistant and negative.
Allow the child to participate in care and to help whenever possible, such as drink medicine from a cup, hold a dressing.

Preschooler: Developing Initiative and Preoperational Thought

Egocentric

Explain procedure in simple terms and in relation to how it affects the child (as with toddler, stress sensory aspects).
Demonstrate use of equipment.
Allow the child to play with miniature or actual equipment.
Encourage "playing out" experience on a doll both before and after procedure to clarify misconceptions.
Use neutral words to describe the procedure.

Increased Language Skills

Use verbal explanation; avoid overestimating comprehension.
Encourage child to express ideas and feelings.

Limited Concept of Time and Frustration Tolerance

Implement the same approaches as for toddlers but a longer teaching session (10 to 15 minutes) may be planned; information may be divided into more than one session.

Illness and Hospitalization Viewed as Punishment

Clarify why each procedure is performed; a child will find it difficult to understand how medicine can make them feel better and can taste bad at the same time.
Ask the child their thoughts about why a procedure is performed.
State directly that procedures are never a form of punishment.

Animism

Keep equipment out of sight, except when shown to or used on the child.

Fears of Bodily Harm, Intrusion, and Castration

Point out on a drawing, a doll, or the child where procedure is performed.
Emphasize that no other body part will be involved.
Use nonintrusive procedures whenever possible, such as axillary temperature, oral medication.
Apply an adhesive bandage over the puncture site.
Encourage parental presence.
Realize that procedures involving genitalia provoke anxiety.
Allow child to wear underpants with a gown.
Explain unfamiliar situations, especially noises or lights.

Continued

BOX 44.1 Age-Specific Preparation of Children for Procedures, Based on Developmental Characteristics—cont'd

Striving for Initiative

Involve the child in care whenever possible, such as holding equipment, removing dressing.

Give choices whenever possible but avoid excessive delays.

Praise child for helping and attempting to cooperate; never shame a child for lack of cooperation.

School-Age Child: Developing Industry and Concrete Thought

Increased Language Skills; Interest in Acquiring Knowledge

Explain procedures, using correct scientific or medical terminology.

Explain reason for procedure, using simple diagrams and photographs.

Explain function and operation of equipment in concrete terms.

Allow child to manipulate equipment; use a doll or another person as a model to practise, using equipment whenever possible (doll play may be considered childish by older school-age children).

Allow time before and after the procedure for questions and discussion.

Improved Concept of Time

Plan for longer teaching sessions (about 20 minutes).

Prepare up to 1 week in advance of procedure to allow for processing information and to ask questions.

Increased Self-Control

Gain the child's trust.

Tell the child what is expected.

Suggest several ways of maintaining control from which the child may select, such as deep breathing, relaxation, counting.

Striving for Industry

Give the child responsibility for simple tasks, such as collecting specimens.

Include the child in decision making, such as time of day to perform procedure, preferred site.

Encourage active participation in removing dressings, handling equipment, opening packages.

Developing Relationships With Peers

Prepare two or more children for the same procedure or encourage one peer to help prepare another.

Provide privacy from peers during procedure to maintain self-esteem.

Adolescent: Developing Identity and Abstract Thought

Increasing Abstract Thought and Reasoning

Supplement explanations with reasons why the procedure is necessary or beneficial.

Explain long-term consequences of procedures; include information about body systems working together.

Realize that the adolescent may fear death, disability, or other potential risks.

Encourage questioning regarding fears, options, and alternatives.

Consciousness of Appearance

Provide privacy; describe how the body will be covered and what will be exposed.

Discuss how the procedure may affect appearance, such as scarring, and what can be done to minimize it.

Emphasize any physical benefits of the procedure.

Concern More With Present Than With Future

Realize that immediate effects of the procedure are more significant than future benefits.

Striving for Independence

Involve adolescent in decision making and planning, such as time and place of procedure, individuals present during procedure, and clothing.

Impose as few restrictions as possible.

Explore which coping strategies have worked in the past; adolescents may need descriptions to identify various techniques.

Accept regression to more childish methods of coping.

Realize that the adolescent may have difficulty accepting new authority figures and may resist complying with procedures.

Developing Peer Relationships and Group Identity

This is the same as for school-age children but assumes greater significance.

Allow adolescents to talk with other adolescents who have had the same procedure.

*Applies to any age.

less pain, and were in less distress (Matziou et al., 2013). However, the nurse should assess the parents' preferences for assisting, observing, or waiting outside the room, as well as the child's preference for parental presence. The child's and parents' choices should be respected. Parental presence is preferable as it can reduce patient and parent anxiety and decrease the need for sedation. Parents who wish to stay should be given an appropriate explanation about the procedure and coached about what to do, and what to say in order to help the child through the procedure. Simple instructions such as clarifying where parents can stand or sit in the room and positioning them where they have eye contact with the child can provide support and lessen anxiety. Parents who do not want to be present or participate should be supported in their decision and encouraged to remain close by so that they can be available to console the child immediately after the procedure. Parents should also know that someone, such as another nurse or child life specialist, will be with their child to provide support.

Provide an explanation. Age-appropriate explanations are one of the most widely used interventions for reducing anxiety in children undergoing procedures. Before performing a procedure, the nurse should explain what is to be done and what is expected of the child. The explanation should be short, simple, and appropriate to the child's level of comprehension. Long explanations may increase anxiety in a young child. When explaining the procedure to parents with the child present, the nurse should use language appropriate to the child because unfamiliar words can be misunderstood (Table 44.1). If the parents need additional preparation, it is done in an area away from the child. Teaching sessions are planned at times most conducive to the child's learning (e.g., after a rest period) and for the usual span of attention.

Special equipment is not necessary for preparing a child, but for young children who cannot yet think conceptually, using objects to supplement verbal explanation is important. Allowing children to handle actual items that will be used in their care, such as a stethoscope, sphygmomanometer, or oxygen mask, helps them develop familiarity with these items and reduces the fear often associated with their use. Miniature versions of hospital items such as stretchers and X-ray and intravenous (IV) equipment can be used to explain what the child can expect and permit them to safely experience situations that are unfamiliar and potentially frightening. Written and illustrated materials are also valuable aids to preparation.

TABLE 44.1 Selecting Nonthreatening Words or Phrases

Words and Phrases to Avoid	Suggested Substitutions
Shot, bee sting, stick	Medicine under the skin
Organ	Special place in body
Test	To see how (specify body part) is working
Incision, cut	Special opening
Edema	Puffiness
Stretcher, gurney	Rolling bed, bed on wheels
Stool	Child's usual term
Dye	Special medicine
Pain	Hurt, discomfort, "owie," "boo-boo," sore, achy, scratchy
Deaden	Numb, make sleepy
Fix	Make better
Take (as in "take your temperature")	See how warm you are
Take (as in "take your blood pressure")	Check your pressure; hug your arm
Put to sleep, anaesthesia	Special sleep so you won't feel anything
Catheter	Tube
Monitor	Television screen
Electrodes	Stickers, ticklers
Specimen	Sample

Preparation for Sedation and Analgesia. One area of special concern is the administration of sedation and analgesia before stressful procedures. Refer to Chapter 34 for information on providing sedation to children.

Performance of the Procedure

Supportive care should continue during the procedure and can be a major factor in a child's ability to assist. Ideally, the same nurse who explains the procedure should perform or assist with the procedure. Before beginning, all equipment is assembled, and the room is readied to prevent unnecessary delays and interruptions that increase the child's anxiety. Minimizing the number of people present during the procedure also can decrease the child's anxiety.

Traumatic procedures should never be performed in "safe" areas, such as the playroom or the child's room, unless the child is a young infant or cannot be safely moved. If the procedure is lengthy, conversation that could be misinterpreted by the child should be avoided during any procedure. As the procedure is nearing completion, the child needs to be informed that it is almost over, in language the child understands.

Expect Success. Nurses who approach children with confidence and who convey the impression that they expect to be successful are less likely to encounter difficulty. It is best to approach a child with a welcoming and inclusive demeanour that encourages the child to assist with the proposed procedure. Children sense anxiety and uncertainty in an adult and may respond by striking out or actively resisting. Although it is not possible to eliminate such behaviour in every child, a firm approach with a positive attitude tends to convey a feeling of security to most children.

Involve the Child. Involving children helps to gain their confidence and willingness to work together. When they are given choices they have some measure of control. However, a choice should be given only in situations in which one is available. Asking children, "Do you want to take your medicine now?" leads them to believe they have an option of not taking it and provides them with the opportunity to legitimately refuse or delay the medication. This places the nurse in an awkward, if not impossible, position. It is much better to state firmly, "It's time to drink your medicine now" and add a choice that they do indeed have, such as "Do you want to drink your medicine plain or with a little water?"

Many children respond to tactics that appeal to their maturity or courage. This also gives them a sense of participation and achievement. For example, preschool and school-age children will be proud that they can hold the dressing during the procedure or remove the tape.

Provide Distraction. Distraction is a powerful coping strategy during painful procedures (Birnie et al., 2018) and involves focusing the child's attention on something other than the procedure. Singing favourite songs, listening to music, counting out loud, or blowing bubbles to "blow the hurt away" are effective techniques. For other nonpharmacological interventions that may lessen discomfort, see Pain Management, Chapter 34.

Allow Expression of Feelings. The child should be encouraged to express feelings of anger, anxiety, fear, frustration, or any other emotion. It is natural for children to strike out in frustration or to try to avoid stress-provoking situations. The child needs to know that it is all right to cry. Behaviour is children's primary means of communication and coping and should be permitted unless it inflicts harm on them or those caring for them.

Postprocedural Support

After the procedure, the child needs reassurance that they performed well and are accepted and loved. If the parents did not participate, the child should be united with them as soon as possible so that they can provide comfort.

Encourage Expression of Feelings. Planned activity after the procedure is helpful in encouraging constructive expression of feelings. For verbal children, reviewing the details of the procedure can clarify misconceptions and garner feedback for improving the nurse's preparatory strategies. Play is an excellent activity for all children. Infants and young children should be given the opportunity for gross motor movement. Older children are able to vent their anger and frustration in acceptable pounding or throwing activities. Play-Doh is a remarkably versatile medium for pounding and shaping. Dramatic play provides an outlet for anger and places the child in a position of control, in contrast to the position of helplessness in the real situation. Play with puppets also enables the child to communicate feelings in a nonthreatening way. One of the most effective interventions is therapeutic play, which includes well-supervised activities, such as permitting the child to give an injection to a doll or stuffed toy to reduce the stress of injections (Figure 44.1).

Provide Positive Reinforcement. Children need to hear from adults that they did the best they could in the situation, no matter how they behaved. It is important for children to know that their worth is not being judged on the basis of their behaviour in a stressful situation. Reward systems, such as earning stars, stickers, bravery beads, or a badge of courage, are appealing to children.

Returning to the child a short while after the procedure can help the nurse strengthen a supportive relationship. Relating with the child

Fig. 44.1 Playing with hospital equipment provides children with the opportunity to play out fears and concerns.

during a relaxed and nonstressful period allows the child to see the nurse not only as someone associated with stressful situations but as someone with whom to share pleasurable experiences.

Use of Play in Procedures

The use of play is an integral part of forming relationships with children. As such, its value in specific situations is discussed throughout this book, such as in Chapter 43, in relation to hospitalization. Many institutions have elaborate and well-organized play areas and programs under the direction of child life specialists. No matter what the institution provides for children, nurses can include play activities as part of nursing care. Play can be used to teach, express feelings, or achieve a therapeutic goal. Consequently, it should be included in preparing children for and encouraging the assistance during procedures. Play sessions after procedures can be structured, as directed toward syringe play, or general, with a wide variety of equipment available for children to play with. Box 44.2 offers suggestions for incorporating play into nursing procedures and activities for the hospitalized child that facilitate learning and adjustment to a new situation.

BOX 44.2 Play Activities for Specific Procedures*

Fluid Intake

Make ice pops using the child's favourite juice.
Cut gelatin into fun shapes.
Make a game out of taking a sip when turning the page of a book or in games such as Simon Says.
Use small medicine cups; decorate the cups.
Colour water with food colouring or powdered drink mix.
Have a tea party; pour at a small table.
Let the child fill a syringe and squirt contents into their mouth or use it to fill small cups.
Cut straws in half and place in a small container (much easier for child to suck liquid).
Use a "crazy" straw.
Make a "progress poster"; give rewards for drinking a predetermined quantity.

Deep Breathing

Blow bubbles with a bubble blower.
Blow bubbles with a straw (no soap).
Blow on a pinwheel, feather, whistle, harmonica, balloon, horn, or party blower.
Practise band instruments.
Have a blowing contest using boats, cotton balls, feathers, ping-pong balls, or pieces of paper; blow objects on a table top over a goal line, over water, through an obstacle course, into the air, against an opponent, or up and down a string.
Suck paper or cloth from one container to another using a straw.
Use blow bottles with coloured water to transfer water from one side to the other.
Dramatize stories such as "I'll huff and puff and blow your house down" from the Three Little Pigs.
Do straw-blowing painting.
Take a deep breath and "blow out the candles" on a birthday cake.
Use a little paint brush to "paint" nails with water and blow nails dry.

Range of Motion and Use of Extremities

Throw beanbags at a fixed or movable target or throw wadded-up paper into a wastebasket.
Touch or kick Mylar balloons held or hung in different positions (if the child is in traction, hang balloon from a trapeze).
Play "tickle toes"; have child wiggle them on request.
Play Twister game or Simon Says.
Play pretend and guessing games (e.g., imitate a bird, butterfly, horse).
Have tricycle or wheelchair races in a safe area.
Play kickball or catch with a soft foam ball in a safe area.
Position bed so that the child must turn to view the television or doorway.
Climb wall like a "spider."
Pretend to teach "aerobic" dancing or exercises; encourage parents to participate.
Encourage swimming, if feasible.
Play video games or pinball (fine motor movement).
Play "hide and seek": hide a toy somewhere in the bed (or room if ambulatory) and have child find it using specified hand or foot.
Provide clay to mould with fingers.
Paint or draw on large sheets of paper placed on the floor or wall.
Encourage combing own hair; play "beauty shop" with the "customer" in different positions.

Soaks

Play with small toys or objects (cups, syringes, soap dishes) in water.
Wash dolls or toys.
Pick up marbles or coins from the bottom of a bath container.
Make designs with coins on the bottom of a container.
Pretend a boat is a submarine by keeping it immersed.
During soaks, read to the child; sing with the child; or play a game, such as cards, checkers, or other board game (if both of the child's hands are immersed, move board pieces for the child).
During a sitz bath, when soaking the perineal and rectal area, give the child something to listen to (music, stories) or look at books or tablets.
Punch holes in the bottom of a plastic cup, fill with water, and let it "rain" on the child.

Injections

Let child handle the syringe, vial, and alcohol swab and give an injection to a doll or stuffed animal.
Use syringes to decorate cookies with frosting, squirt paint, or target shoot into a container.

Continued

BOX 44.2 Play Activities for Specific Procedures—cont'd

Draw a "magic circle" on the area before injection; draw a smiling face in the circle after injection, but avoid drawing on the puncture site.
Allow child to have a "collection" of syringes (without needles); make creative objects with syringes.
If the child has multiple injections or venipunctures, make a "progress poster"; give rewards for a predetermined number of injections.
Have the child count to 10 or 15 during injection.

Ambulation

Give the child something to push.
Toddler—Push-pull toy
School-age child—Wagon or a doll in a stroller or wheelchair
Adolescent—Decorated intravenous stand
Have a parade; make hats, drums, etc.

Extending Environment (e.g., for Patients in Traction)

Make bed into a pirate ship or an airplane with decorations.
Put up mirrors so that the patient can see around the room.
Move the bed frequently to the playroom, hallway, or outside.

*Small objects such as marbles or coins, as well as latex gloves or balloons, are unsafe for young children because of possible aspiration. Latex products also carry the risk of an allergic reaction.

Preparing the Family

The process of patient education involves giving the family information about the child's condition, the regimen that must be followed and why, and other health teaching as indicated. The goal of this education is to enable the family to modify behaviours and complete the regimen that has been mutually established (see Guidelines box: General Principles of Family Education).

GUIDELINES

General Principles of Family Education

- Establish a rapport with the family.
- Avoid using any specialized terms or jargon. Clarify all terms with the family.
- When possible, allow family members to decide how they want to be taught (e.g., all at once or over 1 or 2 days). This gives the family a chance to incorporate the information at a rate that is comfortable.
- Provide accurate information to the family about the illness.
- Assist family members in identifying obstacles to their ability to complete the task and in identifying the means to overcome those obstacles. Then help family members find ways to incorporate the plan into their daily lives.

If equipment will be needed at home (e.g., suction machines, syringes), the nurse needs to make the necessary arrangements in advance so that discharge can proceed smoothly. Whenever possible, arrangements should be made for the family to use the same equipment in the home that they are using in the hospital. This allows them to become familiar with the items. In addition, the staff can help troubleshoot the equipment in a controlled environment. Teaching sessions should be planned well in advance of the time the family will be responsible for performing the care. The more complex the procedure, the more time is needed for training. See Chapter 41, Discharge Planning for more information.

Surgical Procedures

Preoperative Care. Children experiencing surgical procedures require both psychological and physical preparation. In general, psychological preparation is similar to that previously discussed for any procedure and employs many of the same techniques used in preparing a child for hospitalization, such as video, books, play, interactive apps, and tours. Stress points before and after surgery include the admission process, blood tests, IV insertions, injection of preoperative medication (if prescribed), transport to the operating room, and the stay in the postanaesthesia care unit (PACU). Wearing a hospital gown without the security of underpants or pyjama bottoms can also be traumatic. Therefore, these articles of clothing should be worn into the operating room and removed after induction of anaesthesia.

Psychological intervention consists of systematic preparation, rehearsal of the forthcoming events, and supportive care. A family-centred preoperative preparation program may involve a tour of the perioperative areas with short explanations of the events 5 to 7 days before surgery, a video to take home and review a couple of times with additional explanations and demonstrations of perioperative processes, a mask to take home and practise with, pamphlets to guide parents on supporting children during induction, and toys and supplies in the holding area. Therapeutic play is an effective strategy in preparing children, and increased familiarity with medical procedures decreases anxiety.

Parental presence. Parental presence during induction of anaesthesia is allowed in some institutions (Figure 44.2). The results on the benefit of parental presence during induction of anaesthesia are mixed; in one study the authors concluded that parental presence during induction did not reduce a child's anxiety. Other nonpharmacological interventions that hold promise for reducing anxiety include presence of clowns, hypnotherapy, low sensory stimulation, and playing handheld video games (Manyande et al., 2015).

Fig. 44.2 Parental presence during induction of anaesthesia may minimize the child's and parents' anxiety during the preoperative period. (Phanie/Alamy Stock Photo.)

Appropriate education is essential to help parents understand the stages of anaesthesia, what to expect, and how to support their child. When parents choose not to or are not allowed to attend the induction, the child should have a favourite possession with them and be united with the parents as soon as possible after surgery (preferably in the PACU). During surgery, the family should have a designated place to wait and be kept informed of the child's progress. They also should know where and when they can visit their child after surgery.

Aside from possibly being separated from the parents before and after surgery, children may be cared for by a number of unfamiliar practitioners, which can instill fear and uncertainty. Although the same supportive nurse should remain with the child through as many of the procedures as possible, the child may have other nurses, especially if the child returns to a special care unit postoperatively.

Preoperative fasting. An important concern is restriction of food and fluids before surgery to avoid aspiration during anaesthesia. Infants require special attention to fluid needs. They should not be without fluids for an extended period preoperatively, to avoid glycogen depletion and dehydration. In a review of evidence from preoperative trials, the researchers concluded that drinking clear fluids up to a few hours before receiving an anaesthetic did not increase the risk of regurgitation during or after surgery. These children were also less thirsty and hungry (Brady et al., 2009). Current preoperative fasting guidelines are found in Table 44.2. In some facilities guidelines may be different from those listed here.

Preoperative sedation. Historically, the most upsetting event for children has been the preoperative injection. Increasingly, more anaesthesiologists are using preoperative sedatives, usually midazolam (Versed), and including parental presence for children who are about to undergo surgery. When medications are administered, they should be delivered atraumatically via oral or IV routes that have been previously established.

The goals for using preoperative medications include (1) anxiety reduction, (2) amnesia, (3) sedation, (4) antiemetic effect, and (5) reduction of secretions. However, if children have no preoperative pain, are well prepared psychologically for surgery, and have their parents nearby, preoperative medication may be unnecessary.

Induction of anaesthesia in the pediatric patient is commonly accomplished by administering inhalation agents in combination with nitrous oxide and oxygen by mask. Children may fear induction of anaesthesia by mask. Practices that can minimize anxiety related to the inhalation of anaesthesia are (1) disguising the unpleasant odour of anaesthetic gases by applying a pleasant-smelling substance on the mask; (2) using a transparent plastic mask rather than an opaque black mask and gradually bringing it toward the face; (3) directing a stream of gas toward the child's face from the bare tube until the child becomes drowsy, then using the mask; (4) allowing the child to sit up rather than lie down for anaesthesia induction; and (5) using preoperative play with a mask and a doll or manikin.

TABLE 44.2 Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration

Ingested Material	Minimum Fasting Period (Hours)*
Clear liquids†	>2
Breast milk	4
Infant formula‡	6
Nonhuman milk‡	6
Light meal‡	6
Meal that includes meat or fried or fatty foods	8

From Dobson, G., Chow, L., Filteau, L. et al. (2019). Guidelines to the practice of anesthesia. *Canadian Journal of Anaesthesia, 66*(1), 75–108. https://doi.org/10.1007/s12630-018-1248-2.

*Fasting periods noted in chart apply to all ages.

†Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

‡A light meal typically consists of toast and clear liquids. This also includes infant formula or nonhuman milk.

Postoperative Care. Various psychological and physical interventions and observations are required to prevent or minimize possible untoward effects from anaesthesia and the surgical procedure (see Guidelines box: Postoperative Care). Although the incidence of serious postoperative complications in healthy children undergoing surgery is rare, continuous monitoring of cardiopulmonary status is essential during the immediate postoperative period. Postanaesthesia complications such as airway obstruction, postextubation croup, laryngospasm, and bronchospasm make maintaining a patent airway and maximum ventilation critical.

GUIDELINES

Postoperative Care

Ensure that preparations are made to receive the child:
- Bed or crib is ready.
- Intravenous pumps, poles, and monitors (electrocardiogram [ECG] and oximetry) are present.
- Safety equipment: Suction apparatus and oxygen flow meter and age-appropriate masks are at bedside.

Obtain baseline information:
- Take vital signs, including blood pressure; keep blood pressure cuff in place and deflated to lessen amount of disturbance to child.
- Take and record vital signs more frequently if any value fluctuates, and as per hospital protocol.
- Inspect operative area.

Check dressing, if present:
- Outline any bleeding area on dressing or cast with a pen, include time assessed on outline.
- Reinforce, but do not remove, loose dressing.
- Observe areas below surgical site for blood that may have drained toward bed.
- Assess for bleeding and other symptoms in areas not covered with a dressing, such as throat after tonsillectomy.

Assess skin colour and characteristics.

Assess level of consciousness and activity.

Notify health care provider of any irregularities in the child's condition.

Assess for evidence of pain (see Pain Assessment, Chapter 34).

Review surgeon's orders after completing initial assessment, and check that any preoperative orders, such as seizure or cardiac medications, have been reordered and can be given by available routes (oral preparations may be contraindicated).

Monitor vital signs as ordered and more often if indicated.

Check bowel sounds.

Observe for signs of shock, abdominal distension, and bleeding.

Assess for bladder distension.

Observe for signs of dehydration.

Detect presence of infection:
- Take vital signs, as ordered or more frequently as necessary.
- Collect or request needed specimens.
- Inspect wound for signs of infection—redness, swelling, heat, pain, and purulent drainage.

Monitoring the patient's oxygen saturation and providing supplemental oxygen as needed, maintaining body temperature, and promoting fluid and electrolyte balance are important aspects of immediate postoperative care. Vital signs should be continuously monitored, and each vital sign should be evaluated in terms of adverse effects from anaesthesia, **shock**, or respiratory compromise (Table 44.3).

A change in vital signs that demands immediate attention in the perioperative period is caused by malignant hyperthermia (MH), a potentially fatal pharmacogenetic disorder involving a defective calcium channel in the sarcoplasmic reticulum membrane. In susceptible children, inhaled anaesthetics and the muscle relaxant succinylcholine trigger the disorder, producing hypermetabolism. Succinylcholine is rarely administered, except to provide rapid relief of laryngospasm. Intubation of the airway is enabled by a short-acting muscle relaxant, such as rocuronium (Scott, 2020). Symptoms of MH include hypercarbia (increased end-tidal carbon dioxide), elevated temperature, tachycardia, tachypnea, acidosis, muscle rigidity, and rhabdomyolysis (Scott, 2020). A family or previous history of sudden high fever associated with a surgical procedure and certain neuromuscular disorders increase the risk for MH; children who have successfully undergone prior surgery without adverse effects may still be considered susceptible.

Treatment of MH includes immediate discontinuation of the triggering agent, hyperventilation with 100% oxygen, and IV dantrolene sodium. If the child is hyperthermic, cooling measures such as ice packs to the groin, axillae, and neck and iced nasogastric (NG) lavage should be initiated based on institutions policies. The surgery may be discontinued; or, if it is emergent, it may be continued with a different anaesthetic agent. The patient should be transferred to a critical care unit and closely monitored for stabilization of vital signs, metabolic state, and possible recurrence of symptoms.

Managing pain is a major nursing responsibility after surgery (see Chapter 34). The nurse should assess pain frequently and administer analgesics to provide comfort and facilitate postoperative care routines, such as ambulation and deep breathing. **Opioids** are the most commonly used analgesics. Routinely scheduled IV analgesics, patient-controlled analgesia, and epidural infusions, rather than as needed (prn) orders, provide excellent analgesia in postoperative pediatric patients. See discussion in Chapter 34, Postoperative Pain.

Because respiratory infections are a potential complication, every effort should be taken to aerate the lungs and remove secretions. The lungs should be auscultated regularly to identify abnormal sounds or any areas of diminished or absent breath sounds. To prevent pneumonia, respiratory movement should be encouraged with the use of incentive spirometers or other motivating activities (see Box 44.2). If these measures are presented as games, the child is more likely to work with the nurse. The child's position needs to be changed every 2 hours and deep breathing encouraged.

! NURSING ALERT

Because deep breathing is usually painful after surgery, be certain that the child has received analgesics. Have the child splint the operative site (depending on its location) by hugging a small pillow or a favourite stuffed animal.

During the recovery period, the nurse should spend some time with the child to assess their perceptions of surgery. Play, drawing, and storytelling are excellent methods of discovering the child's thoughts. With such information, the nurse can support or correct the child's perceptions and boost their self-esteem for having endured a stressful procedure.

Many pediatric patients are discharged shortly after surgery. Preparation for discharge begins with the preadmission preparation visit.

TABLE 44.3 Potential Causes of Postoperative Vital Sign Alterations in Children

Alteration	Potential Cause	Comments
Heart Rate		
Increase	Decreased perfusion (shock) Elevated temperature Pain Respiratory distress (early) Medications (atropine, morphine, epinephrine)	Heart rate may increase to maintain cardiac output.
Decrease	Hypoxia Vagal stimulation Increased intracranial pressure Respiratory distress (late) Medications	In the young child, bradycardia is of more concern than tachycardia.
Respiratory Rate		
Increase	Respiratory distress Fluid volume excess Hypothermia Elevated temperature Pain	The body responds to respiratory distress primarily by increasing rate.
Decrease	Anaesthetics, opioids Pain	Decreased respiratory rate from opioids may be compensated for by increased depth of respiration.
Blood Pressure		
Increase	Excess intravascular volume Increased intracranial pressure Carbon dioxide retention Pain Medication (ketamine, epinephrine)	This is serious in preterm infants because it increases the risk of intraventricular hemorrhage.
Decrease	Vasodilating anaesthetic agents (halothane, isoflurane, enflurane) Opioids (morphine)	Decreased blood pressure is a late sign of shock because of elasticity and constriction of vessels to maintain cardiac output.
Temperature		
Increase	Shock (late sign) Infection Environmental causes (warm room, excess coverings) Malignant hyperthermia	Fever associated with infection usually occurs later than fever of noninfectious origin. Absence of fever does not rule out infection, especially in infants. Malignant hyperthermia requires immediate treatment.
Decrease	Vasodilating anaesthetic agents (halothane, isoflurane) Muscle relaxants Environmental causes (cool room) Infusion of cool fluids or blood	Newborns are especially susceptible to hypothermia, with serious or fatal consequences.

The nurse should discuss instructions for postoperative care and review them throughout the perioperative visit. After discharge, the nursing staff often makes phone calls to check the patient's status. Patient education and adherence to discharge instructions can also be assessed during these phone calls.

GENERAL HYGIENE AND BASIC CARE

Maintaining Healthy Skin

Maintaining an IV line, removing a dressing, positioning a child in bed, changing a diaper, using electrodes, and using restraints all have the potential to contribute to skin injury. Skin care must go beyond the daily bath and become a part of each nursing intervention (see Guidelines box: Skin Care). See Chapter 26, Bathing and Umbilical Cord Care, for discussion of newborn skin care.

GUIDELINES

Skin Care

- Cleanse skin with mild nonalkaline soap or soap-free cleaning agents for routine bathing.
- Keep skin dry and free of excess moisture such as urine, stool, excessive perspiration, and wound drainage.
- Provide daily cleansing of eyes, oral and diaper or perineal areas, and any areas of skin breakdown.
- Apply non-alcohol-based moisturizing agents after cleansing to retain moisture and rehydrate skin.
- Use minimum amount of tape and adhesives. On very sensitive skin, use a protective, pectin-based or hydrocolloid skin barrier between skin and tape or adhesives.
- Use water or adhesive remover (if skin is not fragile) when removing tape or adhesives.
- Place pectin-based or hydrocolloid skin barriers directly over excoriated skin. Leave barrier undisturbed until it begins to peel off, or for 5 to 7 days. With wet, oozing excoriations, place a small amount of stoma powder on site, remove excess powder, and apply skin barrier. Hold barrier in place for several minutes to allow barrier to soften and mould to skin surface.
- Alternate electrode and probe placement sites (every 24 hours) and thoroughly assess underlying skin, typically every 4 hours.
- Eliminate pressure secondary to medical devices such as tracheostomy, tubes, wheelchairs, braces, and gastrostomy tubes.
- Be certain fingers or toes are visible whenever extremity is used for an intravenous (IV) or arterial line.
- Use a draw sheet to move a child in bed or onto a stretcher; do not drag the child from under the arms.
- Position in neutral alignment; pillows, cushions, or wedges may be needed to prevent hip abduction and pressure to bony prominences such as heels, elbows, and sacral and occipital areas. When child is positioned laterally, placement of pillows or cushions between the knees, under the head, and under the upper arm helps promote neutral body alignment. Avoid using doughnut cushions because they can cause tissue ischemia. Elevate head of bed 30 degrees or less to reduce pressure unless contraindicated.
- Do not massage reddened bony prominences because this can cause deep tissue damage; provide pressure relief to those areas instead.
- Routinely assess the child's nutritional status. A child who is NPO (nothing by mouth) for several days and is receiving only IV fluids is nutritionally at risk, which can also affect the ability of the skin to maintain its integrity. Consider parenteral nutrition.
- Identify children at risk for skin breakdown before it occurs and implement prevention interventions. The Braden QD Scale may be used to assess risk for skin breakdown in pediatric patients as well as for assessing the severity of formed pressure injuries (see Additional Resources).

Assessment of the skin is easiest to accomplish during the bath. The nurse should examine the skin for early signs of injury. Risk factors include impaired mobility, protein malnutrition, **edema**, incontinence, sensory loss, anemia, infection, failure to turn the patient, and intubation. Identification of risk factors helps to determine those children who need a more thorough skin assessment. Several risk assessment scales are available for use in pediatrics, such as the Braden QD Scale (Curley et al., 2018; see Additional Resources) and the Glamorgan Scale (Willock et al., 2009). Assessment should be performed during the admission interview so that pressure injuries and wounds that occurred before admission can be identified (Registered Nurses' Association of Ontario [RNAO], 2011).

Pressure injuries can develop when the pressure on the skin and underlying tissues is greater than the capillary closing pressure, causing capillary occlusion. If the pressure remains unrelieved, vessels can collapse, resulting in tissue anoxia and cellular death. Pressure injuries most often occur over bony prominences and are usually very deep, extending into subcutaneous tissue or even deeper into muscle, tendon, or bone. When capillary blood flow is interrupted by pressure, the blood flows back into the tissue when the pressure is relieved. As the body attempts to reoxygenate the area, a bright red flush appears. This reactive **hyperemia**, or flush, is the earliest sign of tissue compromise and pressure-related ischemia. If pressure is prolonged, reactive hyperemia will not be sufficient to revitalize ischemic tissue.

Pressure injuries are staged to classify the amount of tissue damage that has occurred. Necrotic tissue must be removed so that the tissue depth can be accurately assessed. Accurate documentation of redness or obvious skin breakdown is essential. Colour, size (diameter and depth), location, presence of sinus tracts, odour, exudate, and response to treatment should be observed and recorded at least daily (RNAO, 2011).

Pressure injuries in children typically occur on the occiput, ears, sacrum, and scapula. While pressure injuries in hospitalized children are uncommon, with reported rates of less than 2%, rates are higher in children under 3 years of age (Sánchez-Lorente et al., 2018). Critically ill children are also at a higher risk for pressure injuries and skin breakdown, because they often have several risk factors. Risk factors associated with pressure injuries in pediatric critical care patients include edema, length of stay, increasing positive end-expiratory pressure, lack of turning, and weight loss. Medical devices such as pulse oximeter probes, bilevel and continuous positive airway pressure masks, oxygen cannulas, feeding tubes, stomas, orthotics, and casts can also cause pressure injuries.

Interventions found to prevent pressure injuries in critically ill children include the following:

- Turning children every 2 hours
- Using pillows, blanket rolls, and positioning devices
- Draw sheets to minimize shear
- Utilization of pressure reduction surfaces (foam overlays, gel pads, specialty beds)
- Moisture reduction through the use of dry-weave diapers and disposable underpads
- Skin moisturizer
- Nutrition consults

Friction and shear contribute to pressure injuries. *Friction* occurs when the skin's surface rubs against another surface, such as the bedsheets. The skin may have the appearance of an abrasion. Skin damage is usually limited to the epidermal and upper layers. It most often occurs over the elbows, heels, or occiput. Prevention of friction injury includes the use of customized splinting over infants' heels; gel pillows under the head of toddlers; moisturizing agents; transparent dressings over susceptible areas; and soft, smooth bed linen and clothing. By itself, friction does not cause tissue necrosis; however, when it acts with gravity, it results in shear injury.

Shear is the result of the force of gravity pushing down on the body and friction of the body against a surface, such as the bed or chair. For example, when a patient is in the semi-Fowler position and begins to slide to the foot of the bed, the skin over the sacral area remains in the same place because of the resistance of the bed surface. The blood vessels in the area are stretched and may cause small-vessel thrombosis and tissue death (RNAO, 2011). Prevention of shear injury includes using lift sheets when repositioning a patient, elevating the bed no more than 30 degrees for short periods, and using the knee gatch to interrupt the pull of gravity on the body toward the foot of the bed.

Epidermal stripping results when the epidermis is unintentionally removed with tape removal. These lesions are usually shallow and irregularly shaped and may blister or weep. Babies are at increased risk for epidermal injury. Prevention of injury includes using no tape when possible and securing dressings with laced binders (Montgomery straps) or stretchy netting (Spandage or stockinette). Use of porous or low-tack tapes (e.g., Medipore, paper, hydrogel) and alcohol-free skin sealants (No Sting Barrier Film) or picture framing wounds with hydrocolloid or wafer barriers (e.g., DuoDERM, Coloplast, Stomahesive) and then taping on top of the barrier will also reduce epidermal stripping.

Tape should be placed so that there is no tension, traction, or wrinkles on the skin. To remove tape, it should be slowly peeled away while stabilizing the underlying skin. Adhesive remover may be used to break the adhesive bond but may be drying to the skin; adhesive removers should be avoided in preterms, since absorption rates vary and toxicity may occur. The adhesive is removed with water to prevent absorption and irritation. Wetting the tape with water or alcohol-based foam hand cleansers may facilitate removal.

Chemical factors can also lead to skin damage. Fecal incontinence, especially when mixed with urine; wound drainage; or gastric drainage around gastrostomy tubes can erode epidermis. The skin can quickly progress from redness to denudement if exposure continues. Moisture barriers, gentle cleansing as soon after exposure as possible, and skin barriers can be used to prevent damage caused by chemical factors. In addition, foam dressings that wick moisture away from the skin are helpful around gastrostomy tubes and tracheostomy sites.

Bathing

Most infants and children can be bathed in a basin at the bedside, on the bed, or in a standard bathtub or shower. For infants and young children confined to bed, the towel method can be used. Two towels are immersed in a diluted soap solution and wrung damp. With the child lying supine on a dry towel, one damp towel is placed on top of the child and used to gently clean the body. This towel is discarded, and the child is dried and turned prone. The procedure is repeated using the second damp towel. Commercially available bath cloths may also be used.

Infants and small children should *never* be left unattended in a bathtub, and infants who are unable to sit alone need to be securely held with one hand during the bath. The nurse should securely support the infant's head with one hand, or grasp the farther arm firmly while the head rests comfortably on the nurse's arm. Children who are able to sit without assistance need close supervision and a pad placed in the bottom of the tub to prevent slipping and loss of balance.

School-age children and adolescents may shower or bathe. Nurses need to use judgement regarding the amount of supervision the child requires. Some can assume this responsibility unaided, whereas others will need someone in constant attendance. Children with intellectual disability, physical limitations, or suicidal or psychotic tendencies (who may commit bodily harm) require close supervision.

Areas that require special attention are the ears, between skinfolds, the neck, the back, and the genital area. The genital area should be cleansed carefully and dried, with particular care given to skinfolds. In uncircumcised boys, the foreskin should be retracted gently, only when this is easily done, usually after 3 years of age; the exposed surfaces are cleansed and the foreskin then replaced.

Children who are ill or debilitated need more extensive assistance with bathing but should be encouraged to perform as much as they can without overtaxing their energy. Increasing involvement can be expected with improved strength and endurance.

Oral Hygiene

Mouth care is an integral part of daily hygiene and should be continued in the hospital. Infants and debilitated children require the nurse or a family member to perform mouth care. Although young children can manage a toothbrush and should be encouraged to use it, most need assistance to perform thorough oral hygiene. Older children, although capable of brushing and flossing without assistance, sometimes need to be reminded.

Hair Care

Children should have their hair brushed and combed at least once daily. The hair should not be cut without parental permission, especially if clipping hair is necessary to provide access to a scalp vein for IV insertion.

If children are hospitalized for more than a few days, the hair may need shampooing. With infants the hair may be washed during the bath. For most children, washing the hair and scalp once or twice weekly is sufficient unless there is an indication for more frequent washing, such as following a high fever and profuse sweating. Adolescents normally have increased oily sebaceous secretions that require frequent hair care and more frequent shampoos.

Most children can be transported to an accessible sink for shampooing. Those who are unable to be transported can receive a shampoo in their beds with adequate protection, specially adapted equipment or positioning, or dry shampoo caps.

Feeding the Sick Child

Loss of appetite is a symptom common to most childhood illnesses. Because an acute illness is usually short, the nutritional state is seldom compromised. Urging foods on the sick child may precipitate nausea and vomiting. In most cases children can be permitted to determine their own need for food.

Refusing to eat may also be one way that children can exert power and control in an otherwise helpless situation. For young children, loss of appetite may be related to the depression caused by separation from their parents. Parents' concern with eating can intensify the issue. Forcing a child to eat can be met with rebellion and reinforces the behaviour as a control mechanism. Parents should be encouraged to relax any pressure surrounding oral or nutritional intake during an acute illness. Although it is best to encourage high-quality nutritious foods, the child may desire foods and liquids that contain mostly empty or non-nutritional calories. Some well-tolerated foods include gelatin, diluted clear soups, carbonated drinks, flavoured ice pops, dry toast, and crackers. Even though these substances are not nutritious, they can provide necessary fluid and calories.

Dehydration is always a hazard when children have a fever or anorexia, especially when accompanied by vomiting or diarrhea. For diarrhea episodes the use of Pedialyte or Enfylate is most recommended and can even be made as popsicles. Fluids should not be forced, and the child should not be awakened to take fluids. Forcing fluids may create the same difficulties as urging the child to eat unwanted food. Gentle persuasion with preferred beverages will usually meet with success. Using play techniques can also be effective (see Guidelines box: Feeding the Sick Child).

GUIDELINES

Feeding the Sick Child

Take a dietary history (see Chapter 33) and use information to make eating time as much like home as possible.

Encourage parents or other family members to feed the child or to be present at mealtimes. Allow families to bring food from home.

Make mealtimes pleasant; avoid any procedures immediately before or after eating; make certain the child is rested and pain free.

Serve small, frequent meals rather than three large meals, or serve three meals and nutritious between-meal snacks.

Provide finger foods for young children.

Involve children in food selection and preparation whenever possible.

Serve small portions, and serve each course separately, such as soup first; followed by meat, potatoes, and vegetables; and ending with dessert.

- With young children, camouflage size of food by cutting meat thicker so that less appears on the plate or by folding a cheese slice in half.
- Offer second helpings.

Ensure a variety of foods, textures, and colours.

Provide food selections that are favourites of most children, such as peanut butter and jelly sandwiches, crackers, hot dogs, hamburgers, macaroni and cheese, pizza, spaghetti, tacos, chicken fingers, corn, and fruit yogurt.

Avoid foods that are highly seasoned, have strong odours, or are all mixed together, unless typical of cultural practices.

Provide fluid selections that are favourites of most children, such as fruit punch, ginger ale, sweetened tea, flavoured ice pops, sherbet, ice cream, milk, milkshakes, pudding, gelatin, clear broth, or creamed soups.

Offer nutritious snacks, such as frozen yogurt or pudding, oatmeal, hot cocoa, cheese slices, pieces of raw vegetable or fruit, and dried fruit or cereal.

Make food attractive and different—for example:

- Serve a "picnic lunch" in a paper bag.
- Pack food in a takeout container; decorate the container.
- Put a "face" or a "flower" on a hamburger or sandwich with pieces of vegetable.
- Use a cookie cutter to shape a sandwich.
- Serve pudding, yogurt, or juice frozen as an ice pop.
- Make smoothies or snow cones by pouring flavoured syrup on crushed ice.
- Serve fluids through brightly coloured or unusually shaped straws.
- Make "bowtie" sandwiches by cutting them in triangles and placing two points together.
- Slice sandwiches into "fingers."
- Grate mounds of cheese.
- Cut apples horizontally to make circles.
- Put a banana on a hot dog bun and spread with peanut butter.
- Break uncooked spaghetti into toothpick lengths and skewer cheese, cold meat, vegetables, or fruit chunks.

Praise children for what they do eat.

Do not punish children for not eating by removing their dessert or putting them to bed.

Once the child is feeling better their appetite usually begins to improve. It is best to take advantage of any hungry period by serving high-quality foods and snacks. If the child still refuses to eat, nutritious fluids, such as prepared breakfast drinks, should be encouraged. Parents can help by bringing in food items from home, especially if the family's cultural eating habits differ from the hospital food. A clinical dietitian may also be consulted for alternative food choices.

When children are placed on special diets, such as clear liquids after surgery or during episodes of diarrhea, it is essential to assess their intake and readiness to advance to more complex foods. Regardless of the type of diet, charting of the amount consumed is an important nursing responsibility. Descriptions need to be detailed and accurate, such as "120 mL of orange juice, one pancake, and 240 mL of milk." Comments such as "ate well" or "ate poorly" are inadequate. Charting the percentage of the meal eaten is also inadequate unless food is measured before serving.

If parents are involved in the child's care, they should be encouraged to keep a list of everything eaten. Use of a premeasured cup for fluids ensures a more accurate estimate of intake. A comparison of the intake at each meal can isolate food deficiencies, such as insufficient intake of meat or vegetables. Behaviours associated with mealtime also may point to possible factors influencing appetite. For example, the observation that "child eats well when with other children but plays with food if left alone in room" can help the nurse plan mealtime activities that stimulate the appetite.

Hospitalization provides many opportunities for the nurse to explore parental knowledge of nutrition. If necessary, the nurse can provide nutritional information to the family that will improve the child's level of nutrition after hospitalization.

Controlling Elevated Temperatures

An elevated temperature, most frequently from fever but occasionally caused by hyperthermia, is one of the most common symptoms of illness in children and is of great concern to parents. To facilitate an understanding of fever, the following terms are defined:

Set point—The temperature around which body temperature is regulated by a thermostat-like mechanism in the hypothalamus

Fever (hyperpyrexia)—An elevation in set point such that body temperature is regulated at a higher level; may be arbitrarily defined as temperature above 38°C (100.4°F)

Hyperthermia—Body temperature exceeding the set point, which usually results from the body or external conditions creating more heat than the body can eliminate, as in heatstroke, Aspirin toxicity, seizures, or hyperthyroidism

Body temperature is regulated by a thermostat-like mechanism in the **hypothalamus**. This mechanism receives input from centrally and peripherally located receptors. When temperature changes occur, these receptors relay the information to the thermostat, which either increases or decreases heat production to maintain a constant set point temperature. However, during an infection, **pyrogenic** substances cause an increase in the body's normal set point, a process mediated by prostaglandins. Consequently, the hypothalamus increases heat production until the core temperature reaches the new set point.

During the fever (febrile) state shivering and vasoconstriction generate and conserve heat during the chill phase of the fever, raising central temperatures to the level of the new set point. The temperature reaches a plateau when it stabilizes in the higher range. When the temperature is greater than the set point or when the pyrogen is no longer present, a crisis, or defervescence, of the temperature occurs.

Most fevers in children are of brief duration with limited consequences and are viral in origin. However, children who appear very ill and newborns are at high risk for serious bacterial illness, such as urinary tract infection or bacteremia, and will likely receive a sepsis workup and antibiotics and require hospitalization (Brower & Shah, 2020).

When fever is caused by bacteria, endotoxins are produced that activate the inflammatory process and produce fever. Fever has physiological benefits, including increased white blood cell activity, interferon production and effectiveness, and antibody production and enhancement of some antibiotic effects. Contrary to popular belief, neither the rise in temperature nor its response to antipyretics indicates the severity or cause of infection, which casts doubt on the value of using fever as a diagnostic or prognostic indicator.

Therapeutic Management. Therapeutic management of elevated temperature depends on whether it is due to a fever or hyperthermia. Because the set point is normal in hyperthermia but increased in fever, different approaches must be used to lower body temperature successfully.

Fever. The principal reason for treating fever is the relief of discomfort. Relief measures include pharmacological or environmental intervention. The most effective intervention is the use of antipyretics to lower the set point.

Antipyretic medications include acetaminophen, Aspirin, and nonsteroidal anti-inflammatory drugs (NSAIDs). Acetaminophen is the preferred medication; Aspirin should not be given to children because of its association with influenza virus or chickenpox and Reye syndrome. One nonprescription NSAID, ibuprofen, is approved for fever reduction in children as young as 6 months of age. Ibuprofen dosage is based on the initial temperature level: 5 mg/kg of body weight for temperatures less than 39.2°C or 10 mg/kg for temperatures greater than 39.2°C. The recommended dosage for pain is 5 to 10 mg/kg every 6 to 8 hours, and the recommended maximum daily dose for pain and fever is 40 mg/kg. The duration of fever reduction is generally 6 to 8 hours and is longer with the higher dose. The recommended dose should never be exceeded. Acetaminophen should be given every 4 hours but no more than five times in 24 hours. Because body temperature normally decreases at night, three or four doses at 10 to 15 mg/kg in 24 hours will control most fevers. The nurse should retake the temperature 45 to 60 minutes after the antipyretic is given to assess its effect, but temperature should not be repeatedly measured; the child's level of discomfort is the best indication for continued treatment. Since pediatric dosages are decided on the basis of accurate and current body weights, it is recommended that weighing be repeated at a minimum of once per week or more if severe dehydration or edema exists.

Environmental measures to reduce fever may be used if tolerated by the child and if they do not induce shivering. As noted earlier, shivering is the body's way of maintaining the elevated set point by producing heat. Compensatory shivering greatly increases metabolic requirements above those already caused by the fever.

Traditional cooling measures, such as wearing minimum clothing, exposing the skin to the air, reducing room temperature, increasing air circulation, and applying cool, moist compresses to the skin (e.g., the forehead, neck and axilla, hands, femoral, and feet areas), are effective if used approximately 1 hour *after* an antipyretic is given so that the set point is lowered. Cooling procedures such as sponging or tepid baths are ineffective in treating febrile children (these measures are effective for hyperthermia) when used either alone or in combination with antipyretics, and they cause considerable discomfort.

Seizures associated with a fever occur in 2 to 5% of all children between the ages of 6 months and 5 years (CPS, 2018). These febrile seizures usually stop completely by age 5. The older the child is when the first seizure occurs, the lower the chance of further seizures. A family history of febrile seizures is associated with recurring episodes. There is little evidence to support the use of antipyretic medications or anticonvulsants to prevent a second febrile seizure; nursing interventions should focus on ways to provide care and comfort during a febrile illness. Simple febrile seizures lasting less than 10 minutes do not cause brain damage or other debilitating effects. However, there are some special febrile seizure syndromes that can have some long-term neurological abnormalities. Unless a possible serious central nervous system infection is suspected, a medical extensive workup is not required (Khair & Elmagrabi, 2015). See Chapter 50, Febrile Seizures for more information.

Hyperthermia. Unlike in fever, antipyretics are of no value in hyperthermia because the set point is already normal. Consequently, cooling measures are used. Cool applications to the skin help reduce the core temperature. Cooled blood from the skin surface is conducted to inner organs and tissues, and warm blood is circulated to the surface, where it is cooled and recirculated. The surface blood vessels dilate as the body attempts to dissipate heat to the environment and facilitate the cooling process.

Commercial cooling devices, such as cooling blankets or mattresses, are available to reduce body temperature. They should be placed on the bed and covered with a sheet or lightweight blanket. Frequent temperature monitoring is essential to prevent excessive cooling of the body.

Tepid baths are also used to decrease high temperature. For tepid tub baths it is usually best to start with warm water and gradually add cool water until the desired water temperature of 37°C is reached to accustom the child to the lower water temperature. Generally, the temperature of the water only has to be 1°C less than the child's temperature to be effective. The child should be placed directly in the tub of tepid water for approximately 20 minutes while water is gently squeezed from a washcloth over the back and chest or gently sprayed over the body from a sprayer. In the bed or crib, tepid washcloths or towels are used, exposing only one area of the body at a time. The sponging is continued for approximately 20 minutes.

After the tub or sponge bath, the child can be dried and dressed in lightweight pyjamas, a nightgown, or a diaper and placed in a dry bed. The child is dried by gently rubbing the skin surface with a towel to stimulate circulation. The temperature should be retaken 30 minutes after the tub bath or sponge bath. The tub or sponge bath should not be continued or restarted until the skin surface is warm or if the child feels chilled. Chilling causes vasoconstriction, which defeats the purpose of the cool applications. In this condition, little blood is carried to the skin surface; the blood remains primarily in the viscera to become heated.

Whether a temperature elevation in the critically ill child is caused by fever or hyperthermia, it should be treated aggressively. The metabolic rate increases 10% for every 1°C increase in temperature and three to five times during shivering, thus increasing oxygen, fluid, and caloric requirements. If the child's cardiovascular or neurological system is already compromised, these increased needs are especially hazardous. In all children with elevated temperature, attention to adequate hydration is essential. Most children's needs can be met through ingestion of additional oral fluids.

Family Teaching and Home Care. Fever is one of the most common concerns for which parents seek health care. High levels of parental anxiety (fever phobia) surrounding potential complications of fever such as seizures and dehydration are prevalent and can result in overuse of antipyretics (Purssell, 2009). Parents need to know that sponging is indicated for elevated temperatures from hyperthermia, rather than fever, and that ice water and alcohol are inappropriate, potentially dangerous solutions (CPS, 2020). Parents should know how to take the child's temperature and read the thermometer accurately and should have guidelines for seeking professional care (see Family-Centred Care box: The Child With Fever). Some of the newer temperature-measuring devices, such as plastic strips or digital thermometers, may be better suited for home use than hospital use (see Temperature, Chapter 33). If acetaminophen or ibuprofen is indicated, the parents need instruction in administering the medication. The nurse needs to emphasize accuracy in both the amount of medication given and the time intervals at which it is administered. Parents should be reminded to write down the medication, dose, and time last administered for accuracy. Along with reduced activity, the child should be encouraged to take small, frequent sips of clear liquids.

FAMILY-CENTRED CARE

The Child With Fever

Contact your health care provider or go to the emergency department if your child has any of the following symptoms:

- Your child is younger than 3 months old and has a fever of a temperature over 38.5°C.
- Your child develops a rash and it does not go away when you apply pressure to it with your fingers (blanching).
- Your child cannot keep down fluids and looks dehydrated, or your child's skin looks very pale or grey.
- Your child is having constant pain, is very weak, or you are unable to wake your child up easily.
- Your child has a stiff neck.
- Your child has a seizure associated with fever.
- Your child has sore, swollen, or unresponsive limbs.
- Your child has difficulty breathing.
- Your child is crying in a high pitch and cannot be settled.
- Your child is looking or acting very sick.

Call within 24 hours if your child has a fever over 38.5°C and:

- Your child is between 3 and 6 months old.
- Your child has an earache that doesn't improve.
- Your child has had a fever for more than 3 days.
- The fever went away for over 24 hours and then came back.
- Your child has a bacterial infection that is being treated with an antibiotic, but the fever has not gone away in 2 to 3 days.
- Your child cries when going to the bathroom or the urine smells bad.
- You have other questions or concerns.

SAFETY

While safety is an essential component of any patient's care, children have special characteristics that require an even greater concern for safety. Because small children in the hospital are separated from their usual environment and do not possess the capacity for abstract thinking and reasoning, it is the responsibility of everyone who comes in contact with them to maintain protective measures throughout their hospital stay. Nurses need to understand the age level at which each child is operating and plan for safety accordingly.

Identification bands are particularly important to use with children. Infants and unconscious patients are unable to tell or respond to their names. Toddlers may answer to any name or to a nickname only. Older children may exchange places, give an erroneous name, or choose not to respond to their own names as a form of joke, unaware of the hazards of such practices.

Environmental Factors

The hospital environment requires high vigilance by staff to avoid adverse incidents in children that may stem from the use of products and equipment used in diagnosis, prevention, and treatment. Some important recommendations when caring for children who require tubing (e.g., IV, oxygen, leads) include the following:

- Using continuous IV administration only when necessary. For intermittent IV infusion, saline or heparin-locked IV sites should be considered.
- Providing an appropriate level of supervision for children
- Using equipment accessories that restrain or stabilize flexible lines to reduce the potential for them to become wrapped around the child's neck or limbs

All of the environmental safety measures for the protection of adults apply to children, including good illumination, floors clear of fluid or objects that might contribute to falls, and nonskid surfaces in showers and tubs. All staff members should be familiar with the area-specific fire plan. Elevators and stairways should be made safe.

All windows should be secured and blinds and curtain cord should be out of reach with split cords to prevent strangulation. Pacifiers should not be tied around the neck or attached to an infant by string.

Electrical equipment should be in good working order and only used by personnel familiar with its use. It should not be in contact with moisture or situated near tubs. Electrical outlets should have covers to prevent burns in small children, whose exploratory activities may extend to inserting objects into the small openings.

Staff members should practise proper care and disposal of small objects such as syringe caps, needle covers, and temperature probe covers. There should be limited use of needles for medication administration; instead, needleless syringes should be used. Vanish point needles are associated with enhanced safety and reduced needlestick injuries.

Furniture is safest when it is scaled to the child's proportions, is sturdy, and is well balanced to prevent being tipped over. A special hazard for children is the danger of entrapment under an electronically controlled bed when it is activated to descend. Infants and small children must be securely strapped into infant seats, feeding chairs, and strollers. Infants, young children, and those who are weak, paralyzed, agitated, confused, sedated, or intellectually disabled should *never* be left unattended on treatment tables, on scales, or in treatment areas. Even preterm infants are capable of surprising mobility; therefore, portholes in isolettes must be securely fastened when not in use. Beds of ambulatory patients should remain locked in place and at a height that allows easy access to the floor.

Crib sides should be kept up and fastened securely unless an adult is at the bedside. It is safer to leave crib sides up, regardless of the child's ability to get out and when the crib is unoccupied, to remove the child's temptation to climb in. Anyone attending an infant or small child in a crib with the sides down should never turn away without maintaining hand contact with the child; that is, one hand should be kept on the child's back or abdomen to prevent the child from rolling, crawling, or jumping from the open crib (Figure 44.3).

Fig. 44.3 The nurse maintains hand contact when her back is turned.

Toy Safety. Toys play a vital role in the everyday life of children, and they are no less important in the hospital setting. Nurses are encouraged to educate parents and well-meaning friends about toy safety. Toys should be appropriate to the child's age, condition, and treatment. For example, if the child is receiving oxygen, electrical or friction toys are not safe, since sparks can cause oxygen to ignite. The nurse needs to inspect toys to ensure they are nonallergenic, washable, and unbreakable and have no small, removable parts that can be aspirated or swallowed or in other ways injure a child. All objects within reach of children younger than 3 years should pass the choke tube test. A toilet paper roll is a handy guide. If a toy or object fits into the cylinder (items less than 3 cm across or balls smaller than 4.5 cm), it is a potential choking danger to the child. Broken latex balloons pose a serious aspiration or choking threat to children of all ages if the child puts a piece into their mouth. Latex balloons should *never* be permitted in the hospital setting.

Preventing Falls. Prevention of falls begins with identification of children most prone to falling. Pediatric hospitals use various methods to identify a child's risk for falls, including a fall risk assessment of patients on admission and throughout hospitalization. After a risk assessment is performed, multiple interventions are needed to minimize pediatric patients' risk for falling, including education of patient, family, and staff.

Risk factors for hospitalized children falling include the following:

- Medication effects—Postanaesthesia or sedation; analgesics or opioids, especially in those who have never had opioids in the past and in whom effects are unknown
- Altered mental status—Secondary to seizures, brain tumours, or medications
- Altered or limited mobility—Reduced skill at ambulation secondary to developmental age, disease process, tubes, drains, casts, splints, or other appliances; new to ambulation with assistive devices, such as walkers or crutches
- Postoperative children—Risk of hypotension or syncope secondary to large blood loss, a heart condition, or extended bed rest
- History of falls
- Infants or toddlers in cribs with side rails down or on the daybed with family members

Once children at risk for falls have been identified, staff members need to be alerted by posting signs on the door and at the bedside, applying a special coloured armband labelled "Fall Precautions," labelling the chart with a sticker, or documenting information on the chart.

Prevention of falls requires alterations in the environment, including the following:

- The bed is in the lowest position, with brakes locked and side rails up.
- The call bell is placed within reach.
- All necessary and desired items are within reach, such as water, glasses, tissues, and snacks.
- Toileting is offered on a regular basis, especially if the patient is taking diuretics or laxatives.
- Lights are kept on at all times, including dimmed lights while the patient is sleeping.
- Wheelchairs are locked before transferring patients.
- The patient has an appropriate-size gown and nonskid footwear. Gowns or ties should not drag on the floor when the patient is ambulating.
- The floor is clean and free of clutter. A "Wet Floor" sign is posted if the floor is wet.
- The patient has glasses on if they normally wear them.

To prevent falls, patients also need relevant age-appropriate education. The child should be helped to ambulate even if they ambulated well before hospitalization. Patients who have been lying in bed need to get up slowly, sitting on the side of the bed before standing.

The nurse also needs to educate family members in ways to help prevent their child from falling:

- Call nursing staff for assistance, and do not allow the child to get up independently.
- Keep side rails of the crib or bed up whenever the child is in the crib or bed.
- Do not leave infants on the daybed; put them in the crib with side rails up.
- When all family members need to leave the bedside, notify staff and ensure that the child is in the bed or crib with side rails up and that the call bell is within reach (if appropriate).

Infection Control

Approximately 8% of children in Canadian hospitals develop health care–acquired infection (HAI) at any given time (Government of Canada, 2017). These infections occur when there is interaction among patients, health care personnel, equipment, and bacteria. HAIs are preventable if caregivers practise meticulous cleaning and disposal techniques.

Routine practices are used to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection. Routine practices are used in the routine care of all patients at all times in all health care settings; such practices are determined by the circumstances of the patient, the environment, and the task to be performed (Government of Canada, 2017). They are based on the premise that all blood, body fluids, secretions, excretions, mucous membranes, nonintact skin, or soiled items are potentially infectious. There are five major components to routine practices: risk assessment, hand hygiene (including point-of-care alcohol-based hand rub), personal protective equipment (PPE), and environmental and administrative controls (Canadian Centre for Occupational Health and Safety, 2021). PPE includes gloves, gowns, shoe covers, goggles, glasses with side shields, and masks. PPE is used when there is a risk of disease transmission through touching, spraying, aerosolization, or splashing of blood, bodily fluids, mucous membranes, nonintact skin, body tissues, and contaminated equipment and surfaces (Canadian Centre for Occupational Health and Safety, 2021).

Additional precautions are designed for patients with documented or suspected infection or colonization (presence of microorganism in or on the patient but without clinical signs and symptoms of infection) with highly transmissible or epidemiologically important pathogens for which precautions beyond routine practices are needed to interrupt transmission in hospitals. These precautions should also be used when medical procedures increase the risk of transmission of a specific infectious agent or when the clinical situation prevents consistent application of routine practices (e.g., care of the young child). There are three types of additional precautions: airborne precautions, droplet precautions, and contact precautions. They may be combined when caring for patients with diseases that have multiple routes of transmission (Box 44.3) and are to be used in addition to routine practices.

Airborne precautions can reduce the risk of airborne transmission of infectious agents. Airborne transmission occurs by dissemination of either airborne droplet nuclei (small-particle residue [5 microns or smaller in size] of evaporated droplets that may remain suspended in the air for long periods) or dust particles containing the infectious agent. Microorganisms carried in this manner can be dispersed widely by air currents and may become inhaled by or deposited on a susceptible host within the same room or over a longer distance from the source patient, depending on environmental factors. Airborne precautions apply to patients with known or suspected infection with pathogens transmitted by the airborne route, such as measles, varicella, and tuberculosis.

BOX 44.3 Types of Precautions and Patients Requiring Them

Routine Practices

Routine practices are used at the level of care provided for all patients.

Airborne Precautions

In addition to routine practices, airborne precautions are used for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei. Examples of such illnesses include measles, varicella (including disseminated zoster), and pulmonary or laryngeal tuberculosis.

Health care providers must wear a respiratory mask (N95 or N100), and special air handling and ventilation are required.

Droplet Precautions

In addition to routine practices, droplet precautions are used for patients known or suspected to have serious illnesses transmitted by large-particle droplets. Practice of droplet precautions requires use of a mask when within 1 metre of an isolated patient. Droplet precautions include use of a shielded mask, and when there is a risk of the uniform becoming soiled, use of gown and gloves. Care of pediatric patients requires droplet precautions if patients are known or suspected to have any of the following:

- Invasive *Haemophilus influenzae* type b (until 24 hours of appropriate antibiotic received), including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitides* (until 24 hours of appropriate antibiotic received), including meningitis, pneumonia, and sepsis
- Other serious bacterial respiratory tract infections spread by droplet transmission, including diphtheria (pharyngeal), pertussis, streptococcal group A pharyngitis, respiratory syncytial virus, parainfluenza, and adenovirus. Droplet precautions should be practised for all definite or possible respiratory tract infections until viral infection can be ruled out in pediatric patients.
- Serious viral infections spread by droplet transmission, including adenovirus, influenza, mumps, parvovirus B19, rubella, COVID-19

Contact Precautions

In addition to routine precautions, contact precautions should be used for patients known or suspected to have serious illnesses easily transmitted by direct patient contact or contact with items in the patient's environment. Contact precautions require the use of gloves and gown in addition to routine precautions. Additional precautions may be indicated for certain organisms when routine practices are not sufficient to control transmission, for instance:

- If the organism has a low infective dose
- If the organism may be transmitted from the source patient's intact skin
- If there is potential for widespread environmental contamination

Pediatric patients require care with contact precautions if they are known or suspected to have any of the following:

- Diarrhea due to *Campylobacter, Rotavirus, Salmonella, Giardia, Shigella, C. difficile, Yersinia,* or pathogenic strains of *E. coli*
- Respiratory tract infections due to adenovirus, parainfluenza virus, rhinovirus, respiratory syncytial virus, COVID-19, or influenza (use droplet plus contact precautions)
- Hepatitis A or E, scabies, enteroviral infections, herpes simplex virus: neonatal or disseminated mucocutaneous, antimicrobial-resistant organisms
- Viral or hemorrhagic conjunctivitis
- Viral hemorrhagic infections (Ebola, Lassa, or Marburg)

From Public Health Agency of Canada. (2012). *Routine practices and additional precautions for preventing the transmission of infection in healthcare settings* (HP40-83/2013E-PDF), pp. 52–89. http://publications.gc.ca/collections/collection_2013/aspc-phac/HP40-83-2013-eng.pdf.

Droplet precautions reduce the risk of droplet transmission of infectious agents. Droplet transmission involves contact of the conjunctivae or the mucous membranes of the nose or mouth of a susceptible person with large-particle droplets (larger than 5 microns in size) containing microorganisms generated from a person who has a clinical disease or who is a carrier of the microorganism. Droplets are generated from the source person primarily during coughing, sneezing, or talking and during procedures such as suctioning and bronchoscopy. Transmission requires close contact between source and recipient persons, since droplets do not remain suspended in the air and generally travel only short distances, usually 1 metre or less, through the air. Because droplets do not remain suspended in the air, special air handling and ventilation are not required to prevent droplet transmission, although regular masks are required when within 1 metre of patient. Droplet precautions apply to any patient with known or suspected infection with pathogens that can be transmitted by infectious droplets, including COVID-19 (see Box 44.3).

Contact precautions reduce the risk of transmission of microorganisms by direct or indirect contact. Direct-contact transmission involves a skin-to-skin contact and physical transfer of microorganisms to a susceptible host from an infected or colonized person, such as occurs when turning or bathing patients. Direct-contact transmission also can occur between two patients (e.g., by hand contact). Indirect-contact transmission involves contact of a susceptible host with a contaminated intermediate object, usually inanimate, in the patient's environment. Contact precautions apply to specified patients known or suspected to be infected or colonized with microorganisms that can be transmitted by direct or indirect contact (e.g., wound infections or gastrointestinal infections).

! NURSING ALERT

The most common piece of medical equipment, the stethoscope, can be a potent source of harmful microorganisms and health care–acquired infections.

Nurses caring for young children are frequently in contact with body substances, especially urine, feces, and vomitus. They should exercise judgement in those situations when gloves, gowns, or masks are necessary. For example, nurses should wear gloves for changing diapers and wear gowns when there is the possibility of loose or explosive stools. When wearing gloves, the hands must be washed thoroughly after removing the gloves because gloves fail to provide complete protection. The absence of visible leaks does not indicate that the gloves are intact.

Another essential practice of infection control is disposal of all needles (uncapped and unbroken) in a rigid, puncture-resistant container located near the site of use. These containers should be installed in all patients' rooms. Because children are naturally curious, selecting a suitable type of container and a location that prevents access to the discarded needles is paramount. The use of needleless systems allows secure syringe or IV tubing attachment to vascular access devices without the risk for needlestick injury to the child or nurse.

Antimicrobial-resistant organisms are causing increasing numbers of HAIs. In hospitals, patients are the most significant sources of methicillin-resistant *Staphylococcus aureus* (MSRA), and the main mode of transmission is patient to patient via the hands of a health care provider. The MRSA infection rate has increased in pediatric hospitals more than fivefold between 2011 and 2016, and this increase in pediatric bloodstream infections is concerning and requires closer monitoring (PHAC, 2018).

! NURSING ALERT

Hand hygiene is the most critical infection-control practice. Hand hygiene should be followed using the four moments of hand hygiene: (1) before initial contact with the patient or patient environment, (2) before a clean/aseptic procedure, (3) after body-fluid exposure risk, and (4) after contact with a patient or patient environment.

Transporting Infants and Children

Infants and children need to be transported within the unit and to areas outside the pediatric unit. Infants and small children can be carried for short distances within the unit, but for more extended trips the child should be securely transported in a suitable conveyance (see hospital policy related to transport).

Small infants can be held or carried in the horizontal position (Figure 44.4, *A*) or in the football hold (see Figure 44.4, *B*). Both of these holds leave the nurse's other arm free for activity. The infant also can be held in the upright position in which the infant's head and shoulders are supported by the nurse's other arm in case the infant moves suddenly (see Figure 44.4, *C*).

The method of transporting children is determined by their age, condition, destination, and hospital policy. Older children are safe in wheelchairs or on stretchers. Younger children can be transported in a crib, on a stretcher, in a wagon with raised sides, or in a wheelchair with a safety belt. Stretchers should be equipped with high sides and a safety belt, both of which are secured during transport.

Special care is needed in transporting critically ill patients in the hospital. Critically ill children should always be transported on a bed or stretcher by at least two staff members with monitoring continued during transport. A blood pressure monitor or standard blood pressure cuff, pulse oximeter, and cardiac monitor/defibrillator should accompany every critically ill child. Airway equipment and emergency medication should also accompany the child.

Therapeutic Holding and Restraints

In *therapeutic holding*, the parent or caregiver holds the child in a secure, comfortable position that provides close physical contact for 30 minutes or less (Figure 44.5). The use of restraints can often be avoided with the use of therapeutic holding along with other strategies, such as using volunteers and child youth workers, providing diversional activities such as music, and encouraging participation of the parents.

Fig. 44.5 Therapeutic holding of child with parental assistance.

A *restraint* is any method, physical or mechanical, that restricts a person's movement, physical activity, or normal access to their body. Before initiating use of restraint, the nurse should complete a comprehensive assessment of the patient to determine whether the need for a restraint outweighs the risk of not using one. The nurse needs to assess the child's developmental level, mental status, potential to hurt others or self, and safety. The nurse is responsible for selecting the means of the least restrictive type of restraint. Restraints can result in loss of dignity, violation of patient rights, psychological harm, physical harm, and even death. Thus alternative methods should first be considered and documented in the patient's record.

The use of restraints can often be avoided with adequate preparation of the child, parental or staff supervision of the child, or adequate protection of a vulnerable site, such as an infusion device. This is often possible when the child and parents work together with the nurse.

Nurses cannot use any form of restraint without a patient's or legal guardian's informed consent, except in an emergency situation in which there is a serious threat of harm to the individual or others and all other measures have been unsuccessful. An order must be obtained as soon as possible (during application or within a few minutes) after the initiation of restraints and specify the time frame they can be used, the reason they are being used, and reasons for discontinuation. Discontinuation of

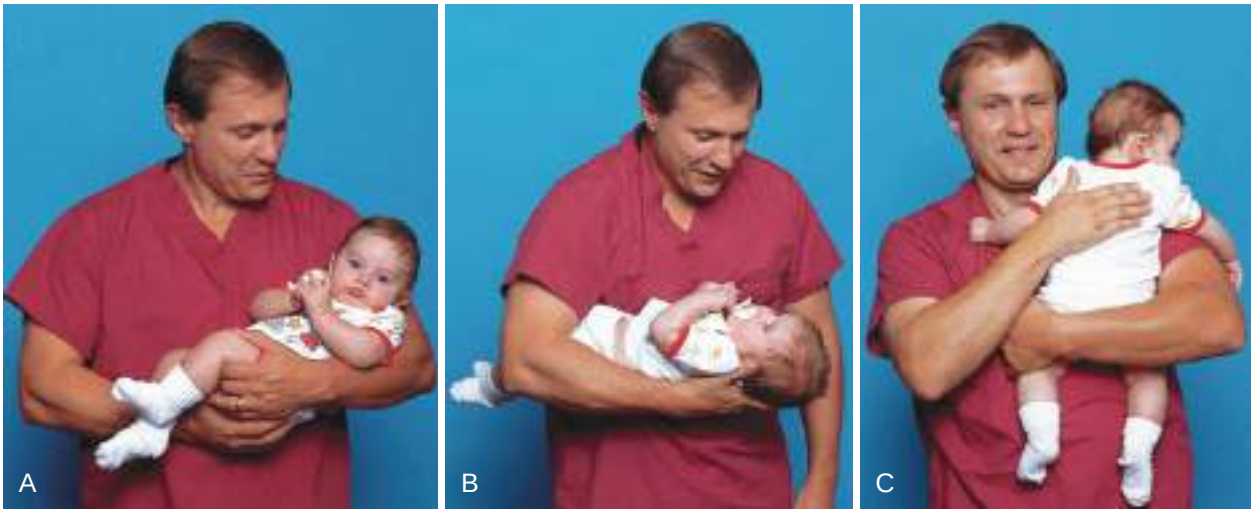

Fig. 44.4 Transporting infants. **A:** Infant's thigh firmly grasped in nurse's hand. **B:** Football hold. **C:** Back supported.

restraints should occur as soon as safe, even if the order time frame has not expired. Continued use of restraints must be renewed each day. Patients need to be monitored at least every 1 hour.

The three types of restraints used with patients include physical, chemical, or environmental restraints.

Physical restraints are used for children with an artificial airway or airway adjunct for delivery of oxygen, in-dwelling catheters, tubes, drains, lines, pacemaker wires, or **suture** sites. The physical restraint is used to ensure that safe care is given to the patient. Physical restraints may be instituted for any of the following reasons:

- Risk for interruption of therapy used to maintain oxygenation or airway patency
- Risk of harm if in-dwelling catheter, tube, drain, line, pacemaker wire, or sutures are removed, dislodged, or ruptured
- Patient confusion, agitation, unconsciousness, or developmental inability to understand direct requests or instructions

Restraints with ties must be secured to the bed or crib frame, not the side rails. Suggestions for increasing safety and comfort while the child is in a restraint include leaving one fingerbreadth between skin and the device; tying knots that allow for quick release; ensuring that the restraint does not tighten as the child moves; decreasing wrinkles or bulges in the restraint; placing jacket restraints over an article of clothing; placing limb restraints below waist level, below knee level, or distal to the IV; and tucking in dangling straps. Assessment components include signs of injury associated with applying restraint, nutrition and hydration, circulation and range-of-motion of extremities, vital signs, hygiene and elimination, physical and psychological status and comfort, and readiness for discontinuation of restraint.

Chemical restraints are pharmaceutical interventions administered to keep the individual safe. Chemical restraints must be ordered by a health care provider and, as with all restraints, informed consent is required. Children in chemical restraints must be observed and assessed every 15 minutes.

Environmental restraint refers to the restraining of an individual within a physical space, such as in a locked unit in a mental health facility. For example, an adolescent with a mental health issue may be admitted to an emergency department and be restricted to an examining room because of aggressive behaviour.

Mummy Restraint or Swaddle. When an infant or small child requires short-term restraint for examination or treatment, such as venipuncture, throat examination, and gavage feeding, a mummy wrap effectively controls the child's movements. A blanket or sheet is opened on the bed or crib with one corner folded to the centre. The infant is placed on the blanket with shoulders at the fold and feet toward the opposite corner. With the infant's right arm straight down against the body, the right side of the blanket is pulled firmly across the infant's right shoulder and chest and secured beneath the left side of the body. The left arm is placed straight against the infant's side, and the left side of the blanket is brought across the shoulder and chest and locked beneath the body on the right side. The lower corner is folded and brought over the body and tucked in. To modify the mummy restraint for chest examination, the folded edge of the blanket is brought over each arm and under the back, after which the loose edge is folded over and secured at a point below the chest to allow visualization of and access to the chest (Figure 44.6, *A*). It is important that swaddling an infant in this manner is only used for short periods of time.

Jacket Restraint. A jacket restraint is sometimes used to keep the child safe in various chairs. The jacket is put on the child with the ties in back so that the child is unable to manipulate them. The jacket restraint is also useful as a means of maintaining the child in a desired horizontal position. The long tapes secured to the understructure of the crib keep the child inside the crib.

Fig. 44.6 Restraint examples. **A:** Mummy restraint. **B:** Wrist restraints. **C:** Elbow restraints.

Arm and Leg Restraints. Occasionally, one or more extremities must be restrained or limited in motion. Several commercial restraining devices are available, including disposable wrist and ankle restraints (see Figure 44.6, *B*). The restraints must be appropriate to the child's size and padded to prevent undue pressure, constriction, or tissue injury; and the extremity must be observed frequently for signs of irritation or impairment of circulation. The ends of the restraints are never

tied to the side rails, since lowering the rail will disturb the extremity, frequently with a jerk that may hurt or injure the child.

Elbow Restraint. Sometimes it is important to prevent the child from reaching the head or face, such as after lip surgery, when a scalp vein infusion is in place, or to prevent scratching in skin disorders. Elbow restraints fashioned from a variety of materials function well (see Figure 44.6, *C*). Commercial elbow restraints are available. An improvised form of elbow restraint consists of a piece of muslin long enough to reach comfortably from just below the axilla to the wrist with a number of vertical pockets into which tongue depressors are inserted. The restraint is wrapped around the arm and secured with tape.

Positioning for Procedures

Infants and small children are unable to assist with many procedures; therefore, the nurse is responsible for minimizing their movement and discomfort with proper positioning. A second nurse should assist with procedures required in infants or young children. Older children usually need only minimal, if any, restraint. Careful explanation and preparation beforehand and support and simple guidance during the procedure are usually sufficient. For painful procedures the child should receive adequate analgesia and sedation to minimize pain and the need for excessive restraint.

Femoral Venipuncture. The nurse places the child supine with the legs in a frog position to provide extensive exposure of the groin area. The infant's legs can be effectively held by the nurse's forearms and hands (Figure 44.7). Only the side used for the venipuncture is uncovered, so the physician or nurse is protected should the infant urinate during the procedure. Pressure is applied to the site to prevent oozing from the site.

Extremity Venipuncture. The most common sites of venipuncture are the veins of the extremities, especially the arm and hand. If possible, it is best to use the policy of least restraint and to use some of the atraumatic techniques described in the venipuncture section of this chapter. If necessary, the child can be placed in the parent's (or assistant's) lap, with the child facing the parent and in the straddle position. Next, the child's arm is placed for venipuncture on a firm surface, such as a treatment table. The child's outstretched arm is partially stabilized by the technician drawing the blood. The parent should hug the child's upper body, preventing movement, and use an arm to immobilize the venipuncture site (see Figure 44.5). This type of restraint also comforts the child because of the close body contact, and it allows each person to maintain eye contact.

Lumbar Puncture. The technique for lumbar puncture (LP) in infants and children is similar to that used in the adult, although modifications are suggested for newborns, who have less distress in a side-lying position with modified neck extension than in flexion or a sitting position.

Children are usually easiest to control in the side-lying position, with the head flexed and the knees drawn up toward the chest (Figure 44.8). Even cooperative children need to be held gently to prevent possible trauma from unexpected, involuntary movement. They can be reassured that, although they are trusted, the holding will serve as a reminder to maintain the desired position. It also provides a measure of support and reassurance to them.

A flexed sitting position may be used, depending on the child's ability to assist and whether sedation will be used. In the sitting position with the hips flexed, the interspinous space is maximized. The child is placed with the buttocks at the edge of the table. The nurse's hands immobilize the infant's arms and legs. Neck flexion is not necessary.

Specimens and spinal fluid pressure are obtained, measured, and sent for analysis in the same manner as for the adult patient. Vital signs should be taken as ordered and the child observed for any changes in level of consciousness, motor activity, or other neurological signs. Post-LP headache may occur and is related to postural changes; this is less severe when the child lies flat for a period of time. Headache is seen much less frequently in young children than in adolescents.

! NURSING ALERT

The sitting position may interfere with chest expansion and diaphragm excursion. In infants, the soft pliable trachea may collapse, so the child must be observed for breathing difficulties.

Bone Marrow Aspiration or Biopsy. The position for a bone marrow aspiration or biopsy depends on the chosen site. In children the posterior or anterior iliac crest is most frequently used, although in infants the tibia may be selected because of easy access to the site and holding of the child.

If the posterior iliac crest is used, the child is positioned prone. Sometimes a small pillow or folded blanket is placed under the hips to facilitate obtaining the bone marrow specimen. Children should receive adequate analgesia or anaesthesia to relieve pain. If the child awakens, they may need to be held; this is best done with two people—one person to immobilize the upper body and a second person to immobilize the lower extremities.

Fig. 44.7 Restraining an infant for femoral venipuncture.

Fig. 44.8 Child in side-lying position for lumbar puncture.

COLLECTION OF SPECIMENS

Many of the specimens needed for diagnostic examination of children are collected in much the same way as for adults. Older children are able to assist if given proper instructions regarding what is expected of them. However, infants and small children are unable to follow direction or control body functions sufficiently to help in collecting some specimens.

Fundamental Procedure Steps Common to All Procedures

The following steps are important for every procedure and should be considered fundamental aspects of care. Although these steps are important, they are not listed in each of the specimen collection procedures.

1. Assemble necessary equipment.
2. Identify the child with patient name and medical record or birth date, cross-checking with parents and reviewing the armband.
3. Perform hand hygiene, maintain aseptic technique, and follow routine practices.
4. Explain the procedure to the parent and child according to the developmental level of the child; reassure the child that the procedure is not a punishment.
5. Provide atraumatic care and position the child securely.
6. Prepare the area with an aseptic agent.
7. Place specimens in appropriate containers and apply a patient identification label to the specimen container in the presence of the child and family.
8. Discard puncture device in puncture-resistant container near the site of use.
9. Wash the procedural preparation agent off if povidone-iodine is used, if skin is sensitive, and for infants.
10. Remove gloves and perform hand hygiene after the procedure. Have children wash their hands if they have helped.
11. Praise the child for helping.
12. Document pertinent aspects of the procedure, such as number of attempts, site, amount of blood or urine withdrawn, and type of test performed.

Urine Specimens

Older children and adolescents can use a bedpan or urinal or can follow directions for collection in the bathroom. However, they may have special needs. School-age children may be curious and concerned about the reasons behind things and are likely to ask questions about the disposition of their specimen and what might be discovered from it. Self-conscious adolescents may be reluctant to carry a specimen through a hallway or waiting room and appreciate a paper bag or other means for disguising the container. The presence of menses may be an embarrassment or a concern to teenage girls; thus, it is a good idea to ask if they are menstruating and to make adjustments as necessary. The specimen can be delayed or a notation made on the laboratory slip to explain the presence of red blood cells.

Preschoolers and toddlers are usually unable to void on request. It is often best to offer them water or other liquids that they enjoy and wait about 30 minutes until they are ready to void voluntarily.

! NURSING ALERT

When obtaining a urine specimen in infants try the following noninvasive technique first. Wipe the abdomen with an alcohol pad and fan it dry; the cooling effect often causes voiding within 2 minutes. Apply pressure over the suprapubic area, or stroke the paraspinal muscles (along the spine) to elicit the Perez reflex; in infants 4 to 6 months of age, this reflex causes crying, extension of the back, flexion of the extremities, and urination.

Children will better understand what is expected if the nurse uses familiar terms, such as "pee-pee," "wee-wee," or "tinkle." Some will have difficulty voiding in an unfamiliar receptacle. Use of a potty chair or placing a potty hat on the toilet is usually helpful. Toddlers who have recently acquired bladder control may be especially reluctant, since they undoubtedly have been admonished for "going" in places other than those approved by parents. Enlisting the parents' help usually leads to success.

For some types of urine testing, such as specific gravity, ketones, glucose, and protein, urine can be aspirated directly from the diaper. To obtain this type of small amount of urine, the nurse can use a needleless syringe to aspirate urine directly from the diaper. If diapers with absorbent gelling material that trap urine are used, the nurse can place a small gauze dressing, some cotton balls, or a urine collection device inside the diaper to collect urine, then aspirate the urine with a syringe or put the cotton balls into the syringe and depress the plunger to extract urine.

Urine Collection Bags. For infants and toddlers who have not achieved toilet independence, special urine collection bags with self-adhering material around the opening at the point of attachment are used. To prepare the infant, the genitalia, perineum, and surrounding skin are washed and dried thoroughly because the adhesive will not stick to a moist, powdered, or oily skin surface. The collection bag is easiest to apply if attached first to the perineum, progressing to the symphysis pubis (Figure 44.9). With girls, the perineum is stretched taut during application to the area to ensure a leak-proof fit. With boys the penis and sometimes the scrotum are placed inside the bag. The adhesive portion of the bag must be firmly applied to the skin all around the genital area to avoid leakage. For low-birth-weight infants, small bags with adhesive that is gentle to the skin are available. When a urine collection bag is used, a small slit is cut in the diaper and the bag pulled through to allow room for urine to collect and to facilitate checking on the contents. The bag is checked frequently and removed as soon as the specimen is available, since the moist bag may become loosened on an active

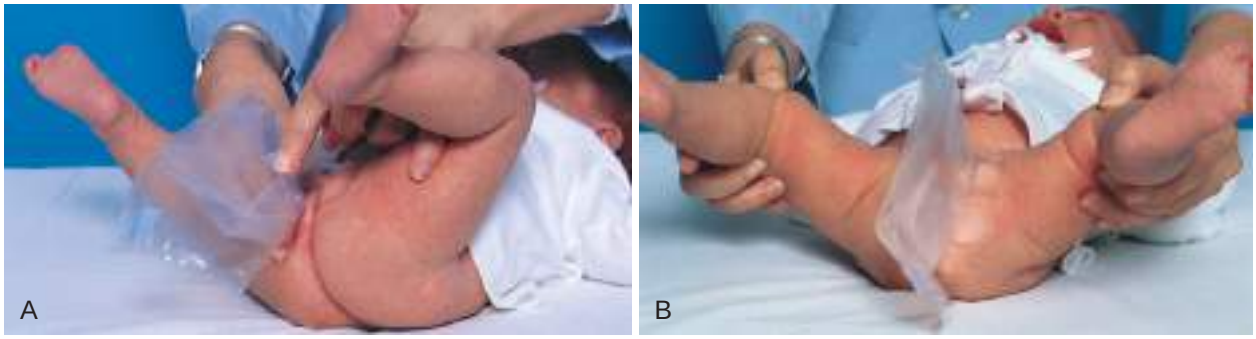

Fig. 44.9 Application of urine collection bag. **A:** On female infants, the adhesive portion is applied to the exposed and dried perineum first. **B:** The bag adheres firmly around the perineal area to prevent urine leakage.

child. When urine is collected for culture, the bag is removed immediately. See Nursing Skills on Evolve: Urine Specimen Collection Using a Collection Bag.

Clean-Catch Specimens. *Clean-catch specimens* traditionally refer to a urine sample obtained for culture after the urethral meatus is cleaned and the first few millilitres of urine are voided before the urine is collected (*midstream specimen*). In girls, the perineum is wiped with an antiseptic pad from front to back. In boys, the tip of the penis is cleansed.

Bladder Catheterization and Other Techniques. Bladder catheterization or suprapubic aspiration is employed when a specimen is urgently needed or when the child is unable to void or otherwise provide an adequate specimen. The CPS recommends that a diagnosis of urinary tract infection made with a bag urine specimen in young infants be confirmed with a suprapubic or urethral catheterization before treatment (Robinson et al., 2014/2020).

Preparation for catheterization includes instruction on pelvic muscle relaxation, but this can be difficult to achieve in this age group. Alternatively, nurses can wait until the child relaxes with crying. If the toddler, preschooler, or younger child can follow instructions, the child is taught to blow a pinwheel and to press the hips against the bed or procedure table during catheterization to relax the pelvic and periurethral muscles. For the older child or adolescent, the location and function of the pelvic muscles are described. The patient is then taught to contract and relax the pelvic muscles, and the relaxation procedure is repeated during catheter insertion. If the patient vigorously contracts the pelvic muscles when the catheter reaches the striated sphincter (proximal urethra in boys and midurethra in girls), catheter insertion is temporarily stopped. The catheter is neither removed nor advanced; instead, the child is helped to press the hips against the bed or examining table and relax the pelvic muscles. The catheter is then gently advanced into the bladder.

Children and adolescents may experience some discomfort and anxiety during this procedure. Assistance and gentle holding may be necessary, especially for the younger child. Most children prefer to have the parents remain with them during the procedure. The parent should be encouraged to talk softly and hold the child's hand as the catheter is inserted. Using distractions such as reading a book, singing a song, or playing with small toys may decrease the child's anxiety. Older children and adolescents may wish to listen to music with headphones or watch a video on an electronic device. Adolescents should be asked if they would like a parent to remain with them during the procedure. The decision should be made before the perineum is exposed and the sterile field is prepared.

Some parents may not understand the procedure of catheterization and may need some explanation to allay their concerns (see Cultural Awareness box: Bladder Catheterization).

CULTURAL AWARENESS

Bladder Catheterization

Parents may be upset when their child is catheterized. Aside from the trauma the child experiences, some parents may fear that the procedure affects the daughter's virginity. To correct this misconception, the family may benefit from a detailed explanation of the genitourinary anatomy, preferably with a model that shows the separate vaginal and urethral openings. The nurse can also indicate that catheterization has no effect on virginity.

Catheterization is a sterile procedure. If the catheter is to remain in place, an in-dwelling catheter is used. The supplies needed for this procedure include sterile gloves, sterile lubricant anaesthetic, an appropriately sized catheter, povidone-iodine (Betadine) swabs or an alternative cleansing agent and 10 × 10-cm gauze squares, a sterile drape, and a syringe with sterile water if a Foley catheter is used.

NURSING ALERT

Identify patients who have allergies to povidone-iodine or alternative cleanser or latex before using these items in catheterization.

Adolescent boys and children with a history of urethral surgery may be catheterized using a coudé-tipped catheter. The child with myelodysplasia or one who has been identified as being sensitive or allergic to latex is catheterized with a catheter manufactured from an alternative material. When an in-dwelling catheter is indicated for urinary drainage, a lubricious-coated or silicone catheter is selected, because these materials produce less irritation of the urethral mucosa than does a Silastic or latex catheter when the catheter is left in place for more than 72 hours.

SAFETY ALERT

Do not advance the catheter too far into the bladder. Knotting of catheters and tubes within the bladder has been reported. Feeding tubes should not be used for urinary catheterization because they are more flexible, long, and prone to knotting than commercially designed urinary catheters.

Suprapubic aspiration is mainly used when the bladder cannot be accessed through the urethra (such as with some congenital urological birth defects, such as a fused labia) or to reduce the risk of contamination that may be present when passing a catheter. With the advent of small catheters (5 and 6 French), the need for suprapubic aspiration has decreased. Access to the bladder via the urethra has a much higher success rate than suprapubic aspiration, where success depends on the practitioner's skill at assessing the location of the bladder and the amount of urine in the bladder.

Suprapubic aspiration involves aspirating bladder contents by inserting a 20- or 21-gauge needle in the midline approximately 1 cm above the symphysis pubis and directed vertically downward, performed by a physician or trained nurse practitioner. The nurse prepares the skin as for any needle insertion and the bladder should contain an adequate volume of urine. This can be assumed if the infant has not voided for at least 1 hour or the bladder can be palpated above the symphysis pubis. This technique is useful for obtaining sterile specimens from young infants, since the bladder is an abdominal organ and is easily accessed. Suprapubic aspiration is painful, thus pain management during the procedure is important (see Atraumatic Care box: Bladder Catheterization or Suprapubic Aspiration). Use of distraction and comfort measures through touch and voice, during and after the procedure, help to decrease the child's distress.

ATRAUMATIC CARE

Bladder Catheterization or Suprapubic Aspiration

- Use distraction to help the child relax (e.g., blowing bubbles, deep breathing, singing a song).
- Use lidocaine jelly to anaesthetize the area before insertion of the catheter. EMLA cream (a eutectic mix of lidocaine and prilocaine) or LMX cream (lidocaine) may lessen an infant's discomfort as the needle passes through the skin for suprapubic aspiration, but care should be taken that the site is thoroughly cleaned and prepped before the procedure.
- Children often become agitated at being restrained for either procedure. Use comfort measures through touch and voice, both during and after the procedure, to help reduce the child's distress.

Twenty-Four–Hour Collection. For a 24-hour collection, collection bags are required to collect specimens from infants and small children. Older children require special instruction about notifying someone when they need to void or have a bowel movement so that urine can be collected separately and not discarded. Some older school-age children and adolescents can take responsibility for collection of their own 24-hour specimens and can keep output records and transfer each voiding to the 24-hour collection container.

The collection period always starts and ends with an empty bladder. At the time the collection begins, the child is instructed to void and the specimen is discarded. All urine voided in the subsequent 24 hours is saved in a container with a preservative or is placed on ice. Twenty-four hours from the time the precollection specimen was discarded, the child is again instructed to void, the specimen is added to the container, and the entire collection is taken to the laboratory.

Infants and small children who are bagged for a 24-hour urine collection require a special collection bag. Frequent removal and replacement of adhesive collection devices can produce skin irritation. A thin coating of sealant, such as Skin-Prep, applied to the skin helps to protect it and aids adhesion, unless its use is contraindicated, such as in premature infants or children with irritated skin. Plastic collection bags with collection tubes attached are ideal when the container must be left in place for a time. These can be connected to a collecting device or emptied periodically by aspiration with a syringe. When such devices are not available, a regular bag with a feeding tube inserted through a puncture hole at the top of the bag serves as a satisfactory substitute. However, it is important to empty the bag as soon as the infant urinates to prevent leakage and loss of contents. An in-dwelling catheter may also be placed for the collection period.

Stool Specimens

Stool specimens are frequently collected from children to identify parasites and other organisms that cause diarrhea, to assess gastrointestinal function, and to check for occult (hidden) blood. Ideally, stool should be collected without contamination with urine, but in children wearing diapers this is difficult unless a urine bag is applied. Children who have achieved toilet independence should urinate first, flush the toilet, then defecate in the toilet, a bedpan (preferably one that is placed on the toilet to avoid embarrassment), or a commercial potty hat and cover with plastic wrap to collect stool.

Stool specimens should be large enough to obtain an ample sampling, not merely a fecal fragment. Specimens should be placed in an appropriate container, which is covered and labelled. If several specimens are needed, the containers are marked with the date and time and kept in a specimen refrigerator. The specimen should be handled carefully to prevent contamination.

Blood Specimens

Whether the specimen is collected by the nurse or others, the nurse is responsible for making certain that specimens, such as serial examinations and fasting specimens, are collected on time and that the proper equipment is available. The collecting, transporting, and storing of specimens can have a major impact on laboratory results.

Venous blood samples can be obtained by venipuncture or by aspiration from a peripheral or central access device. Withdrawing blood specimens through peripheral lock devices in small peripheral veins has met with varying degrees of success and can only be performed with certain blood work. Although it avoids an additional venipuncture for the child, attempting to aspirate blood from the peripheral lock may shorten the life of the device. When using an IV infusion site for specimen collection, the type of fluid being infused needs to be considered. For example, a specimen collected for glucose level would be inaccurate if removed from a catheter through which glucose-containing solution was being administered.

When venipuncture is performed, the needed specimens are collected quickly, and pressure is applied to the puncture site with dry gauze until bleeding stops. The arm should be extended, not flexed, while pressure is applied for a few minutes after venipuncture in the antecubital fossa to reduce bruising. The nurse then covers the site with an adhesive bandage. In young children adhesive bandages pose an aspiration hazard; thus it is good to avoid using them or remove the adhesive bandage as soon as the bleeding stops. Applying warm compresses to ecchymotic areas increases circulation, helps remove extravasated blood, and decreases pain.

! NURSING ALERT

To obtain a blood specimen from a peripheral lock when the infusion solution may interfere with tests results, first aspirate a quantity of blood equal to the volume of fluid in the catheter and discard; then aspirate the blood sample. However, ensure that this is in accordance with hospital policy.

For a blood culture, use the first sample of blood, since organisms are most likely to collect within the catheter itself.

! NURSING ALERT

On small or anemic children, keep track of the amount drawn over time. Frequent taking of blood specimens can rapidly decrease a child's blood volume. Coordinate blood samples and ask the laboratory to save as much blood as possible to reduce the frequency.

Arterial blood samples are sometimes needed for blood gas measurement, although noninvasive techniques, such as **transcutaneous oxygen monitoring** and pulse oximetry, are used frequently. Arterial samples may be obtained by arterial puncture using the radial, brachial, or femoral arteries, or from in-dwelling arterial catheters. Adequate circulation should be assessed before arterial puncture by observing capillary refill or performing the *Allen test*, a procedure used to assess the circulation of the radial, ulnar, or brachial arteries (see Chapter 33). Because unclotted blood is required, only heparinized collection tubes are used. In addition, no air bubbles should enter the tube, since they can alter the blood gas concentration. Crying, fear, and agitation also affect blood gas values; every effort should be made to comfort the child. The nurse should pack the sample in ice to reduce blood cell metabolism and should take it to the laboratory for immediate analysis.

Capillary blood samples are taken from older children by a finger stick. A common method for taking certain peripheral blood samples from infants younger than 6 months of age is with a heel stick. Before the blood sample is taken, the heel is warmed for 3 minutes (see Figure 26.14). The area is cleansed with alcohol, the infant's foot is firmly restrained with the free hand, and the heel is punctured with an automatic lancet device. An automatic device delivers a more precise puncture depth and is less painful than using a lance.

The most serious complications of infant heel puncture are necrotizing osteochondritis from lancet penetration of the underlying calcaneus bone, infection, and abscess of the heel. To avoid osteochondritis, the puncture should be no deeper than 2 mm and should be made at the outer aspect of the heel. The boundaries of the calcaneus can be marked by an imaginary line extending posteriorly from a point between the fourth and fifth toes and running parallel to the lateral aspect of the heel and another line extending posteriorly from the middle of the great toe and running parallel to the medial aspect of the heel (Figure 44.10). Repeated trauma to the walking surface of the heel can cause fibrosis and scarring that may interfere with ambulation.

Fig. 44.10 Puncture site (coloured stippled area) on sole of infant's foot.

No matter how or by whom the specimen is collected, children (even some older ones) fear the loss of their blood. This is particularly true for children whose condition requires frequent blood specimens. They mistakenly believe that blood removed from their body is a threat to their lives. Explaining to them that their body continuously produces blood can provide them a measure of reassurance. When the blood is drawn, a comment such as, "Just look how red it is. You're really making a lot of nice red blood," confirms this information and affords them an opportunity to express their concern. An adhesive bandage gives them added assurance that the vital fluids will not leak out through the puncture site.

Children also dislike the discomfort associated with venous, arterial, and capillary punctures. These procedures have been identified as those most frequently causing pain during hospitalization and an arterial puncture as being one of the most painful of all procedures experienced. Toddlers are most distressed by venipuncture. Consequently, nurses need to institute pain-reduction techniques to lessen the discomfort of these procedures (see Atraumatic Care box: Guidelines for Skin and Vessel Punctures).

ATRAUMATIC CARE

Guidelines for Skin and Vessel Punctures

For Reduction of Pain Associated With Heel, Finger, Venous, or Arterial Punctures

- Apply EMLA (a eutectic mixture of lidocaine and prilocaine) topically or an EMLA patch over the site if time permits (at least 60 minutes). LMX (lidocaine) cream also may be used and requires a shorter application time (30 minutes). To remove the transparent dressing atraumatically, grasp opposite sides of the film and pull the sides away from each other to stretch and loosen the film. After the film begins to loosen, grasp the other two sides of the film and pull. Use a vapocoolant spray or buffered lidocaine (injected intradermally near the vein with a 30-gauge needle) to numb the skin.
- Use nonpharmacological methods to lessen pain and anxiety, such as asking the child to take a deep breath when the needle is inserted and again when the needle is withdrawn, exhaling a large breath or blowing bubbles to "blow hurt away," or counting slowly and then faster and louder if pain is felt.
- Keep all equipment out of sight until used.
- Enlist parents' presence or assistance, if they wish to be present for the procedure.
- Use therapeutic holding; restrain the child *only as needed* to perform the procedure safely (see Therapeutic Holding and Restraints above).
- Allow the skin preparation to dry completely before penetrating the skin.
- Use the smallest-gauge needle (e.g., 25 gauge) that permits free flow of blood; a 27-gauge needle can be used for obtaining 1 to 1.5 mL blood and for prominent veins (needle length is only 13 mm).
- If possible, avoid putting an IV line in the dominant hand or the hand the child uses to suck the thumb.
- Use an automatic lancet device for precise puncture depth of the finger or heel; press the device lightly against the skin; avoid steadying the finger against a hard surface.
- Have a "two-try" only policy to reduce excessive insertion attempts—two operators each have two insertion attempts; if insertion is not successful after four punctures, consider alternative venous access, such as a peripherally inserted central catheter (PICC); have a policy for identifying children with difficult access and appropriate interventions, such as most experienced operator for the first attempt.

For Multiple Blood Samples

- Use an intermittent infusion device (saline lock) to collect additional samples; consider PICC lines early, not as a last resort.
- Coordinate care to allow several tests to be performed on one blood sample using micromethods of testing.
- Anticipate tests (e.g., medication levels, chemistry, immunoglobulin levels) and ask the laboratory to save blood for additional testing.

For Heel Lancing in Newborns

- Heel lancing has been shown to be more painful than venipuncture; consider venipuncture when the amount of blood from the heel would require much squeezing, such as genetic screening tests.
- Place diapered newborn against the mother's bare chest in skin-to-skin contact or have mother breastfeed 10 to 15 minutes before and during heel lance.
- During the procedure, allow newborn to suck a pacifier coated with a solution of 24% sucrose. Use this solution to coat the pacifier, or administer 2 mL to the tongue 2 minutes before the procedure (see Chapter 26, Evidence-Informed Practice box: Nonpharmacological Pain Relief for Newborns).

Respiratory Secretion Specimens

Collection of sputum or nasal discharge is sometimes required for diagnosis of respiratory infections, especially tuberculosis. Older children and adolescents are able to cough and supply sputum specimens when given proper directions. It must be made clear to them that a coughed specimen, not mucus that is cleared from the throat, is needed. It is helpful to demonstrate a deep cough. Infants and small children are unable to follow directions to cough and will swallow any sputum produced; thus gastric washings (**lavage**) may be used to collect a sputum specimen. Sometimes a satisfactory specimen can be obtained using a suction device such as a mucus trap if the catheter is inserted into the trachea and the cough reflex is elicited. A catheter inserted into the back of the throat is not sufficient. For children with a tracheostomy, a specimen is easily aspirated from the trachea or major bronchi by attaching a collecting device to the suction apparatus.

Nasopharyngeal aspiration is the preferred method over nasal washings to diagnose a respiratory infection. For nasal washings, the child is placed supine, and 1 to 3 mL sterile normal saline is instilled with a sterile syringe (without needle) into one nostril. The contents are aspirated using a small, sterile bulb syringe and are placed in a sterile container. Another method involves use of a syringe with 5 cm of 18- to 20-gauge

tubing. The saline is quickly instilled and then aspirated to recover the nasal specimen. To prevent additional discomfort, all of the equipment should be ready before beginning the procedure.

Other respiratory secretion collection methods include nasopharyngeal swabs to diagnose *Bordetella pertussis*, respiratory syncytial virus (RSV), Entero/Rhino virus, influenza, or COVID-19 and throat cultures. The nurse swabs both the tonsils and the posterior pharynx when obtaining a throat culture. The swab stick is inserted into the culture tube. Some culture kits require squeezing an ampoule to release the culture medium.

ADMINISTRATION OF MEDICATION

Determination of Medication Dosage

Because the administration of medication is a nursing responsibility, nurses need to have not only knowledge of drug action and patient responses, such as adverse effects and signs of toxicity, but also resources for estimating safe dosages for children. Unlike with adult medications, there are few standardized pediatric dosage ranges.

Factors related to growth and maturation significantly alter an individual's capacity to metabolize and excrete medications. Immaturity or defects in any of the important processes of absorption, distribution, biotransformation, or excretion can significantly alter the effects of a medication. Newborn and preterm infants with immature enzyme systems in the liver (where most medications are broken down and detoxified), lower plasma concentrations of protein for binding with medications, and immaturely functioning kidneys (where most medications are excreted) are particularly vulnerable to the harmful effects of medications. Beyond the newborn period, many medications are metabolized more rapidly by the liver, necessitating larger doses or more frequent administration. This is particularly important in pain control, since the dosage of analgesics may need to be increased or the interval between doses decreased.

Various formulas involving age, weight, and body surface area (BSA) have been devised to determine children's medication dosage. Children's dosages are most often expressed in units of measure per body weight (mg/kg). The most reliable method for determining children's dosages is to calculate the proportional amount of BSA to body weight. The ratio of BSA to weight varies inversely with length; the infant who is shorter and weighs less than an older child or adult has relatively more surface area than would be expected from the weight. The usual determination of BSA requires the use of the *West nomogram* (widely available on the Internet). See Nursing Skills on Evolve: Calculating Safe Dosages for Children.

Checking Dosage. Administering the correct dosage of a medication is a shared responsibility between the health care provider who prescribes the medication and the nurse who carries out that order. Children react with unexpected severity to some medications, and ill children are especially sensitive to them. When a dose is ordered that is outside the usual range or when there is some question about the preparation or the route of administration, the nurse should always check with the prescribing practitioner before proceeding with the administration, since the nurse is legally liable for any medication administered.

Even when it has been determined that the dosage is correct for a particular child, many medications are potentially hazardous or lethal. Most facilities have regulations requiring specified medications to be double-checked by another nurse before they are given to a child. Among medications that require such safeguards are antiarrhythmics, anticoagulants, chemotherapeutic agents, electrolytes, and insulin. Others frequently included are epinephrine, opioids, and sedatives. Even if this precaution is not mandatory, nurses are wise to observe it. Errors in decimal point placement may occur and result in a tenfold or greater dosage error.

Identification

Before the administration of any medication, the child must be correctly identified using two identifiers (name and medical record number or birth date). With an infant, young child, or a nonverbal child, a parent can identify the child, along with the identification bracelet. After verbal verification of the child's identity (by the parent, guardian, or child), the ID band should be verified using two identifiers. Bedside computers to scan the ID bracelet for electronic record updating may also be used.

Oral Administration

The oral route is preferred for giving medications to children because of the ease of administration. Most oral medications are dissolved or suspended in liquid preparations. Although some children are able to swallow or chew solid medications at an early age, solid preparations are not recommended for young children because of the danger of aspiration.

Most pediatric medications come in palatable and colourful preparations for ease of administration. Some have a slightly unpleasant aftertaste, but most children will swallow these liquids with little if any resistance. When the child dislikes the taste it can be camouflaged by various means. Most pediatric units have preparations available for this purpose (see Atraumatic Care box: Encouraging a Child's Acceptance of Oral Medication and Nursing Skills on Evolve: Administering Oral Medications).

It is important to discuss with the parents how they usually give medications successfully at home. A child will often accept medications more willingly from a parent.

ATRAUMATIC CARE

Encouraging a Child's Acceptance of Oral Medication

- Give the child a flavoured ice pop or small ice cube to suck to numb the tongue before giving the medication.
- Mix the medication with a small amount (about 5 mL) of sweet-tasting substance, such as honey (except in infants because of the risk of botulism), flavoured syrups, jam, fruit purees, sherbet, or ice cream; avoid essential food items, since the child may later refuse to eat them.
- Give a "chaser" of water, juice, soft drink, ice pop, or frozen juice bar after taking the medication.
- If nausea occurs, give a carbonated beverage poured over finely crushed ice before or immediately after taking the medication.
- When medication has an unpleasant taste, have the child pinch their nose and drink the medicine through a straw. Much of what we taste is associated with smell.
- Flavourings such as apple, banana, and bubble gum can be added at many pharmacies (e.g., FLAVORx) at nominal additional cost. An alternative is to have the pharmacist prepare the medication in a flavoured, chewable troche or lozenge.
- Infants will suck medicine from a needleless syringe or dropper in small increments (0.25 to 0.5 mL) at a time. Use a nipple or special pacifier with a reservoir for the medication.

Preparation. The devices available to measure medicines are not always sufficiently accurate for measuring the small amounts needed in pediatric nursing practice. The most accurate means for measuring small amounts of medication is the plastic disposable calibrated oral syringe. Not only does the syringe provide a reliable measure, but it also

serves as a convenient means for transporting and administering the medication. The medication can be placed directly into the child's mouth from the syringe.

Moulded plastic calibrated cups offer reasonable accuracy in measuring moderate doses of liquids; paper cups are likely to have irregular shapes or crumpled bottoms and retain considerable amounts of thick medication. Measures of less than 5 mL are impossible to determine accurately with a cup.

The teaspoon is an inaccurate measuring device and is subject to error. Teaspoons vary greatly in capacity, and different persons using the same spoon will pour different amounts. Therefore, a medication ordered in teaspoons should be measured in millilitres; the established standard is 5 mL per teaspoon. A convenient hollow-handled medicine spoon is available to accurately measure and administer the medication. Household measuring spoons can also be used when other devices are not available. The volume of a drop will vary according to the *viscosity* (thickness) of the liquid measured; viscous fluids produce much larger drops than thin liquids. Many medications are supplied with caps or droppers designed for measuring each specific preparation. These are accurate when used to measure that specific medication but are not reliable for measuring other liquids. Emptying dropper contents into a medicine cup invites additional error. Because some of the liquid clings to the sides of the cup, a significant amount of the medication can be lost.

Young children and some older children have difficulty swallowing tablets or pills. Because a number of medications are not available in pediatric preparations, the tablet needs to be crushed before it can be given to these children. Commercial devices are available, or simple methods can be employed for crushing tablets. Not all medications can be crushed (e.g., medication with an enteric or protective coating or formulated for slow release).

Children who must take oral medication for an extended period can be taught to swallow tablets or capsules. A child life specialist can assist with practising and training sessions including verbal instruction, demonstration, reinforcement for swallowing progressively larger candy or capsules, no attention for inappropriate behaviour, and gradual withdrawal of guidance once children can swallow their medication.

Because pediatric doses often require dividing adult preparations of medication, the nurse may be faced with the dilemma of accurate dosage. With tablets, only those that are scored can be halved or quartered accurately. If the medication is soluble, the tablet or contents of a capsule can be mixed in a small, premeasured amount of liquid and the appropriate portion given. For example, if half a dose is required, the tablet is dissolved in 5 mL water or flavoured liquid and 2.5 mL is given.

Administration. Although administering liquids to infants is relatively easy, the nurse must be careful to prevent aspiration. With the infant held in a semi-reclining position, the medication is placed in the mouth from a spoon, plastic cup, dropper, or syringe (without needle). The dropper or syringe is best placed along the side of the infant's tongue, and the liquid is administered slowly in small amounts, allowing the child to swallow between deposits.

Medicine cups can be used effectively for older infants who are able to drink from a cup. Because of the natural outward tongue thrust in infancy, medications may need to be retrieved from the lips or chin and refed. Techniques such as allowing the infant to suck medication that has been placed in an empty nipple or inserting the syringe or dropper into the side of the mouth, parallel to the nipple, while the infant breastfeeds are other convenient methods for giving liquid medications to infants. Medication should not be added to the infant's formula feeding because the child may subsequently refuse the formula. Plastic covers on the ends of syringes should be disposed of, as these covers are small enough to be aspirated by young children.

The young child who refuses to take medication or resists consistently despite explanation and encouragement may require mild physical restraint. If so, it should be carried out quickly and carefully. Every effort should be made to determine why the child resists, and the reasons for the coercion need to be explained to the child in such a way that the child will know that it is being carried out for their well-being and not as a form of punishment. There is always a risk in using even mild forceful techniques. A crying child can aspirate a medication, particularly when lying on their back. If the nurse holds the child in the lap with the child's right arm behind the nurse, the left hand firmly grasped by the nurse's left hand, and the head securely restrained between the nurse's arm and body, the medication can be slowly poured into the child's mouth (Figure 44.11).

Intramuscular Administration

Selecting the Syringe and Needle. The volume of medication prescribed for small children and the small amount of tissue available for intramuscular (IM) injection require that a syringe be selected that can measure small amounts of solution. For volumes of less than 1 mL, the tuberculin syringe, calibrated in $^{1}/_{100}$-mL increments, is appropriate. Minute doses may require the use of a 0.5-mL, low-dose syringe. These syringes, along with specially constructed needles, minimize the possibility of inadvertently administering incorrect amounts of a medication because of dead space, which allows fluid to remain in the syringe and needle after the plunger is pushed completely forward. A minimum of 0.2 mL of the solution remains in a standard needle hub; thus when very small amounts of two medications are combined in the syringe, such as mixtures of insulin, the ratio of the two medications can be altered significantly. Measures that minimize the effect of dead space are as follows:

- When two medications are combined in the syringe, always draw them up in the same order to maintain a consistent ratio between the drugs.

Fig. 44.11 The nurse partially restrains the child for easy and comfortable administration of oral medication.

- Use the same brand of syringe (dead space may vary between brands).
- Use one-piece syringe units (needle permanently attached to the syringe).

Dead space is also an important factor to consider when injecting medication, since flushing the syringe with an air bubble adds an additional amount of medication to the prescribed dose. This can be hazardous when very small amounts of a medication are given. Consequently, flushing is not advisable, especially when less than 1 mL of medication is given. Syringes are calibrated to deliver a prescribed medication dose, and the amount of medication left in the hub and needle is not part of the syringe barrel calibrations. Certain medications such as iron dextran and diphtheria and tetanus toxoid may cause irritation when tracked into the subcutaneous tissue. The Z-track method is recommended for use in infants and children rather than an air bubble. Changing the needle after withdrawing the fluid from the vial is another technique to minimize tracking.

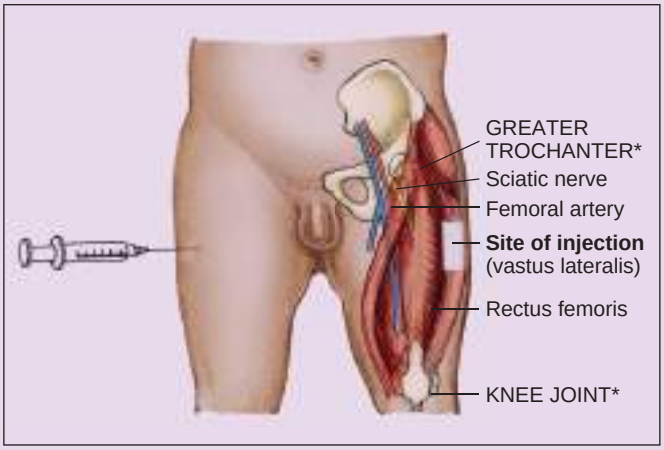
The needle length must be sufficient to penetrate the subcutaneous tissue and deposit the medication into the body of the muscle. The needle gauge should be as small as possible to deliver fluid safely. Smaller-diameter (25- to 30-gauge) needles cause the least discomfort, but larger diameters are needed for viscous medication and prevention of accidental bending of longer needles.

Determining the Site. Factors to consider when selecting a site for an IM injection on an infant or child include the following:

- The amount and character of the medication to be injected
- The amount and general condition of the muscle mass
- The frequency or number of injections to be given during the course of treatment
- The type of medication being given
- Factors that may impede access to or cause contamination of the site
- The child's ability to assume the required position safely

Older children and adolescents usually pose few challenges in selecting a suitable site for IM injections, but infants, with their small and underdeveloped muscles, have fewer available sites. It is sometimes difficult to assess the amount of fluid that can be safely injected into a single site. Usually 1 mL is the maximum volume that should be administered in a single site to older infants and small children. The muscles of small infants may not tolerate more than 0.5 mL. As the child approaches adult size, volumes approaching those given to adults may be used. However, the larger the amount of solution, the larger the muscle must be into which it is injected.

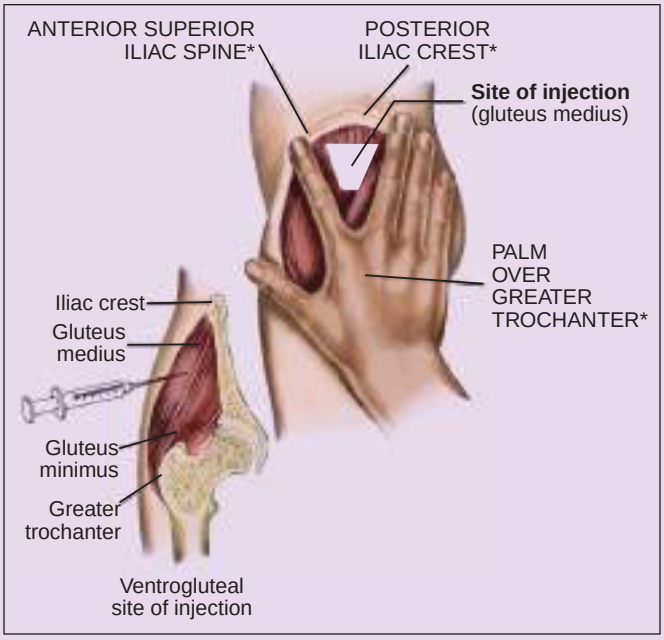
Injections must be placed in muscles large enough to accommodate the medication while avoiding major nerves and blood vessels. The preferred site for infants is the vastus lateralis (the rectus femoris is not an acceptable site). However, the ventrogluteal site is also recommended as it is relatively free of major nerves and blood vessels. The ventrogluteal site is a relatively large muscle with less subcutaneous tissue than the dorsal site, is a well-defined landmark for safe site location, is less painful than the vastus lateralis, and is easily accessible in several positions. Distraction and prevention of unexpected movement may be more easily achieved by placing the child supine on a parent's lap for using a ventrogluteal site.

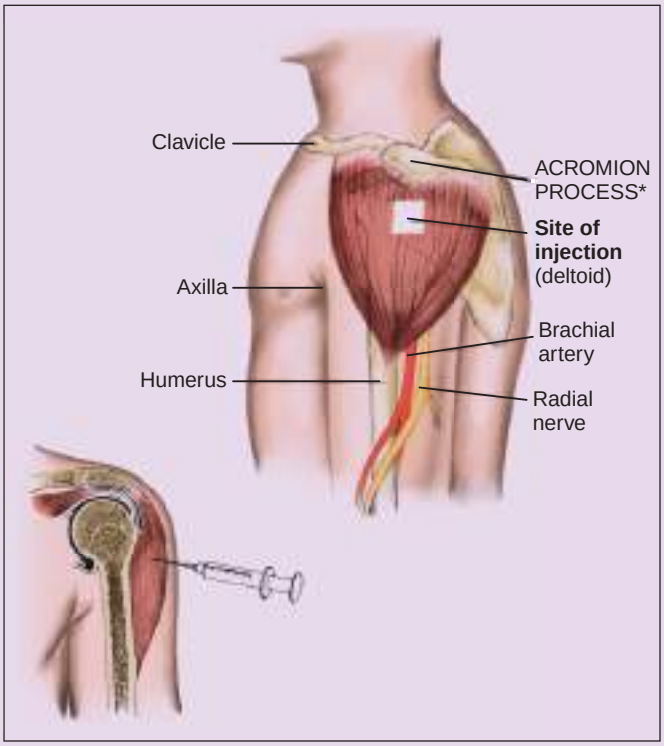


The deltoid muscle, a small muscle near the axillary and radial nerves, can be used for small volumes of fluid in children as young as 18 months of age. Its advantages are less pain and fewer adverse effects from the injectate (as observed with immunizations) than with the vastus lateralis.

Table 44.4 summarizes the three major injection sites and illustrates the location of the preferred IM injection sites for children.

Administration. Although injections executed with care seldom cause trauma to the child, there have been reports of serious disability related to IM injections in children. Repeated use of a single site has been associated with fibrosis of the muscle with subsequent muscle contracture. Injections close to large nerves, such as the sciatic nerve, have been responsible for permanent disability, especially when potentially neurotoxic medications are administered. When such medications are injected, great care must be used in locating the correct site. The straighter the path of needle insertion at 90-degree angle, the less displacement and shear to tissue, and possibly less discomfort.





A potential hazard with medication in glass ampoules is the presence of glass particles in the ampoule after the container is broken. When the medication is withdrawn into the syringe, the glass particles may also be withdrawn and subsequently injected into the patient. As a precaution, medication from glass ampoules should be drawn up only through a needle with a filter.

TABLE 44.4 Intramuscular Injection Sites in Children

Site	Discussion
Vastus Lateralis	
	*Location** Palpate to find greater trochanter and knee joints; divide vertical distance between these two landmarks into thirds; inject into middle third. *Needle Insertion and Size* Insert needle perpendicular to knee in infants and young children or perpendicular to thigh or slightly angled toward anterior thigh. 22–25 gauge, 1.6–2.5 cm (⅝–1 inch)† *Advantages* Large, well-developed muscle that can tolerate larger quantities of fluid (0.5 mL [infant] to 2.0 mL [child]) Easily accessible if child is supine, side lying, or sitting *Disadvantages* Thrombosis of femoral artery from injection in midthigh area Sciatic nerve damage from long needle injected posteriorly and medially into small extremity More painful than deltoid or gluteal sites

Continued

TABLE 44.4 Intramuscular Injection Sites in Children—cont'd

Site	Discussion
Ventrogluteal 	*Location** Palpate to locate greater trochanter, anterior superior iliac tubercle (found by flexing thigh at hip and measuring up to 1–2 cm above crease formed in groin), and posterior iliac crest; place palm of hand over greater trochanter, index finger over anterior superior iliac tubercle, and middle finger along crest of ileum posteriorly as far as possible; inject into centre of V formed by fingers. *Needle Insertion and Size* Insert needle perpendicular to site but angled slightly toward iliac crest. 22–25 gauge, 1.3–2.5 cm (½–1 inch)† *Advantages* Free of important nerves and vascular structures Easily identified by prominent bony landmarks Thinner layer of subcutaneous tissue than in dorsogluteal site, thus reducing chance of depositing medication subcutaneously rather than intramuscularly Can accommodate larger quantities of fluid (0.5 mL [infant] to 2.0 mL [child]) Easily accessible if child is supine, prone, or side lying Less painful than vastus lateralis
Deltoid 	*Location** Locate acromion process; inject only into upper third of muscle that begins about two fingerbreadths below acromion. *Needle Insertion and Size* Insert needle perpendicular to site but angled slightly toward shoulder. 22–25 gauge, 1.3–2.5 cm (½–1 inch) *Advantages* Faster absorption rates than gluteal sites Easily accessible with minimal removal of clothing Less pain and fewer local adverse effects from vaccines than with vastus lateralis *Disadvantages* Small muscle mass; can accommodate only limited amounts of medication (0.5–1.0 mL) Small margins of safety with possible damage to radial nerve and axillary nerve (not shown; lies under deltoid at head of humerus)

*Locations are indicated by asterisks on illustration.
†A 2.5-cm (1-inch) needle is needed for adequate muscle penetration in infants 4 months old and possibly in infants as young as 2 months.

Most children are unpredictable in their movements and few can remain still when receiving an injection. Even children who appear to be relaxed and constrained can start moving under the stress of the procedure. It is advisable to have someone available to help hold the child if needed. Because children often jerk or pull away unexpectedly, the nurse should carry an extra needle to exchange for a contaminated one so that the delay is minimal. The child, even a small one, should be told that they are receiving an injection (preferably using a phrase such as "putting medicine under the skin"), and then the procedure carried out as quickly and skillfully as possible to avoid

prolonging the stressful experience. Invasive procedures such as injections are especially anxiety provoking in young children. Because injections are painful, the nurse should employ excellent injection technique and effective pain-reduction measures to reduce discomfort (see Guidelines box: Intramuscular Administration of Medication).

GUIDELINES

Intramuscular Administration of Medication

Use safety precautions in administering medication (e.g., check two different identifications for a child).

Apply an eutectic mix of lidocaine and prilocaine (EMLA) topically over site if time permits or LMX cream (lidocaine) topically over site if time permits (see Pain Management, Chapter 34).

Prepare medication:

- Select needle and syringe appropriate to the following: (1) amount of fluid to be administered (syringe size), (2) viscosity of fluid to be administered (needle gauge), and (3) amount of tissue to be penetrated (needle length).
- Maximum volume to be administered in a single site is 1 mL for older infants and small children.
- Have medication at room temperature before injection.
- If withdrawing medication from an ampoule, use a needle equipped with a filter that removes glass particles; then use a new, nonfilter needle for injection.

Determine site of injection (see Table 44.4), making certain that muscle is large enough to accommodate the volume and type of medication.

- Acceptable sites for infants and small or debilitated children are the vastus lateralis muscle or the ventrogluteal muscle.
- The dorsogluteal muscle should not be used to give an injection to any child unless there are no other alternatives.

Obtain sufficient help in restraining the child.

Explain briefly what is to be done and, if appropriate, what the child can do to help.

Expose injection area for unobstructed view of landmarks.

Select a site where skin is free of irritation and danger of infection; palpate for and avoid sensitive or hardened areas.

With multiple injections, rotate sites.

Place child in a lying or sitting position; the child is not allowed to stand because (1) landmarks are more difficult to assess, (2) restraint is more difficult, and (3) the child may faint and fall.

- **Ventrogluteal**—Place child on their side with upper leg flexed and placed in front of lower leg.
- **Vastus lateralis**—Child can be supine, lying on their side, or sitting.

Use a new, sharp needle with the smallest diameter that permits free flow of the medication.

Spread skin with thumb and index finger to displace subcutaneous tissue and grasp muscle deeply on each side. Grasp muscle firmly between the thumb and fingers to isolate and stabilize muscle for deposition of medication in its deepest part.

Allow skin preparation to dry completely before skin is penetrated.

Decrease perception of pain.

- Distract child with conversation.
- Give child something on which to concentrate, such as squeezing a hand or side rail, pinching their own nose, humming, counting, or yelling "Ouch!"
- Spray vapocoolant (e.g., ethyl chloride or fluorimethane) on site 10 to 15 seconds before injection or place a cold compress or wrapped ice cube on site about a minute before injection, or apply cold to contralateral site.
- Have the child hold a small adhesive bandage and place it on puncture site after IM injection is given.

Insert needle quickly, using a dartlike motion at a 90-degree angle unless contraindicated.

- Use new needle, not one that has pierced the rubber stopper on vial.

Avoid tracking any medication through superficial tissues:

- Replace needle after withdrawing medication, or wipe medication from needle with sterile gauze.
- Use the Z-track or air-bubble technique as indicated.
- Avoid depressing plunger during insertion of the needle.

Aspiration is not recommended, but if blood appears in the syringe, remove the needle and dispose of the medication and syringe properly. Prepare another dose of medication for injection.

Remove needle quickly; hold gauze sponge firmly against skin near needle when removing it to avoid pulling on tissue.

Apply firm pressure to the site after injection; massage site to hasten absorption unless contraindicated, as with irritating medications.

Place a small adhesive bandage on puncture site; with young children decorate it by drawing a smiling face or other symbol of acceptance.

Hold and cuddle young child and encourage parents to comfort the child; praise an older child.

Allow expression of feelings.

Discard syringe and uncapped, uncut needle in puncture-resistant container located near site of use.

Document time of injection, medication, dose, and injection site.

Small infants offer little resistance to injections. Although they squirm and may be difficult to hold in position, they can usually be restrained without assistance. The body of a larger infant can be securely held between the nurse's arm and body.

If the medication is given around the clock, the nurse must wake the child. Although it may seem easier to surprise the sleeping child and do it quickly, this can cause the child to fear going back to sleep. When awakened first, children know that nothing will be done unless they are forewarned.

A needleless injection system delivers IM or subcutaneous injections without the use of a needle and eliminates the risk of accidental needle puncture. This needle-free injection system involves a carbon dioxide cartridge that provides the power to deliver the medication through the skin. Although it is not painless, it may reduce pain and also the anxiety of seeing the needle.

Subcutaneous and Intradermal Administration

Subcutaneous and intradermal injections are frequently administered to children; the technique differs little from the method used with adults. Examples of subcutaneous injections include insulin, hormone replacement, allergy desensitization, and some vaccines. Tuberculin testing, local anaesthesia, and allergy testing are examples of frequently administered intradermal injections.

Techniques to minimize the pain associated with these injections include changing the needle if it pierced a rubber stopper on a vial, using 26- to 30-gauge needles (only to inject the solution), and injecting small volumes (up to 0.5 mL). The angle of the needle for the subcutaneous injection is typically 90 degrees. In children with little subcutaneous tissue, some practitioners insert the needle at a 45-degree angle. However, the benefit of using the 45-degree angle rather than the 90-degree angle remains unsubstantiated by research. For intradermal injections the angle is 15 degrees with bevel up.

Although subcutaneous injections can be given anywhere there is subcutaneous tissue, common sites include the centre third of the lateral aspect of the upper arm, the abdomen, and the centre third of the anterior thigh. When giving an intradermal injection into the volar

surface of the forearm, the nurse should avoid the medial side of the arm, where the skin is more sensitive.

! NURSING ALERT

Families often need to learn injection techniques to administer medications, such as insulin, at home. Begin teaching as early as possible to allow the family the maximum amount of practice time.

Intravenous Administration

The IV route for administering medications is frequently used in pediatric therapy. It is important for nurses to follow their institution's individual nursing care protocols when delivering IV line care. For some medications it is the only effective route. This method is used for giving medications to children who:

- Have poor absorption as a result of diarrhea, dehydration, or peripheral vascular collapse
- Need a high serum concentration of a medication
- Have resistant infections that require parenteral medication over an extended time
- Need continuous pain relief
- Require emergency treatment

Several factors need to be considered in relation to IV medication. When a medication is administered intravenously, the effect is almost instantaneous and further control is limited. Most medications for IV administration require a specified minimum dilution, rate of flow, or both, and many are highly irritating or toxic to tissues outside the vascular system. In addition to the precautions and nursing observations related to IV therapy, factors to consider when preparing and administering medications to infants and children by the IV route include the following:

- Amount of medication to be administered
- Minimum dilution of medication and whether child is fluid restricted
- Type of solution in which medication can be diluted
- Length of time over which medication can be safely administered
- Rate limitations of child, vascular system, and infusion equipment
- Time that this or another medication is to be administered
- Compatibility of all medications that child is receiving intravenously
- Compatibility with infusion fluids

Before any IV infusion, the site of insertion needs to be checked for patency. Medications are never administered with blood products. Only one antibiotic should be administered at a time. Extra fluids needed to administer IV medications can be problematic for infants and fluid-restricted children. Syringe pumps are often used to deliver IV medication because they minimize fluid requirements and more precisely deliver small volumes of medication compared with large-volume infusion pumps. Regardless of the technique, the nurse must know the minimum dilutions for safe administration of IV medications to infants and children.

Peripheral Intermittent Infusion Device. The *peripheral lock*, also known as an *intermittent infusion device* or *saline or heparin lock*, is an alternative to a keep-open infusion when extended access to a vein is required without the need for continuous fluid. It is most frequently employed for intermittent infusion of medication into a peripheral venous route. A short, flexible catheter is used as the lock device, and a site is selected where there will be minimal movement, such as the forearm. The catheter is inserted and secured in the same manner as for any IV infusion device, but the hub is occluded with a stopper or injection cap.

The type of device used may vary, and the care and use of the peripheral lock are carried out according to the protocol of the institution or unit. However, the general concept is the same. The catheter remains in place and is flushed with saline after infusion of the medication.

Central Venous Access Device. Patients with chronic illnesses who require repeated blood sampling or medications, long-term chemotherapy, or frequent hyperalimentation or antibiotic therapy are best managed with a central venous catheter (CVC). These children may be discharged with a CVC in place to continue receiving medications outside the hospital and need to be referred to a home care agency.

Central venous access devices (CVADs) comprise different types of catheters that are inserted into and positioned within a vein in the body. Factors that can influence the type of CVAD include the reason for placement of the catheter (diagnosis), length of therapy, risk to the patient in placement of the catheter, and availability of resources to help the family maintain the catheter.

Short-term or nontunnelled catheters are used in acute care, emergency, and critical care units. These catheters are made of polyurethane and are placed in large veins such as the subclavian, femoral, or jugular vein. Insertion is by surgical incision or large percutaneous threading. A chest X-ray film should be taken to verify placement of the catheter tip before administration of fluids or medications.

Peripherally inserted central catheters (PICCs) can be used for short-term to moderate-length therapy. These catheters consist of silicone or polymer material and are placed by specially trained nurses, physicians, or interventional radiologists. The most common insertion site is above the antecubital area using the median, cephalic, or basilic vein. The catheter is threaded either with or without a guidewire into the superior vena cava. PICCs can be trimmed before insertion, and the decision can be made to insert the catheter midline, which is considered between the insertion site and the axilla. If the catheter is threaded midline, total **parenteral nutrition (TPN)** or any medication known to irritate a peripheral vein (e.g., chemotherapy medications) should not be administered. The high concentration of glucose in TPN makes it irritating to the vessel; it should be infused through a central catheter.

The decision to insert a PICC needs to be made before several attempts at IV insertion are made. When the antecubital veins have been punctured repeatedly, they are not considered candidates for this type of catheter. Because it is the least costly and has less chance of complications than other CVADs, it is an excellent choice for many pediatric patients.

! NURSING ALERT

Most PICC lines are not sutured into place, so care is needed when changing the dressing. Review the institution policy and procedure on dressing management. If a central venous catheter is removed accidently, apply pressure to the entry site to the vein, not the exit site on the skin.

Long-term central CVADs include tunnelled catheters and implanted infusion ports (implanted venous access devices) (Figure 44.12). They may have single, double, or triple lumens. Multilumen (several lumens) catheters allow more than one therapy to be administered at the same time. Reasons to use multilumen catheters include repeated blood sampling, TPN, administration of blood products or infusion of large quantities or concentrations of fluids, administration of incompatible medications or fluids at the same time (through different lumens), and central venous pressure monitoring.

With any of the CVCs, medication is easily instilled through the injection port. Maintenance of the catheter includes dressing changes,

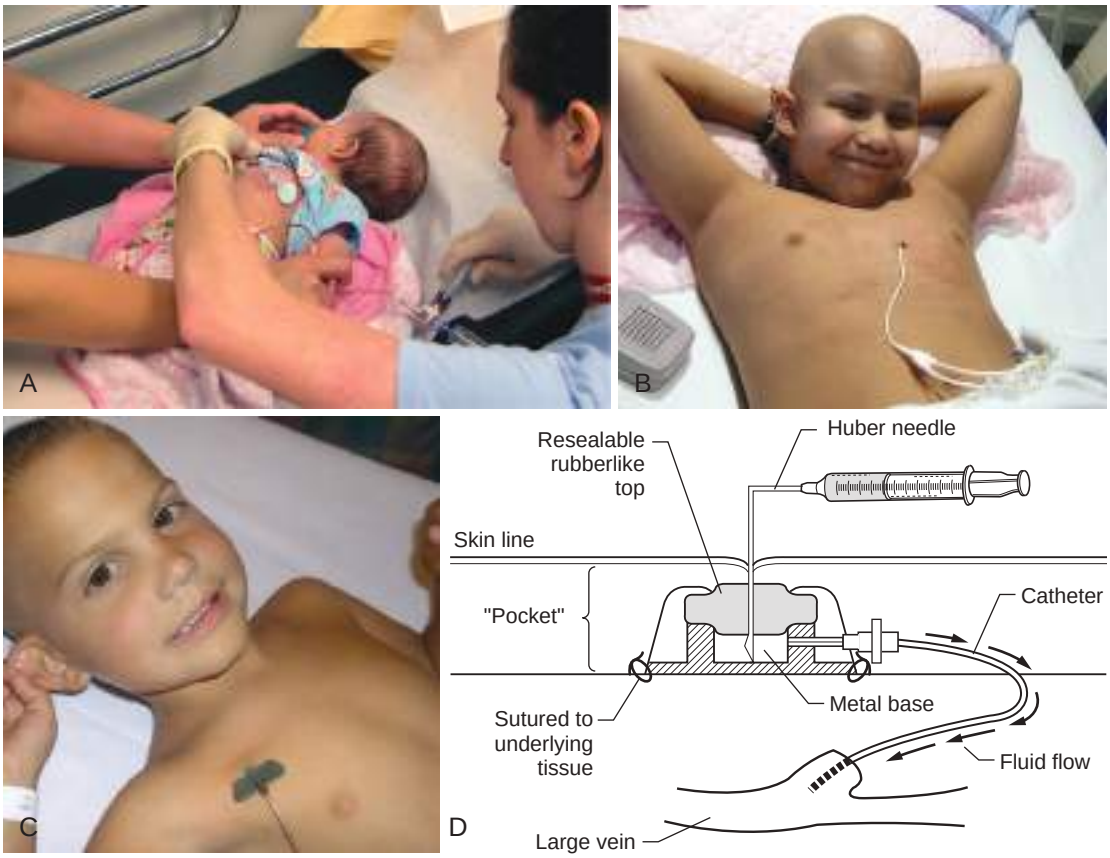


Fig. 44.12 Venous access devices. **A:** Blood being drawn from a central venous catheter. **B:** Child with external central venous catheter. **C:** Child with implanted port with Huber needle in place. **D:** Side view of implanted port.

flushing to maintain patency, and prevention of occlusion or dislodgment.

! NURSING ALERT

When working with tunnelled catheters, PICCs, and peripheral intravenous lines (PIVs), avoid using scissors around the tubing or dressing. Removal is best accomplished using fingers and much patience. In the event that a tunnelled catheter is cut, use a padded clamp to clamp the catheter proximal to the exit site to avoid blood loss. Emergency equipment in case of dislodgement or breakage should be with patients at all times. Repair kits are available, which may save the catheter and avoid surgery to replace a cut catheter.

With the implanted device the port must be palpated for placement and stabilized, the overlying skin cleansed, and only special noncoring Huber needles used to pierce the port's diaphragm on the top or side, depending on the style. To avoid repeated skin punctures, a special infusion set with a Huber needle and extension tubing with a Luer connection can be used (see Figure 44.12, *C*). With this attached, the injection procedure is the same as for an intermittent infusion device or a CVC. To prevent infection, meticulous aseptic technique must be used any time the devices are entered, including instillation of heparin or saline to prevent clotting. There should be a protocol stating that the Huber needle needs to be changed at established intervals, usually every 5 to 7 days.

The type of flushing solution that is used to maintain patency of the IV lines has been under review. A heparin or saline flush is used to maintain line patency. Cochrane reviewers have concluded that there is no evidence that one method is better than the other as a locking method (López-Briz et al., 2018), although Upadhyay et al. (2015) found that heparin increased the functional duration of peripheral IV catheters.

The children and parents need to be taught the procedure for care of the CVAD. This teaching is provided before discharge from the hospital, including preparation and injection of the prescribed medication, the flush, and dressing changes. A protective device may be recommended for some active children to prevent accidental dislodgment of the needle. Many children take responsibility for preparing and administering medications. Both verbal and written step-by-step instructions should be provided.

Infection and catheter occlusion are two of the most common complications of CVCs. They require treatment with antibiotics for infection and a fibrinolytic agent, such as alteplase, for clots (Anderson et al., 2013). Uncapping can be prevented by taping the cap securely to the catheter and the clamped line to the dressing. Leaks can be prevented by using a smooth-edged clamp only. The parents are cautioned to keep scissors away from the child to prevent accidental cutting of the catheter. If the catheter leaks, the parents are instructed to tape it above the leak and then clamp the catheter at the taped site. The child should be taken to their health care provider as soon as possible to prevent infection or clotting after a catheter leak.

Intraosseous Infusion

Situations may occur in which rapid establishment of systemic access is vital, and venous access may be hampered by peripheral circulatory collapse, hypovolemic shock (secondary to vomiting or diarrhea, burns, or trauma), cardiopulmonary arrest, or other conditions. It is

recommended that intraosseous access be obtained if venous access cannot be readily achieved in a pediatric resuscitation. Intraosseous infusion provides a rapid, safe, and lifesaving alternate route for administration of fluids and medications until intravascular access can be obtained, especially in children who are 6 years of age and younger.

A large-bore needle, such as a bone marrow aspiration needle (e.g., Jamshidi) or an intraosseous needle (e.g., Cook), is inserted into the medullary cavity of a long bone, most often the proximal tibia. This procedure is painful, therefore appropriate and sufficient analgesia should be administered prior to the procedure. Local anaesthesia should be used for semiconscious patients.

A battery-powered (EZ-IO) intraosseous needle driver is also available for use in prehospital and hospital settings and has a high rate of success in pediatric resuscitation and stabilization (Greene et al., 2012).

Once the bone marrow needle is in place, the needle should stand alone and feel secure. Tape and gauze are used to secure the needle to the leg. Gauze should be built up around the needle to provide support and prevent trauma or dislodgment. Medications may be pushed and fluids delivered via an infusion pump. The dependent tissue needs to be closely observed for swelling because extravasation may be hidden under the leg, and compartment syndrome may result. Other complications, although rare, include fractures, skin necrosis, osteomyelitis, and cellulitis (Tobias & Ross, 2010). The intraosseous line may be discontinued after IV access has been achieved.

Nasogastric, Orogastric, or Gastrostomy Administration

When a child has an in-dwelling feeding tube or a gastrostomy, oral medications may be given via that route. Advantages of this method include the ability to administer oral medications around the clock without disturbing the child and ensuring that the child actually takes the medication. A disadvantage of this method is the risk of occluding or clogging the tube, especially when giving viscous solutions through small-bore feeding tubes. The most important preventive measure is adequate flushing after the medication is instilled (see Guidelines box: Nasogastric, Orogastric, or Gastrostomy Medication Administration in Children).

GUIDELINES

Nasogastric, Orogastric, or Gastrostomy Medication Administration in Children

Use elixir or suspension (rather than tablet) preparations of medication whenever possible.

Dilute viscous medication or syrup with a small amount of water, if possible.

If administering tablets, crush tablet to a fine powder and dissolve medication in a small amount of warm water.

Never crush enteric-coated or sustained-release tablets or capsules.

Avoid oily medications because they tend to cling to the side of the tube.

Do not mix medication with enteral formula unless fluid is restricted. If adding a medication:

- Check with the pharmacist for compatibility.
- Shake formula well and observe for any physical reaction (e.g., separation, precipitation).
- Label formula container with name of medication, dosage, date, and time infusion started.

Check for correct placement of nasogastric (NG) or orogastric (OG) tube (see Gavage Feeding: Procedure later in the chapter).

Attach syringe (with adaptable tip but without plunger) to tube.

Pour medication into syringe.

Unclamp tube and allow medication to flow by gravity.

Adjust height of container to achieve desired flow rate (e.g., increase height for faster flow).

As soon as syringe is empty, pour in water to flush tubing.

- The amount of water depends on the length and gauge of tubing.
- Determine amount before administering any medication by using a syringe to fill completely an unused nasogastric or orogastric tube with water. The amount of flush solution is usually 1.5 times this volume.
- With certain medication preparations (e.g., suspensions), more fluid may be needed. If administering more than one medication at the same time, flush tube between each medication with clear water.

Clamp tube after flushing unless it is left open.

Rectal Administration

The rectal route for administration is less reliable but is sometimes used when the oral route is difficult or contraindicated. It is also used when oral preparations are unsuitable to control vomiting. Some of the medications available in suppository form are acetaminophen, sedatives, and antiemetics. The difficulty in using the rectal route is that, unless the rectum is empty at the time of insertion, the absorption of the medication may be delayed, diminished, or prevented by the presence of feces. Sometimes the medication is later evacuated, securely surrounded by stool.

To administer a medication rectally, the wrapper on the suppository is removed and the suppository lubricated with warm water (water-soluble jelly may affect medication absorption). Rectal suppositories are inserted with the apex (pointed end) foremost. Reverse contractions or the pressure gradient of the anal canal may help the suppository slip higher into the canal. Using a glove, the nurse inserts the suppository quickly but gently into the rectum, beyond both of the rectal sphincters. The buttocks are then held together firmly to relieve pressure on the anal sphincter until the urge to expel the suppository has passed—5 to 10 minutes. Sometimes the amount of medication ordered is less than the dosage available. The irregular shape of most suppositories makes the process of dividing them into a desired dose difficult if not dangerous. If the suppository must be halved, it should be cut lengthwise. However, there is no guarantee that the medication is evenly dispersed throughout the petrolatum base.

If medication is administered via a retention enema, the same procedure is used. The medication should be diluted in the smallest amount of solution possible to minimize the likelihood of the child expelling it.

Optic, Otic, and Nasal Administration

There are few differences between administering eye, ear, and nose medication to children and giving them to adults. The major difficulty is in gaining children's assistance with the procedure. Older children need only explanation and direction. Although the administration of optic, otic, and nasal medication is not painful, these medications can cause unpleasant sensations that can be reduced with various techniques.

! NURSING ALERT

The following steps help reduce unpleasant sensations when administering medications:

Eye—Apply finger pressure to the lacrimal punctum at the inner aspect of the eyelid for 1 minute to prevent drainage of medication to the nasopharynx and the unpleasant "tasting" of the medication.

Ear—Allow medications stored in the refrigerator to warm to room temperature before instillation.

Nose—Position the child with their head hyperextended to prevent strangling sensations caused by medication trickling into the throat, rather than up into the nasal passages.

To instill eye medication, the nurse places the child supine or sitting with the head extended, and asks the child to look up. One hand is used to pull the lower lid downward; the hand that holds the dropper rests on the head so that it may move synchronously with the child's head, thus reducing the possibility of trauma to a struggling child or of dropping medication on the child's face (Figure 44.13). As the lower lid is pulled down, a small conjunctival sac is formed; the solution or ointment is applied to this area, never directly on the eyeball. Another effective technique is to pull the lower lid down and out to form a cup effect, into which the medication is dropped. The nurse gently closes the lids to prevent expression of the medication, and asks the child to look in all directions to enhance even distribution of the preparation. Excess medication from the inner canthus is then wiped outward to prevent contamination to the contralateral eye.

Instilling eye drops in infants can be difficult, since they often clench the lids tightly closed. One approach is to place the drops in the nasal corner where the lids meet. The medication pools in this area, and when the infant opens the lids, the medication flows onto the conjunctiva. For young children, playing a game can be helpful, such as instructing the child to keep their eyes closed until the count of three and then open them, at which time the drops are quickly instilled. Ointment can be applied by gently pulling down the lower lid and placing the ointment in the lower conjunctival sac. If both eye ointment and drops are ordered, the nurse gives the drops first, waits 3 minutes, and then applies the ointment to allow each medication to work. When possible, eye ointments should be administered before bedtime or naptime, since the child's vision will be blurred temporarily.

Ear drops are instilled with the child in the prone or supine position and the head turned to the appropriate side. For children younger than 3 years of age, the external auditory canal is straightened by gently pulling the pinna downward and straight back. The pinna is pulled upward and back in children older than 3 years of age (see Figure 33.19, *B*). To place the drops deep in the ear canal without contaminating the tip of the dropper, a disposable ear speculum is placed in the canal and the drops administered through the speculum. After instillation, the child should remain lying on the unaffected side for a few minutes. Gentle massage of the area immediately anterior to the ear facilitates the entry of drops into the ear canal. The use of cotton balls prevents medication from flowing out of the external canal. However, the cotton balls should be loose enough to allow any discharge to exit from the ear. Premoistening the cotton with a few drops of medication prevents the wicking action from absorbing the medication instilled in the ear.

Nose drops are instilled in the same manner as in an adult patient. First, mucus is removed from the nose with a clean tissue or washcloth. Unpleasant sensations associated with medicated nose drops can be minimized when care is taken to position the child with the head extended well over the edge of the bed or a pillow (Figure 44.14). Depending on the infant's size, the infant can be positioned in the football hold (see Figure 44.4, *B*); in the nurse's arm with the head extended and stabilized between the nurse's body and elbow, and the arms and hands immobilized with the nurse's hands; or as shown in Figure 44.14. After instillation of the drops, the child should remain in position for 1 minute to allow the drops to come in contact with the nasal surfaces. Nasal spray dispensers are inserted into the naris vertically and then angled to avoid trauma to the septum and direct medication toward the inferior turbinate.

Aerosol Therapy

Aerosol therapy can be effective in depositing medication directly into the airway. This route of administration can be useful in avoiding the systemic adverse effects of certain medications and in reducing the amount of medication necessary to achieve the desired effect. Bronchodilators, steroids, and antibiotics, suspended in particulate form, can be inhaled so that the medication reaches the small airways. Aerosol therapy is particularly challenging in children who are too young to be able to control the rate and depth of breathing. Administration of this therapy requires skill, patience, and creativity.

MEDICATION ALERT

Medications can be aerosolized or nebulized with air or with oxygen-enriched gas. The metered-dose inhaler (MDI) is a self-contained, handheld device that allows for intermittent delivery of a specified amount of medication. Many bronchodilators are available in this form and are successfully used by children with asthma. A spacer device attached to the MDI can help with coordination of breathing and aerosol delivery. It also allows the aerosolized particles to remain in suspension longer. Handheld nebulizers discharge a medicated mist into a small plastic mask, which the child holds over the nose and mouth. To avoid particle deposition in the nose and pharynx, the child is instructed to take slow, deep breaths through an open mouth during the treatment. For home use, an air compressor is necessary to force air through the liquid medication to form the aerosol. Compact, portable units can be obtained from health equipment companies (see also Asthma, Chapter 45).

Assessment of breath sounds and the work of breathing should be done before and after treatments. Young children who become upset by having a mask held close to their face may become fatigued with fighting the procedure and may actually appear worse during and immediately after the therapy. It may be necessary to spend a few minutes calming the child after the procedure and allowing the vital signs to return to baseline in order to accurately assess changes in breath sounds and the work of breathing.

Family Teaching and Home Care

The nurse usually assumes the responsibility for preparing families to administer medications at home. The family should understand why the child is receiving the medication and the effects that might be expected, as well as the amount, frequency, and length of time the medication is to be administered. Instruction should be carried out in an unhurried, relaxed manner, preferably in an area away from a busy ward or office.

The caregiver needs to be carefully instructed in the correct dosage. Some people have difficulty understanding medical terminology; the nurse should not assume that the message is clear just because they nod or otherwise indicate an understanding. For example, it is important to ascertain their interpretation of a teaspoon and be certain they have accurate measuring devices. If the medication is packaged with a dropper, syringe, or plastic cup, the nurse should show or mark the point with tape, for example, on the device that indicates the prescribed dose and demonstrate how the dose is drawn up into a dropper or syringe, how it is measured, and how bubbles are eliminated. The parent should then give a return demonstration. This is essential when a medication such as insulin or digoxin has potentially serious consequences from incorrect dosage or when more complex administration such as parenteral injections is required. When teaching a parent to give an injection, the nurse must allot adequate time for instruction and practice.

Home modifications are often necessary because the availability of equipment or assistance can differ from the hospital setting. For example, the parent may need guidance in devising methods that allow for one person to hold the child and safely give the medication.

! NURSING ALERT

To administer oral, nasal, or optic medication when only one person is available to hold the child, use the following procedure:

- Place the child supine on a flat surface (bed, couch, floor).
- Sit facing the child so that the child's head is between the operator's thighs and the child's arms are under the operator's legs.
- Place your lower legs over the child's legs to restrain the lower body, if necessary.
- To administer oral medication, place a small pillow under the child's head to reduce risk of aspiration.
- To administer nasal medication, place a small pillow under the child's shoulders to aid flow of liquid through nasal passages.

The time that the medication is to be administered should be clarified with the parent. For instance, when a medication is prescribed in association with meals, the number of meals that the family is accustomed to eating influences the amount of medication the child receives. Does the child have meals twice a day or five times a day? When a medication is to be given several times during the day, together the nurse and parents can work out a schedule that accommodates the family's routine. This is particularly significant if the medication must be given at equal intervals throughout a 24-hour period. For example, telling parents that the child needs 1 teaspoon of medicine four times a day is subject to misinterpretation, and a preplanned schedule based on 6-hour intervals should be set up with the number of days required for therapeutic dosage listed. Written instruction should accompany all medication prescriptions.

! NURSING ALERT

Colour-Coded Instructions

If parents have difficulty reading or understanding English, use colours to convey instructions. For example, mark each medication with a colour and place the appropriate colour on a calendar chart or on a drawing of a clock to identify when the medication needs to be given. If a liquid medication and syringe are used, also mark the syringe with colour-coded tape at the place the plunger needs to be.

MAINTAINING FLUID BALANCE

Measurement of Intake and Output

Accurate measurements of fluid intake and output (I&O) are essential to the assessment of fluid balance. Measurements are from all sources—intake includes gastrointestinal and parenteral sources and output must include that from urine, stools, vomitus, nasogastric suction, and drainage from wounds. Although the health care provider usually indicates when I&O measurements are to be recorded, it is a nursing responsibility to keep an accurate I&O record on certain children, including those:

- Receiving IV therapy
- Who have undergone major surgery
- Receiving diuretic or corticosteroid therapy
- With severe thermal burns or injuries
- With renal disease or damage
- With heart failure
- With dehydration
- With diabetes mellitus
- With oliguria
- In respiratory distress
- With chronic lung disease

Infants or small children who are unable to use a bedpan or those who have bowel movements with every void require the application of a collecting device. If collecting bags are not used, wet diapers or pads are carefully weighed to ascertain the amount of fluid lost, including liquid stool, vomitus, and other losses. The specific gravity as a measure of osmolality is determined with a refractometer or urine dipsticks and assists in assessing the degree of hydration.

! NURSING ALERT

In infants with diapers, the nurse weighs all dry diapers to be used and notes in an indelible marker the dry weight of the diaper. When there is fluid (urine or liquid stool) in the diaper, the amount of output can be approximated by subtracting the weight of the dry diaper from the weight of the wet diaper.

1 g of wet diaper weight = 1 mL of urine

Disadvantages of the weighed-diaper method of fluid measurement include (1) inability to differentiate one type of loss from another because of admixture, (2) loss of urine or liquid stool from leakage

or evaporation (especially if the infant is under a radiant warmer), and (3) additional fluid in the diaper (superabsorbent disposable type) from absorption of atmospheric moisture (in high-humidity isolettes). Changing diapers as soon as they are soiled can decrease these insensible losses.

Special Needs When the Child Is NPO

Infants or children who are unable or not permitted to take fluids by mouth (NPO) have special needs. To ensure that they do not receive fluids, a sign can be placed in some obvious place, such as over their bed or on their shirt, to alert others to the NPO status. To prevent the temptation to drink, fluids should not be left at the bedside.

To keep the child's mouth feeling moist when they are NPO, give ice chips (if this is permitted by the health care provider) or spray the mouth with an atomizer. To meet the need to suck, the infant can be provided with a safe commercial pacifier (if the parents agree).

Oral hygiene, a part of routine hygienic care, is especially important when fluids are restricted or withheld. For the young child who cannot brush their teeth or rinse their mouth without swallowing fluid, the mouth and teeth can be cleaned and kept moist by swabbing with saline-moistened gauze.

The child who is fluid restricted presents an equal challenge. Limiting fluids is often more difficult for the child than being NPO, especially when IV fluids are also eliminated. To make certain the child does not drink the entire amount allowed early in the day, the daily allotment is calculated to provide fluids at periodic intervals throughout the child's waking hours. Serving the fluids in small containers gives the illusion of larger servings. No extra liquid should be left at the bedside.

PARENTERAL FLUID THERAPY

Site and Equipment

The site selected for peripheral intravenous line (PIV) infusion depends on accessibility and convenience. Although it is possible to use any accessible vein in older children, the child's developmental, cognitive, and mobility needs must be considered when selecting a site. Ideally, in older children, the superficial veins of the forearm should be used, leaving the hands free. An older child can help select the site and thereby maintain some measure of control. For veins in the extremities it is best to start with the most distal site and avoid the child's favoured hand so that the child can still do things with that hand. The child's movements should be restricted as little as possible; a site over a joint in an extremity must be avoided, such as the antecubital space. In small infants a superficial vein of the hand, wrist, forearm, foot, or ankle is usually most convenient and most easily stabilized (Figure 44.15). Foot veins should be avoided in children learning to walk or already walking. Superficial veins of the scalp have no valves, insertion is easy, and they can be used in infants up to about 9 months of age, but they should be used only when other site attempts have failed.

A transilluminator can aid in finding and evaluating veins for access (Figure 44.16). Although not as powerful as ultrasound, a transilluminator requires minimal training and experience to use. Small veins that may not be visible or palpable (especially in infants and toddlers) are often more readily visualized using a transilluminator and more often result in successful cannulation on the first or second attempt. Some devices require assistance to hold in place. Commercial devices have not caused burns in infants or children. Because veins stand out so clearly with transillumination, they appear more superficial than they really are. Practice in this technique is necessary for optimal outcomes.

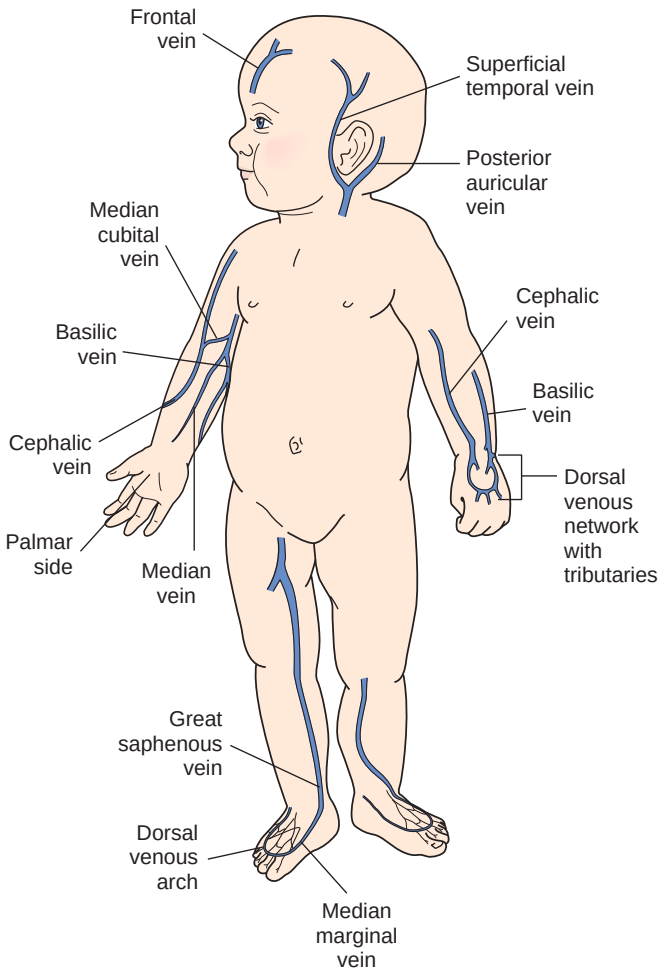

Fig. 44.15 Preferred sites for venous access in infants.

Fig. 44.16 Transilluminator: low-heat light-emitting diode (LED) light placed on the skin to illuminate veins; an opening allows cannulation of the vein.

Selection of a scalp vein may require clipping the area around the site to better visualize the vein and provide a smoother surface on which to tape the catheter hub and tubing. Clipping a portion of the infant's hair can be upsetting to parents; therefore, they should be asked first and

reassured that the hair will grow in again rapidly (the hair should be saved because parents often wish to keep it). As little hair as possible should be removed, directly over the insertion site and taping surface. A rubber band slipped onto the head from brow to occiput will usually suffice as a tourniquet, although if the vessel is visible, a tourniquet may not be necessary.

! NURSING ALERT

A tab of tape should be placed on the rubber band to help grasp it when removing it from the infant's head. The rubber band should be cut to avoid accidentally dislodging the catheter when moving the rubber band over the IV insertion site. The tape tab will lift the rubber band and allow it to be cut. Hold the rubber band in two places and cut between these areas to prevent the rubber band from snapping on the head.

For most IV infusions in children, a 22- to 24-gauge catheter may be used if therapy is expected to last less than 5 days. The smallest-gauge and shortest-length catheter that will accommodate the prescribed therapy should be chosen. The length of the catheter may be directly related to infection or embolus formation—the shorter the catheter, the fewer the complications. The gauge of the catheter should maintain adequate flow of the infusate into the cannulated vein while allowing adequate blood flow around the catheter walls to promote proper hemodilution of the infusate.

Determining the best catheter for the patient early in the therapy provides the best chance of avoiding catheter-related complications. As the length of therapy increases, decisions regarding the type of infusion device (short peripheral, midline, PICC, or CVC) should be explored.

Prior to insertion of a PIV catheter the skin should be disinfected with an appropriate antiseptic; it should be allowed to dry before catheter insertion. Disinfectants have risks for newborns. Chlorhexidine gluconate with alcohol should be used with caution in premature infants or infants less than 2 months of age, as these products may cause chemical burns. Cleansers should be removed from infants with sterile water or normal saline to prevent absorption of the disinfectant (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2018).

Safety Catheters and Needleless Systems

Over-the-needle IV inserters with hollow-bore needles carry a high risk for transmission of blood-borne pathogens from needlestick injuries. Safety catheters prevent accidental needlesticks with the use of over-the-needle IV catheters.

Needleless IV systems are designed to prevent needlestick injuries during administration of IV push medications and IV piggyback medications. Some needleless devices can be used with any tubing, whereas others require the use of the entire IV delivery system for compatibility. Needleless IV systems rely on prepierced septa that are accessed by blunted plastic cannulas or systems that use valves that open and close a fluid path when activated by insertion of a syringe.

Blunt plastic cannulas and preslit injection port sites (Figure 44.17) eliminate the need for steel needles and conventional injection port sites but remain accessible via hypodermic needles, a drawback except in emergent situations. Systems that do not permit needled access enhance safety by preventing health care workers from attempting to use needles.

! NURSING ALERT

Misconnections of tubing have occurred, resulting in patient deaths. Many needleless IV systems allow other types of tubing, such as blood pressure and oxygen tubing, to connect and instill air directly into the IV line. Before tubing is connected or reconnected to a patient, trace it completely from the patient to the point of origin for verification.

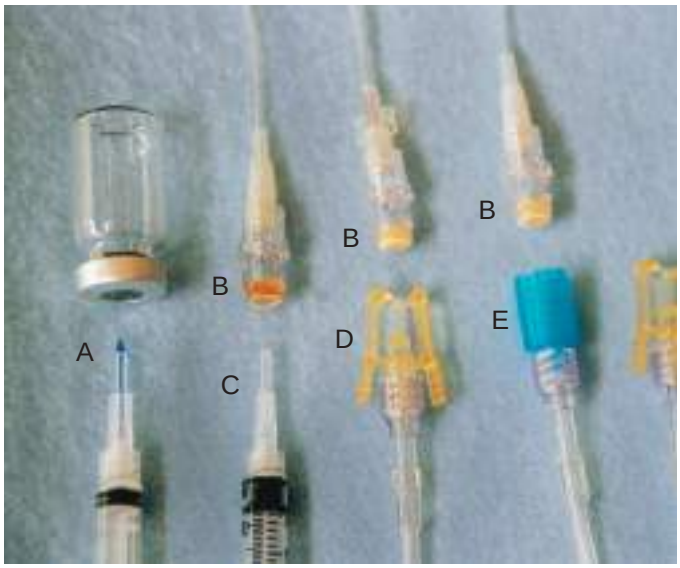

Fig. 44.17 Interlink intravenous access systems. **A:** Blue spike syringe. **B:** Preslit injection port (needleless). **C:** Blunt plastic cannula syringe. **D:** Lever lock cannula. **E:** Threaded lock cannula.

Infusion Pumps

A variety of infusion pumps are available and used in nearly all pediatric infusions to accurately administer medication and minimize the possibility of overloading the circulation. It is important to calculate the amount to be infused in a given length of time, set the infusion rate, and monitor the apparatus frequently (at least every 1 to 2 hours) to make certain that the desired rate is maintained, the integrity of the system remains intact, the site remains intact (free of redness, edema, infiltration, or irritation), and the infusion does not stop. Continuous infusion pumps, although convenient and efficient, are not without risks. Overreliance on the accuracy of the machine can cause either too much or too little fluid to be infused; its use does not eliminate the need for careful periodic assessment by the nurse. Excess pressure can build up if the machine is set at a rate faster than the vein is able to accommodate (or continues to pump when the needle is out of the lumen).

Securement of a Peripheral Intravenous Line

Catheters must be stabilized for easy monitoring and evaluation of the access site, to promote delivery of therapy and to prevent damage, dislodgement, or migration of the catheter. To maintain the integrity of the IV line, adequate protection of the site is required. The catheter hub should be firmly secured at the puncture site with a transparent dressing and commercial securement device, for example, StatLock (Figure 44.18), or clear, nonallergenic tape. Transparent dressings are ideal because the insertion site is easily observed. Minimal tape should be used at the puncture site and on about 2.5 to 5 cm of skin beyond the site to avoid obscuring the insertion site for early detection of infiltration.

A protective cover is applied directly over the catheter insertion site to protect the infusion site. Easy access to the IV site for frequent (hourly) assessments must be considered. Improvised plastic cups cut in half with the ridged edges covered with tape should not be used, as they have injured patients. A commercial site protector, I.V. House, is available in different sizes (Figure 44.19). Its ventilation holes prevent moisture from accumulating under the dome. This device is designed to protect the IV site and enables visibility of the site. It also minimizes use of padded boards, splints, or other restraints and tape and maintains skin integrity. The connector tubing or extension tubing can be looped to make it small enough to fit under the protective cover to prevent

Fig. 44.18 StatLock securement devices enhance peripheral intravenous line dwell time and decrease phlebitis.

Fig. 44.19 I.V. House used to protect intravenous site.

accidental snagging of the catheter. It is important to safely secure the IV tubing to prevent infants and children from becoming entangled in the tubing or from accidentally pulling the catheter or needle out. Securing the tubing in this manner also eliminates movement of the catheter hub at the insertion site (mechanical manipulation). A colourful sticker can be applied to the protecting device to add a positive note to the procedure.

Finger or toe areas should be left unoccluded by dressings or tape to allow for assessment of circulation. The thumb is never immobilized, because of the danger of contractures with limited movement later on. An extremity should never be encircled with tape. The use of roll gauze, self-adhering stretch bandages, and Ace bandages can cause the same constriction and hide signs of infiltration.

! NURSING ALERT

Opaque covering should be avoided; however, if any type of opaque covering is used to secure the IV line, the insertion site and extremity distal to the site should be visible to detect an infiltration. If these sites are not visible, they must be checked frequently to detect potential issues early.

Traditionally, padded boards and splints have been used to partially immobilize the IV site. Padded boards and splints and restraints were appropriate when metal needles were inserted into the vein to prevent the sharp end from puncturing the vessel, especially at a joint. With the more recent use of soft, pliable catheters, arm or leg boards may not be necessary, and their use has several disadvantages. If they are not placed properly, they can obscure the IV site, constrict the extremity, excoriate the underlying tissue and promote infection, cause a contracture of a joint, and restrict useful movement of the extremity, and they are uncomfortable. Unfortunately, no research has been conducted to demonstrate their proposed benefit of increasing dwell time (patency of the IV line). In most situations, the approach with the least restraint can be used, but restraint methods may be necessary to ensure patency and prevent dislodgement of IV lines. Older children who are alert and receptive can usually be trusted to protect the IV site.

Removal of a Peripheral Intravenous Line

When it comes time to discontinue an IV infusion, many children are distressed by the thought of catheter removal. They need a careful explanation of the process and suggestions for helping. Encouraging children to remove or help remove the tape from the site provides them with a measure of control and often encourages their assistance. The procedure consists of turning off any pump apparatus, occluding the IV tubing, removing the tape, pulling the catheter out of the vessel in the opposite direction of insertion, and exerting firm pressure at the site. A dry dressing (adhesive bandage strip) is placed over the puncture site. The use of adhesive-removal pads can decrease the pain of tape removal, but the skin should be washed after use to avoid irritation. To remove transparent dressings, for example, OpSite or Tegaderm, the opposing edges should be pulled parallel to the skin to loosen the bond. The nurse needs to inspect the catheter tip to ensure that the catheter is intact and that no portion remains in the vein.

! NURSING ALERT

Consider the child's age, development, neurological status, and predictability (how the child responds to painful treatments) when determining the need for assistance to maintain safety. Manual removal of tape is the preferred method. Only if absolutely necessary should a small cut be made in the tape, using bandage scissors, to facilitate its removal. Before cutting the tape:

- Ensure that all digits are visible.
- Remove any barrier that hinders visibility, such as a protective covering.
- Protect the child's skin and digits by sliding your own finger(s) between the tape and the child's skin so that the scissors do not touch the patient.
- Cut on the tape on the medial aspect (thumb side) of the extremity.

Maintenance

The following guidelines are recommended related to the care of PIVs or central lines:

- Use transparent dressings to allow site visualization. If diaphoresis, bleeding, or oozing prevents adequate adhesion, gauze dressings can be used (Infusion Nurses Society, 2016).
- Replace any dressing when damp, visibly soiled, or loose. Routinely replace transparent dressings every 7 days and gauze dressings every 2 days unless the risk for central catheter dislodgement outweighs the benefits of the dressing change.
- During dressing changes, use chlorhexidine to cleanse skin surrounding central lines and either chlorhexidine, tincture of iodine, an iodophor, or alcohol surrounding PIV lines. No recommendations can be made for the use of chlorhexidine in infants younger than 2 months of age.

- Chlorhexidine-impregnated sponge dressings should not be used in preterm newborns because of the risk of serious adverse skin reactions. No recommendation can be made about the use of chlorhexidine-impregnated dressings to protect the site of short-term, nontunneled CVCs for pediatric patients less than 18 years old and non-premature newborns given the lack of sufficient evidence from published, high-quality studies about efficacy and safety in this age group (Centers for Disease Control and Prevention, 2017).
- For PIVs, the catheter site should be checked every 1 to 2 hours (Spencer & Gilliam, 2017), although it is important to check the facility policy regarding this; the catheter site for central lines should be assessed every 7 to 8 hours to ensure that the catheter has not migrated (Infusion Nurses Society, 2016).
- Do not apply ointments to the insertion site; they promote fungal growth and antimicrobial resistance.
- Replace IV administration sets at the following frequencies (although it is important to review agency protocols related to this):
  - Continuous infusions of crystalloids at no less than 96-hour intervals, but at least every 7 days
  - Blood products or lipid emulsions sets within 24 hours of starting the infusion
  - Include all needleless components (including injection caps at the catheter hub) in administration set changes.
- In pediatric patients, PIV catheters may remain in place until a complication occurs or the therapy is complete.
- Promptly remove temporary central catheters or PIV catheters as soon as they are no longer needed.

Complications

The same precautions regarding maintenance of asepsis, prevention of infection, and observation for infiltration need to be carried out with patients of any age. However, infiltration is more difficult to detect in infants and small children than in adults. The increased amount of subcutaneous fat and the amount of tape used to secure the catheter often obscure the early signs of infiltration. When the fluid appears to be infusing too slowly or ceases, the usual assessment for obstruction within the apparatus—kinks, screw clamps, shutoff valve, and positioning interference such as a bent elbow—often locates the difficulty. When these actions fail in detecting obstruction, it may be necessary to carefully remove some of the dressing to obtain a clear view of the venipuncture site. Dependent areas, such as the palm and undersides of the extremity or the occiput and behind the ears, should be examined.

Whenever possible, the IV infusion should be placed in an extremity to which the ID band (or bracelet) is not attached. Serious circulatory impairment can result from infiltrated solution distal to the band, which acts as a tourniquet, preventing adequate venous return. To check for return blood flow through the catheter, the tubing is removed from the infusion pump, and the bag is lowered below the level of the infusion site. Resistance during flushing or aspiration for blood return also indicates that the IV infusion may have infiltrated surrounding tissue. A good blood return, or lack thereof, is not always an indicator of infiltration in small infants. Flushing the catheter and observing for edema, redness, or streaking along the vein are appropriate for assessment of the IV.

IV therapy in pediatrics tends to be difficult to maintain because of mechanical factors such as vascular trauma resulting from the catheter, the insertion site, vessel size, vessel fragility, pump pressure, the patient's activity level, operator skill and insertion technique, forceful administration of boluses of fluid, and infusion of irritants or vesicants through a small vessel. These factors cause infiltration and extravasation injuries. *Infiltration* is defined as inadvertent administration of a nonvesicant solution or medication into surrounding tissue. *Extravasation* is defined as inadvertent administration of vesicant solution or medication into surrounding tissue (Infusion Nurses Society, 2016). A *vesicant* or *sclerosing agent* causes varying degrees of cellular damage when even minute amounts escape into surrounding tissue. Guidelines are available for determining the severity of tissue injury by staging characteristics, such as the amount of redness, blanching, the amount of swelling, pain, the quality of pulses below infiltration, capillary refill, and warmth or coolness of the area (Infusion Nurses Society, 2016) (see Additional Resources at the end of this chapter).

Treatment of infiltration or extravasation varies according to the type of vesicant. Guidelines are available outlining the sequence of interventions and specific treatment of infiltration or extravasation with antidotes.

! NURSING ALERT

When infiltration or extravasation is observed (signs include erythema, pain, edema, blanching, streaking on the skin along the vein, and darkened area at the insertion site), immediately stop the infusion, elevate the extremity, notify the health care provider, and initiate the ordered treatment as soon as possible. Remove the IV line when it is no longer needed, such as after infusing an antidote.

Phlebitis, or inflammation of the vessel wall, may also develop in children who require IV therapy. Three types of phlebitis can occur: mechanical (caused by rapid infusion rate, manipulation of the IV), chemical (caused by medications), and bacterial (caused by staphylococcal organisms). The initial sign of phlebitis is erythema (redness) at the insertion site. Pain may or may not be present.

PIV catheters are the most commonly used intravascular device. Heavy cutaneous colonization of the insertion site is the single most important predictor of catheter-related infection with all types of short-term, percutaneously inserted catheters. Phlebitis, largely a mechanical rather than infectious process, remains the most important complication associated with the use of peripheral venous catheters.

! NURSING ALERT

The most effective ways to prevent infection of an IV site are to cleanse hands between each patient, wear gloves when inserting a catheter, and closely inspect the insertion site and physical condition of the dressing. Proper education of the patient and family regarding signs and symptoms of an infected site can help prevent infections from going unnoticed.

PROCEDURES FOR MAINTAINING RESPIRATORY FUNCTION

Inhalation Therapy

Oxygen Therapy. Oxygen is administered for **hypoxemia** and may be delivered by nasal cannula, hood, face mask, or ventilator. The mode of delivery is selected on the basis of the concentration needed and the child's ability to assist in its use. Oxygen is dry and therefore must be humidified. Oxygen therapy is frequently administered in the hospital, although increasing numbers of children are receiving oxygen in the home.

Oxygen delivered to infants is well tolerated by using a plastic hood (Figure 44.20). A minimum flow rate of 6 to 7 L/minute is necessary to maintain oxygen concentrations and remove the exhaled carbon dioxide. The humidified oxygen should not be blown directly into the infant's face. Older infants and children can use a nasal cannula or prongs (see Figure 28.1), which can supply a concentration of oxygen

Fig. 44.20 Oxygen administered to infant by means of a plastic hood. Note oxygen analyzer (blue machine).

of about 50%. A high-flow nasal cannula (5 to 8 L/min using pediatric tubing) may be used to avoid intubation, postextubation, in palliative care, and as a mode of ventilatory support in very low–birthweight newborns. Care with prong size, placement, and maintenance is important to prevent breakdown of the nasal alae. A mask is not well tolerated by children.

MEDICATION ALERT

Prolonged exposure to high oxygen tension can damage some body tissues and functions. The organs most vulnerable to the adverse effects of excessive oxygenation are the retina of the extremely preterm infant and the lungs of persons at any age.

NURSING ALERT

Inspect all toys for safety and suitability (e.g., vinyl or plastic, not stuffed items that absorb moisture and are difficult to keep dry). The high-level oxygen environment makes any source of sparks (e.g., mechanical or electrical toys) a potential fire hazard.

Oxygen-induced carbon dioxide narcosis is a physiological hazard of oxygen therapy that may occur in persons with chronic pulmonary disease, such as cystic fibrosis. In these patients the respiratory centre has adapted to the continuously higher arterial carbon dioxide tension ($Paco_2$) levels, and hypoxia becomes the more powerful stimulus for respiration. When the arterial oxygen tension (Pao_2) level is elevated during oxygen administration, the hypoxic drive is removed, causing progressive hypoventilation and increased $Paco_2$ levels, and the child rapidly becomes unconscious. Carbon dioxide narcosis can also be induced by the administration of sedation in these patients.

Monitoring Oxygen Therapy. *Pulse oximetry* is a continuous, noninvasive method of determining oxygen saturation (Sao_2) to guide oxygen therapy. A sensor composed of a light-emitting diode (LED) and a photodetector is placed in opposition around a foot, hand, finger, toe, or earlobe, with the LED placed on top of the nail when digits are used (Figure 44.21). The diode emits red and infrared lights that pass through the skin to the photodetector. The photodetector measures the amount of each type of light absorbed by functional hemoglobins. Hemoglobin saturated with oxygen (oxyhemoglobin) absorbs more infrared light than does hemoglobin not saturated with oxygen

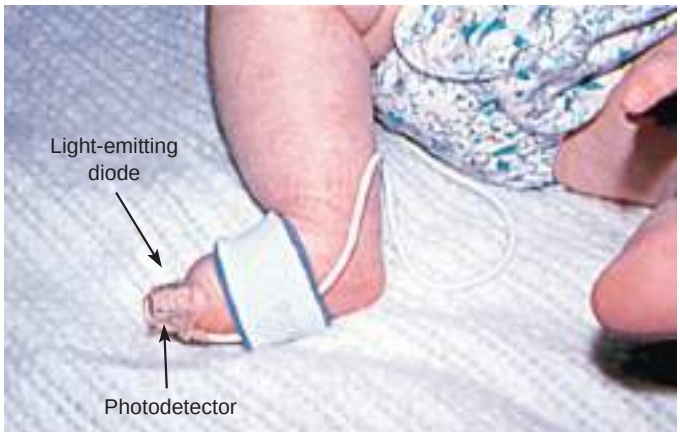

Fig. 44.21 Pulse oximeter sensor. Note that the sensor is positioned with light-emitting diode (LED) opposite the photodetector.

(deoxyhemoglobin). Pulsatile blood flow is the primary physiological factor that influences accuracy of the pulse oximeter. In infants, the probe should be repositioned at least every 3 to 4 hours to prevent pressure necrosis; poor perfusion and very sensitive skin may necessitate more frequent repositioning. See Nursing Skills on Evolve: Measuring Oxygen Saturation.

Another noninvasive method is *transcutaneous monitoring (TCM)*, which provides continuous monitoring of transcutaneous partial pressure of oxygen in arterial blood ($tcPao_2$) and, with some devices, of carbon dioxide in arterial blood ($tcPaco_2$). An electrode is attached to the warmed skin to facilitate arterialization of cutaneous capillaries. The site of the electrode must be changed every 3 to 4 hours to avoid burning the skin, and the machine must be calibrated with every site change. TCM is used frequently in neonatal intensive care units, but it may not reflect Pao_2 in infants with impaired local circulation.

Oximetry is insensitive to hyperoxia because hemoglobin approaches 100% saturation for all Pao_2 readings greater than approximately 100 mm Hg, which is a dangerous situation for the preterm infant at risk for developing retinopathy of prematurity (see Chapter 28). Therefore, the preterm infant being monitored with oximetry should have upper limits identified, such as 90 to 95%, and a protocol established for decreasing oxygen when saturations are high.

Oximetry offers several advantages over TCM. It (1) does not require heating the skin, thus reducing the risk of burns; (2) eliminates a delay period for transducer equilibration; and (3) maintains an accurate measurement regardless of the patient's age or skin characteristics or the presence of lung disease.

NURSING ALERT

It is important to make certain that sensor connectors and oximeters are compatible. Wiring that is incompatible can generate considerable heat at the tip of the sensor, causing second- and third-degree burns under the sensors. Pressure necrosis can also occur from sensors attached too tightly. Inspect the skin under the sensor frequently.

Correct application of the sensor is essential for accurate Sao_2 measurements. Because the sensor must identify every pulse beat to calculate the Sao_2, movement can interfere with sensing. Some devices synchronize the Sao_2 reading with the heartbeat, thereby reducing the interference caused by motion. Sensors are not placed on extremities used for blood pressure monitoring or with in-dwelling arterial catheters, since pulsatile blood flow may be affected.

! NURSING ALERT

Infant—Secure the sensor to the great toe and tape the wire to the sole of the foot (or use a commercial holder that fastens with a self-adhering closure). Place a snugly fitting sock over the foot, but check the site frequently (every hour) for colour, temperature, and pulse.

Child—Secure the sensor securely to the index finger and tape the wire to the back of the hand.

Ambient light from ceiling lights and phototherapy, as well as high-intensity heat and light from radiant warmers, can interfere with readings. Thus, the sensor should be covered to block these light sources. IV dyes; green, purple, or black nail polish; nonopaque synthetic nails; and possibly ink used for foot printing can also cause inaccurate Sa_{O_2} measurements. The dyes should be removed or, in the case of porcelain nails, a different area used for the sensor. Skin colour, thickness, and edema do not affect the readings.

Blood gas measurements are sensitive indicators of change in respiratory status in acutely ill patients. They provide valuable information regarding lung function, lung adequacy, and tissue perfusion. The pH, $PaCO_2$, bicarbonate (HCO_3), and PaO_2 levels can provide information about whether the child is compensating and guide critical treatment decisions.

End-Tidal Carbon Dioxide. End-tidal carbon dioxide ($ETCO_2$) monitoring measures exhaled carbon dioxide noninvasively. Capnometry provides a numeric display, and continuous capnometry is available in many bedside physiological and stand-alone monitors. $ETCO_2$ differs from pulse oximetry in that it is more sensitive to the mechanics of ventilation than oxygenation. Hypoxic episodes can be proven through the early detection of hypoventilation, apnea, or airway obstruction.

Children who are experiencing an asthma exacerbation, receiving procedural sedation, or mechanically ventilated may have $ETCO_2$ monitoring. Special sampling cannulas are used for nonintubated patients, and a small device is placed between the endotracheal (ET) tube and the ventilator tubing in intubated patients. Although $ETCO_2$ monitoring is not a substitute for arterial blood gases, it does provide ventilation information continuously and noninvasively. Normal $ETCO_2$ values are 30 to 43 mm Hg, which is slightly lower than normal arterial PCO_2 of 35 to 45 mm Hg. During cardiopulmonary resuscitation (CPR), $ETCO_2$ values consistently below 15 mm Hg indicate ineffective compressions or excessive ventilation. Changes in waveform and numeric display follow changes in ventilation by a very few seconds and precede changes in respiratory rate, skin colour, and pulse oximetry values.

When there is a change in $ETCO_2$ value or waveform, the nurse needs to assess the patient quickly for adequate airway, breathing, and circulation. Sedated patients may be hypoventilating and need stimulation. Intubated patients may need suctioning, have self-extubated or dislodged the tube, or have equipment failure or disconnection. Patients with asthma may have a worsening condition. Issues with the $ETCO_2$ monitoring system can include a kink in the sample line or disconnection. In general, the nurse should check the patient first and then the equipment.

Bronchial (Postural) Drainage

Bronchial drainage is indicated whenever excessive fluid or mucus in the bronchi is not being removed by normal ciliary activity and cough. Positioning the child to take maximum advantage of gravity facilitates removal of secretions. Postural drainage can be effective in children with chronic lung disease characterized by thick mucus, such as cystic fibrosis.

Postural drainage is carried out three or four times daily and is more effective when it follows other respiratory therapy, such as bronchodilator or nebulization medication (see Aerosol Therapy above). Bronchial drainage is generally performed before meals (or 1 to 1½ hours after meals) to minimize the chance of vomiting and is repeated at bedtime. The duration of treatment depends on the child's condition and tolerance; it usually lasts 20 to 30 minutes. Several positions facilitate drainage from all major lung segments.

Chest Physiotherapy

Chest physiotherapy (CPT) usually refers to the use of postural drainage in combination with adjunctive techniques that are thought to enhance the clearance of mucus from the airway. These techniques include manual percussion, vibration, and squeezing of the chest; cough; forceful expiration; and breathing exercises. Special mechanical devices are also used to perform CPT, such as vest-type percussors. Postural drainage in combination with forced expiration has been shown to be beneficial.

Common techniques used in association with postural drainage include manual percussion of the chest wall and percussion with mechanical devices such as a high-frequency handheld chest compression device. A "popping," hollow sound, not a slapping sound, should be the result. The procedure should be done over the rib cage only and should be painless. Percussion can be performed with a soft circular mask (adapted to maintain air trapping) or a percussion cup marketed especially for the purpose of aiding in loosening secretions. CPT is contraindicated when patients have pulmonary hemorrhage, pulmonary embolism, end-stage renal disease, increased intracranial pressure, osteogenesis imperfecta, or minimal cardiac reserves.

Intubation

Rapid-sequence intubation (RSI) is commonly performed in pediatric and some newborn patients to induce an unconscious, neuromuscular blocked condition in order to avoid the use of positive-pressure ventilation and the risk of possible aspiration (Scott, 2020). Atropine, fentanyl, and vecuronium or rocuronium are commonly used during RSI. In newborns, ET intubation is often a stressful event, and hypoxia and pain are commonly associated with it (Scott, 2020). RSI in newborns may prevent such adverse effects.

Indications for intubation include the following:

- Respiratory failure or arrest, agonal or gasping respirations, apnea
- Upper airway obstruction
- Significant increase in the work of breathing
- Potential for developing partial or complete airway obstruction—respiratory effort with no breath sounds, facial trauma, and inhalation injuries
- Potential for or actual loss of airway protection, increased risk for aspiration
- Anticipated need for mechanical ventilation related to chest trauma, shock, increased intracranial pressure
- Hypoxemia despite supplemental oxygen
- Inadequate ventilation

In preparation for intubation, the child should be preoxygenated with 100% oxygen using an appropriate-size bag and mask. Historically, uncuffed ET tubes were used in children younger than 8 years of age, but there is evidence that use of these tubes in small children does not produce a higher incidence of complications; newer cuff designs are reported to decrease complications, such as stridor and tracheal mucosal injury (Kuch, 2013). Air or gas delivered directly to the trachea must be humidified. During intubation the cardiac rhythm, heart rate, and oxygen saturation should be monitored continuously

with audible tones. ET tube placement should be verified by at least one clinical sign and at least one confirmatory technology:

- Visualization of bilateral chest expansion
- Auscultation over the epigastrium (breath sounds should not be heard) and the lung fields bilaterally in the axillary region (breath sounds should be equal and adequate)
- Water vapour in the tube (helpful, not definitive)
- Colour change on $ETCO_2$ detector during exhalation after at least three to six breaths or wave form/value verification with continuous capnography
- Chest X-ray

A protective skin barrier is applied and the ET tube secured with tape or a securement device. An NG tube is typically inserted after intubation.

Mechanical Ventilation. ET intubation can be accomplished via the nasal (nasotracheal), oral (orotracheal), or direct tracheal (tracheostomy) routes. Although it is more difficult to place, nasotracheal intubation is preferred to orotracheal intubation because it facilitates oral hygiene and provides more stable fixation, which reduces the complication of tracheal erosion and the danger of accidental extubation.

Basic ongoing assessment of the mechanically ventilated patient includes observing the chest rise and fall for symmetry, bilateral breath sounds equal or unchanged from last assessment, level of consciousness, capillary refill and skin colour, and vital signs. A heart rate that is too fast or too slow is a possible indication of hypoxemia, air leak, or low cardiac output. Pulse oximetry and $ETCO_2$ monitoring is also routine, along with periodic arterial blood gas analysis. If sudden deterioration of an intubated patient occurs, the nurse needs to assess for the following etiologies:

DOPE

- **D**isplacement—Tube not in the trachea or had moved into a bronchus (right mainstream is more common)
- **O**bstruction—Secretions or kinking of the tube
- **P**neumothorax—Chest trauma, barotraumas, or noncompliant lung disease
- **E**quipment failure—Check the oxygen source, AMBU bag, and ventilator (American Heart Association, 2015).

Placement should be verified again during each transport and when patients are moved to different beds.

To maintain skin integrity in the mechanically ventilated patient, the patient needs to be repositioned at least every 2 hours as the patient's condition tolerates. The nurse can apply a hydrocolloid barrier to protect the facial cheeks. Pillows can be placed under pressure points, such as occiput, heels, elbows, and shoulder. No tubes, lines, wires, or wrinkles in bedding should be allowed under the patient. The nurse needs to provide meticulous skin care.

Analgesia and sedation are provided as needed. A system for communication can be used that includes sign boards, pointing, and opening and closing eyes. To ensure safety, soft restraints may be used, if necessary, to maintain a critical airway.

Ventilator-associated pneumonia is a complication that can be prevented through the use of aggressive hand hygiene, oral care, and elevation of the head of the bed between 30 and 45 degrees (unless contraindicated). Enteral nutrition is often provided to decrease the risk of bacterial translocation. The nurse needs to routinely assess the patient's intestine motility by auscultating bowel sounds and measuring residual gastric volume or abdominal girth and adjusting the rate and volume of enteral feeding to avoid regurgitation. In high-risk patients (decreased gag reflex, delayed gastric emptying, gastroesophageal reflux, severe bronchospasm), postpyloric (duodenal, jejunal) feeding tubes are often used. To prevent the aspiration of pooled secretions, the nurse needs to suction the hypopharynx before suctioning the ET tube, before repositioning the ET tube, and before repositioning the patient. Ventilator circuits' condensate should be prevented from entering ET tube or in-line medication nebulizers. Additional measures to prevent ventilator-associated pneumonia include oral intubation and changing ventilator circuits only when they are visibly soiled (Kline-Tilford et al., 2013).

Readiness for extubation should be assessed daily. Indications that a child is ready to be extubated include an improvement in underlying condition, hemodynamic stability, and mechanical support no longer being necessary. Level of consciousness and ability to maintain a patent airway can be assessed by having the patient mobilize pulmonary secretions through effective coughing. NPO status should be maintained 4 hours before extubation. After extubation, the child should be monitored for respiratory distress, which may develop within minutes or hours. Signs of postintubation respiratory distress include stridor, hoarseness, increased work of breathing, unstable vital signs, and desaturations.

Tracheostomy

A *tracheostomy* is a surgical opening in the trachea; the procedure may be done on an emergency basis or may be an elective one, and it may be combined with mechanical ventilation. Pediatric tracheostomy tubes are usually made of plastic or Silastic (Figure 44.22). The most common types are the Bivona, Tracoe, Arcadia, Hollinger, and Shiley tubes. These tubes are constructed with a more acute angle than that of adult tubes, and they soften at body temperature, conforming to the contours of the trachea. Because these materials resist the formation of crusted respiratory secretions, they are made without an inner cannula.

Children who have undergone a tracheostomy must be closely monitored for complications such as hemorrhage, edema, aspiration, accidental decannulation, tube obstruction, and the entrance of free air into the pleural cavity. Nursing care focuses on maintaining a patent airway, facilitating the removal of pulmonary secretions, providing humidified air or oxygen, cleansing the stoma, monitoring the child's ability to swallow, and teaching while simultaneously preventing complications.

Because the child may be unable to signal for help, direct observation and use of respiratory and cardiac monitors are essential. Respiratory assessments include breath sounds and the work of breathing, vital signs, tightness of the tracheostomy ties, and the type and amount of secretions. Large amounts of bloody secretions are uncommon and

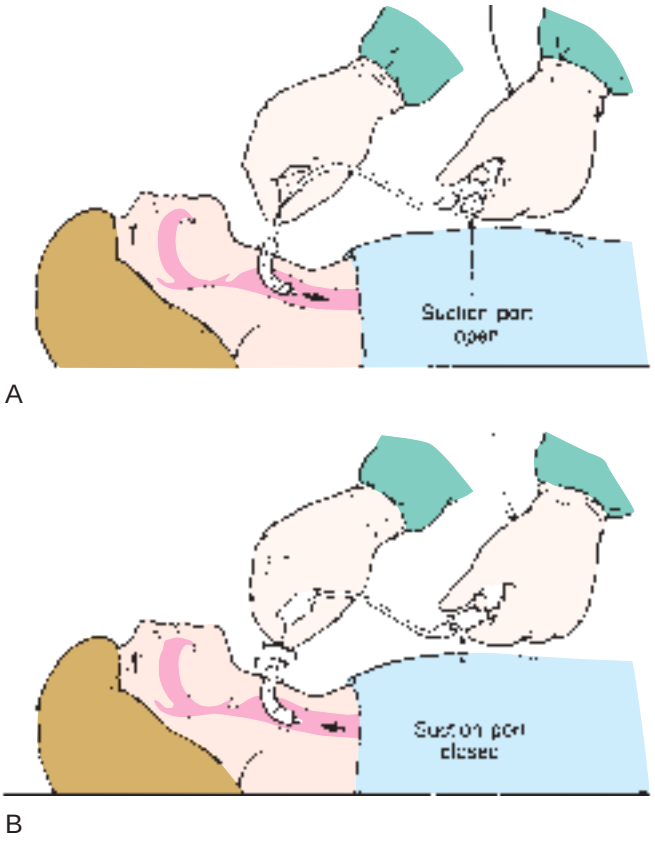

Fig. 44.22 Silastic pediatric tracheostomy tube and obturator.

should be considered a sign of hemorrhage. The primary health care provider should be notified immediately if this occurs.

The child is positioned with the head of the bed raised or in the position most comfortable to the child, with the call light easily available. Suction catheters, suction source, gloves, sterile saline, sterile gauze for wiping away secretions, scissors, an extra tracheostomy tube of the same size with ties already attached, another tracheostomy tube one size smaller, and the obturator are kept at the bedside. A source of humidification is provided because the normal humidification and filtering functions of the airway have been bypassed. IV fluids ensure adequate hydration until the child is able to swallow sufficient amounts of fluids.

Suctioning. The airway must remain patent and requires frequent suctioning during the first few hours after a tracheostomy to remove mucous plugs and excessive secretions. Proper vacuum pressure and suction catheter size are important to prevent atelectasis and decrease hypoxia from the suctioning procedure. Vacuum pressure should range from 60 to 100 mm Hg for infants and children and from 40 to 60 mm Hg for preterm infants. Unless secretions are thick and tenacious, the lower range of negative pressure is recommended. Tracheal suction catheters are available in a variety of sizes. The catheter selected should have a diameter one-half the diameter of the tracheostomy tube. If the catheter is too large, it can block the airway. The catheter is constructed with a side port so that the catheter is introduced without suction and removed while simultaneous intermittent suction is applied by covering the port with the thumb (Figure 44.23).

A

B

Fig. 44.23 Tracheostomy suctioning. **A:** Insertion, port open. **B:** Withdrawal, port occluded. Note that the catheter is inserted just slightly beyond the end of the tracheostomy tube.

The catheter is inserted just to the end of the tracheostomy tube; it is recommended that the catheter length be premeasured before suctioning. The practice of instilling sterile saline in the tracheostomy tube before suctioning is not supported by research and is no longer recommended.

! NURSING ALERT

Suctioning should require no more than 5 seconds. Counting one one-thousand, two one-thousand, three one-thousand, and so on while suctioning is a simple means of monitoring the time. Without a safeguard, the airway may be obstructed for too long. Hyperventilating the child with 100% oxygen before and after suctioning (using a bag-valve-mask or increasing the fraction of inspired oxygen concentration [Fio_2] ventilator setting) may be performed to prevent hypoxia. Closed tracheal suctioning systems that allow for uninterrupted oxygen delivery may also be used.

The child should be allowed to rest for 30 to 60 seconds after each suctioning pass to allow oxygen saturation to return to normal; then the process is repeated until the trachea is clear. Suctioning should be limited to about three passes in one period. Oximetry is used to monitor suctioning and prevent hypoxia.

! NURSING ALERT

Suctioning is carried out only as often as needed to keep the tube patent. Signs of mucus partially occluding the airway include an increased heart rate, a rise in respiratory effort, a drop in Sao_2, cyanosis, and an increase in the positive inspiratory pressure on the ventilator.

In the acute care setting, aseptic technique is used during care of the tracheostomy. Secondary infection is a major concern, since the air entering the lower airway bypasses the natural defences of the upper airway. Gloves should be worn during the suctioning procedure, although a sterile glove is needed only on the hand touching the catheter. A new tube and gloves should be used each time.

! NURSING ALERT

In a closed suction system, a suction catheter is directly attached to the ventilator tubing. This system has several advantages. First, there is no need to disconnect the patient from the ventilator, which allows for better oxygenation. Second, the suction catheter is enclosed in a plastic sheath, which reduces the risk that the nurse will be exposed to the patient's secretions.

Routine Care. The tracheostomy stoma requires daily care. Assessments of the stoma area include observations for signs of infection and breakdown of the skin. The skin needs to be kept clean and dry, and crusted secretions around the stoma may be gently removed with half-strength hydrogen peroxide. Hydrogen peroxide should not be used with sterling silver tracheostomy tubes because it tends to pit and stain the silver surface. The nurse should be aware of wet tracheostomy dressings, which can predispose the peristomal area to skin breakdown. Several products are available to prevent or treat excoriation.

The tracheostomy tube is held in place with tracheostomy ties made of a durable, nonfraying material. The ties can be changed daily but are normally replaced when soiled. Ties fastened with self-adhering Velcro closures are commonly used. If Velcro ties are not available, cotton ties are looped through the flanges and tied snugly

Fig. 44.24 Tracheostomy ties are snug but allow one finger to be inserted.

in a triple knot at the side of the neck before the soiled ties are cut and removed. The ties should be tight enough to allow just a fingertip to be inserted between the ties and the neck (Figure 44.24). It is easier to ensure a snug fit if the child's head is flexed rather than extended while the ties are being secured.

Routine tracheostomy tube changes are usually carried out weekly after a tract has been formed to minimize the formation of granulation tissue. The first change is usually performed by the surgeon; subsequent changes are performed by the nurse and, if the child is discharged home with the tracheostomy, by either a parent or a visiting nurse. Ideally, two caregivers participate in the procedure to assist with positioning the child.

Changing the tracheostomy tube is accomplished using sterile technique. Tube changes should occur before meals or 2 hours after the last meal. Continuous feedings should be turned off at least an hour before a tube change. The new, sterile tube is prepared by inserting the obturator and attaching new ties. The child is suctioned before the procedure to minimize secretions, then held and positioned with the neck slightly extended. One caregiver cuts the old ties and removes the tube from the stoma. The new tube is inserted gently into the stoma (using a downward and forward motion that follows the curve of the trachea), the obturator is removed, and the ties are secured. The adequacy of ventilation must be assessed after a tube change because the tube can be inserted into the soft tissue surrounding the trachea; breath sounds and respiratory effort should be carefully monitored.

Supplemental oxygen is always delivered with a humidification system to prevent drying of the respiratory mucosa. Humidification of room air for an established tracheostomy can be intermittent if secretions remain thin enough to be coughed or suctioned from the tracheostomy. Direct humidification via a tracheostomy mask can be provided during naps and at night so that the child is able to be up and around unencumbered during much of the day. Room humidifiers are also used successfully.

The inner cannula, if used, should be removed with each suctioning, cleaned with sterile saline and pipe cleaners to remove crusted material, dried thoroughly, and reinserted.

Emergency Care: Tube Occlusion and Accidental Decannulation. Occlusion of the tracheostomy tube is life-threatening, and infants and children are at greater risk than adults because of the smaller diameter of the tube. Patency of the tube is maintained with suctioning and routine tube changes to prevent the formation of crusts that can occlude it.

> **! NURSING ALERT**
>
> Life-threatening occlusion is apparent when the child displays signs of respiratory distress and a suction catheter cannot be passed to the end of the tube despite several attempts. This situation requires an immediate tube change, after attempting a cannula change and repositioning the child.

Accidental decannulation also requires immediate tube replacement. Some children have a fairly rigid trachea, so the airway remains partially open when the tube is removed. However, others have malformed or flexible tracheal cartilage, which causes the airway to collapse when the tube is removed or dislodged. Because many infants and children with upper airway difficulties have little airway reserve, if replacement of the dislodged tube is impossible, a smaller-sized tube should be inserted. If the stoma cannot be cannulated with another tracheostomy tube, oral intubation should be performed.

Chest Tube Procedures

A chest tube is placed to remove fluid or air from the pleural or pericardial space. Chest tube draining systems collect air and fluid while inhibiting a backflow into the pleura or pericardial space. Indications for chest tube placement include tension pneumothorax, hemothorax, chylothorax, empyema, pleural or pericardial effusion, and prevention of accumulation of fluid in the pleural and pericardial space after cardiothoracic surgery. Nursing responsibilities include assisting with chest tube placement, managing chest tubes, monitoring chest tube dressings, and assisting with chest tube removal.

Before chest tube insertion it is important to assess hematological and coagulation results for any risk of bleeding during the procedure. The health care provider should be notified of any abnormal findings. The nurse should prepare the drainage system with sterile water as described in the package insert (some systems may not require this step) and administer pain and sedation medications as ordered. Airway, breathing, circulation, and pulse oximetry need to be monitored throughout the procedure.

After the tube has been inserted and connected to the chest drainage system, the tubing should be secured so it does not become disconnected. If suction is required, connection tubing is used to join the drainage system to a wall suction adapter and suction on the drainage system adjusted as ordered (usually 10–20 cm H_2O). There should be gentle, continuous bubbling in the suction chamber. An occlusive dressing is placed over the chest tube insertion site per hospital policy. The nurse needs to note the date, time, and initials on the dressing. If gauze is used it should be presplit; gauze cut by scissors may leave loose threads in the wound. The nurse needs to ensure that the drainage system is positioned below the patient's chest and secured to the floor or bed. The drainage tubing should be kept free of dependent loops. A chest X-ray is used to confirm placement of the chest tube immediately after insertion. Chest X-rays assist health care providers in monitoring placement of the chest tube and resolution of the pneumothorax or effusion and in decision making for chest tube removal.

Disposable chest drainage systems typically consist of three chambers next to one another in one drainage unit (Figure 44.25). The fluid collection chamber collects drainage from the patient's pleural or pericardial space. The water-seal chamber is connected directly to the fluid collection chamber and acts as a one-way valve, protecting patients from air returning to the pleural or pericardial space. The suction chamber may be a dry suction or calibrated water chamber. It is connected to external vacuum suction set to the amount of suction ordered and controls the amount of suction that patients experience. There are some chest drainage systems that only contain two chambers; these are considered dry systems.

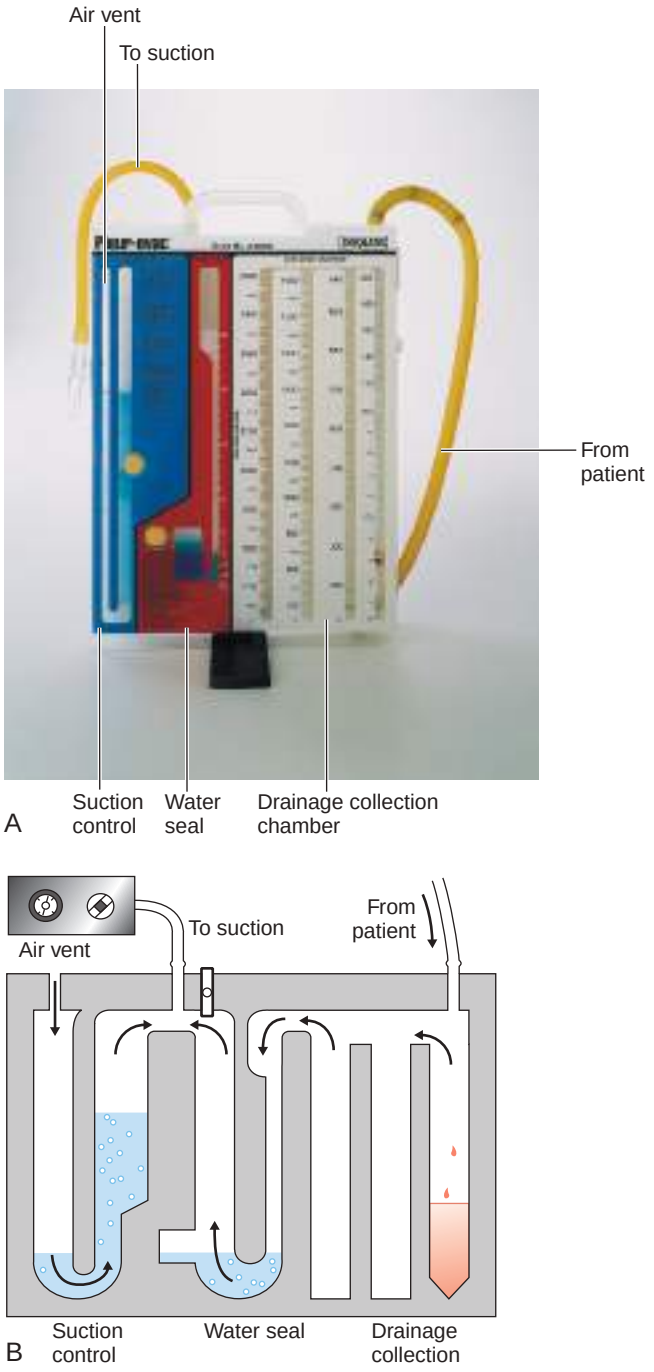

Fig. 44.25 **A:** Pleur-Evac drainage system, a commercial three-bottle chest drainage device. **B:** Schematic of drainage device. (From Ignatavicius, D. D., & Workman, L. M. [2010]. *Medical-surgical nursing: Patient-centered collaborative care* [6th ed.]. Saunders.)

The nurse needs to assess for blood clots and fibrin strands in tubes with sanguineous or serosanguineous drainage and ensure that there are no obstructions to drainage in the tube. Chest tube clearance is maintained per hospital policy. Milking or stripping of chest tubes is not recommended for chest tube clearance because of the high negative intrathoracic pressure that is created. However, some special circumstances, such as maintaining chest tube patency while a patient is bleeding, warrant chest tube clearance with these methods. The nurse needs to notify the health care provider immediately if chest tube obstruction is suspected. Generally, chest tubes should not be clamped. However, it may be necessary to clamp a chest tube when exchanging the collection chamber or determining the site of an air leak (see Guidelines box: Ongoing Patient and Chest Drainage System Assessment).

GUIDELINES

Ongoing Patient and Chest Drainage System Assessment

- Determine drainage type (sanguineous, serosanguineous, serous, chylous, empyemic), colour, amount, and consistency. If there is a marked decrease in the amount of drainage, assess for drainage around chest tube insertion site.
- Dressing is clean, dry, and intact.
- Chest tube sutures are intact. Sometimes they are not visible under the dressing; do not lift chest tube dressing to assess for this.
- The prescribed amount of suction is applied.
- Water level is at 2 cm. If the water column is too high, the flow of air from the chest may be impeded.
- Bubbling in water-seal chamber is normal if the chest tube was placed to evacuate a pneumothorax. Bubbling will stop when the pneumothorax has resolved.
- Fluctuations may be seen in the water column because of changes in intrathoracic pressure. Substantial fluctuations may reflect changes in a patient's respiratory status.
- Note signs and symptoms of infection or skin breakdown.
- Palpate for presence of subcutaneous air.

Interventions

- Notify health care provider of any changes in the quantity or quality of drainage.
- If 3 mL/kg/hr or greater of sanguineous drainage occurs for 2 to 3 consecutive hours after cardiothoracic surgery, it may indicate active hemorrhaging and warrants immediate attention of the health care provider.
- Change dressing and perform site care as per hospital policy. Typically, an occlusive dressing is applied.
- When the collection chamber is almost full, exchange existing drainage system with a new one per manufacturer instructions using sterile technique.
- To lower the water column, depress the manual vent on the back of the unit until the water level reaches 2 cm. *Do not depress the filtered manual vent when the suction is not functioning or connected.*
- If evacuation of a pneumothorax was not the indication for placement of the chest tube, bubbling in the water-seal chamber may be the result of a leak in the chest drainage system. Check for leak in the system from closest to patient down to drainage system. Identify the break in the system by briefly clamping the system between the drainage unit and the system; the bubbling will stop. Tighten any loose connections. If the air leak is suspected to be at the patient's chest wall, notify the health care provider.
- Encourage patient ambulation. Secure chest tube drainage system to prevent chest tube dislodgment from the patient or disconnection from the drainage system.

ALTERNATIVE FEEDING TECHNIQUES

Some children are unable to take nourishment by mouth because of anomalies of the throat, esophagus, or bowel; impaired swallowing capacity; severe debilitation; respiratory distress; or unconsciousness.

These children are frequently fed by way of a tube inserted orally or nasally into the stomach (*orogastric [OG]* or *nasogastric [NG] gavage*) or duodenum-jejunum (**enteral** *gavage*), or by a tube inserted directly into the stomach (*gastrostomy*) or jejunum (*jejunostomy*). Such feedings may be intermittent or by continuous drip.

Feeding resistance may result from any long-term feeding method that bypasses the mouth. During gavage or gastrostomy feedings, infants can be given a pacifier for non-nutritive sucking. However, to prevent the possibility of aspiration, only pacifiers with a safe design may be used (see Figure 26.27).

! NURSING ALERT

When a child is concurrently receiving continuous-drip gastric or enteral feedings and parenteral (IV) therapy, the potential exists for inadvertent administration of the enteral formula through the circulatory system, especially when the parenteral solution is a fat emulsion, which looks milky. Safeguards to prevent this potentially serious error include the following:

- Use a separate, specifically designed enteral feeding pump mounted on a separate pole for continuous-feeding solutions.
- Label all tubing for continuous enteral feeding with brightly coloured tape or labels.
- Use specifically designed continuous-feeding bags to contain the solutions instead of parenteral equipment, such as a burette.
- Whenever access or connections are made, trace the tubing all the way from the patient to the bag to ensure that the correct tubing source is selected.

Gavage Feeding

Infants and children can be fed simply and safely by means of a tube passed into the stomach through either the nares or the mouth. The tube can be left in place or inserted and removed with each feeding. In older children it is usually less traumatic to tape the tube securely in place between feedings. When this alternative is used, the tube should be removed and replaced with a new tube according to hospital policy, specific orders, and the type of tube used. Meticulous hand hygiene should be practised during the procedure to prevent bacterial contamination of the feeding, especially during continuous-drip feedings (see Atraumatic Care box: Reducing the Distress of Nasogastric Tube Insertion).

ATRAUMATIC CARE

Reducing the Distress of Nasogastric Tube Insertion

Numerous strategies can be used to decrease discomfort during nasogastric (NG) tube insertion. Most important, the nurse performing the procedure should be competent in NG tube placement. The nurse should discuss the procedure with the child in a developmentally appropriate way and give family members the details of what to expect during the procedure. A smaller-calibre, soft, flexible tube should be used. To prevent the trauma of reinsertion, the NG tube must be well secured after placement. Administration of sedation and analgesia should be considered before NG insertion.

Preparation. The equipment needed for gavage feeding includes the following:

- A suitable tube that is selected according to the child's size, viscosity of the solution being fed, and anticipated duration of these treatments
- A receptacle for the fluid: for small amounts a 10- to 30-mL syringe barrel or Asepto syringe is satisfactory; for larger amounts a 60-mL syringe with a catheter tip is more convenient
- A 10-mL syringe to aspirate stomach contents after the tube has been placed
- Water or water-soluble lubricant to lubricate the tube; sterile water is used for infants
- Paper or nonallergenic tape to mark the tube and attach the tube to the child's cheek (and nose if placed through the nares)
- pH paper to determine the correct placement in the stomach
- The solution for feeding

Not all feeding tubes are the same. Polyethylene and polyvinylchloride types lose their flexibility and need to be replaced frequently, usually every 3 or 4 days. Polyurethane and silicone tubes remain flexible; thus they can remain in place for up to 30 days. Advantages of small-bore tubes include a reduced incidence of pharyngitis, otitis media, aspiration, and discomfort. Disadvantages include difficulty during insertion (may require a stylet or metal guidewire), collapse of the tube during aspiration of gastric contents to test for correct placement, dislodgment during forceful coughing, migration out of position, knotting, occlusion, and unsuitability for thick feedings.

Procedure. It is easier to insert a feeding tube in an infant if they are first wrapped in a mummy restraint (see Figure 44.6, *A*). Even tiny infants with random movements can grasp and dislodge the tube. Preterm infants do not ordinarily require restraints, but if they do, a small blanket folded across the chest and secured beneath the shoulders is usually sufficient. Care should be taken so that breathing is not compromised.

Whenever possible, the infant should be held and provided with a means for non-nutritive sucking during the procedure to associate the comfort of physical contact with the feeding. When this is not possible, gavage feeding is carried out with the infant or child on their back or toward the right side and the head and chest elevated. Feeding the child in a sitting position helps to maintain placement of the tube in the lowest position, thus increasing the likelihood of correct placement in the stomach. The Guidelines box: Nasogastric Tube Feedings in Children describes the procedure for gavage feeding.

Although the most accurate method for testing tube placement is X-ray, this practice is not always possible before each feeding. In hospitalized children, there are often placement errors, particularly with children who are comatose, semiconscious, or inactive; have swallowing difficulties; or had Argyle tubes. Bedside assessment of gastrointestinal aspirate colour and pH testing is useful in predicting feeding tube placement. If doubt exists regarding correct placement, the health care provider should be consulted and an X-ray may be ordered to check tube placement.

Studies evaluating NG and OG tube length found that age-specific methods for predicting the distance based on height is the more accurate estimate of internal distance to the stomach (Beckstrand et al., 2007). The morphological measure most commonly used by clinicians, nose–ear–xiphoid distance, is often too short to locate the entire tube pore span in the stomach. However, the nose–ear–midxiphoid umbilicus span approached the accuracy of the age-specific prediction equations and is easier to use in a clinical setting. The best option is to adapt the nose–ear–midxiphoid umbilicus measurement for NG or OG tube length (see Figure 44.26, *A* and Guidelines box, Nasogastric Tube Feedings in Children). For very low–birth-weight infants, daily weight can be used to predict insertion length.

GUIDELINES

Nasogastric Tube Feedings in Children

Place child supine with head slightly hyperflexed or in a sniffing position (nose pointed toward ceiling).

Measure tube for approximate length of insertion, and mark the point with a small piece of tape.

Insert a tube that has been lubricated with sterile water or water-soluble lubricant through either the mouth or one of the nares to the predetermined mark. Because most young infants are obligatory nose breathers, insertion through the mouth causes less distress and helps to stimulate sucking. In older infants and children, the tube is passed through the nose and alternated between nostrils. An in-dwelling tube is almost always placed through the nose.

- When using the nose, slip the tube along the base of the nose and direct it straight back toward the occiput.
- When entering through the mouth, direct the tube toward the back of the throat (see Figure 44.26, *B*).
- If the child is able to swallow on command, synchronize passing the tube with swallowing.
- Confirm placement by X-ray examination, if available. Document pH and colour of aspirate.

Stabilize tube by holding or taping it to the cheek, not to the forehead, because of possible damage to the nostril. To maintain correct placement, measure and record the amount of tubing extending from the nose or mouth to the distal port when the tube is first positioned. Recheck this measurement before each feeding.

Warm formula to room temperature. Do not heat it in the microwave! Document pH and colour of aspirate before each feeding to confirm tube placement. Pour formula into the barrel of the syringe or feeding bag attached to the feeding tube. To start the flow, give a gentle push with the plunger, but then remove the plunger and allow the fluid to flow into the stomach by gravity. The rate of flow should not exceed 5 mL every 5 to 10 minutes in preterm and very small newborns and 10 mL/min in older infants and children to prevent nausea and regurgitation. The rate is determined by the diameter of the tubing and height of the reservoir containing the feeding and is regulated by adjusting the height of the syringe. A usual feeding may take 15 to 30 minutes to complete.

Flush tube with sterile water (1 or 2 mL for small tubes to 5 to 15 mL or more for large ones) or see earlier discussion of flushing for administering medication through nasogastric (NG) tubes in the Guidelines box: Nasogastric, Orogastric, or Gastrostomy Medication Administration in Children to clear it of formula.

Cap or clamp in-dwelling tubes to prevent loss of feeding.

If the tube is to be removed, first pinch it firmly to prevent escape of fluid as the tube is withdrawn. Withdraw the tube quickly.

Position child with their head elevated 30 to 45 degrees or on their right side for 30 to 60 minutes in the same manner as after any infant feeding to minimize the possibility of regurgitation and aspiration. If the child's condition permits, burp the child after the feeding.

Record the feeding, including the type and amount of residual, the type and amount of formula, and how it was tolerated.

For most infant feedings, any amount of residual fluid aspirated from the stomach is refed to prevent electrolyte imbalance, and the amount is subtracted from the prescribed amount of feeding. Check policy or order regarding residual fluid checks prior to feeds. For example, if the infant is to receive 30 mL and 10 mL is aspirated from the stomach before the feeding, the 10 mL of aspirated stomach contents is refed along with 20 mL of feeding. Another method can be used in children. If residual fluid is more than one fourth of the last feeding, return the aspirate and recheck in 30 to 60 minutes. When residual fluid is less than one fourth of the last feeding, give the scheduled feeding. If large amounts of aspirated fluid persist and the child is due for another feeding, notify the health care provider.

Gastrostomy Feeding

Feeding by way of a gastrostomy, or G tube, is a variation of tube feeding that is often used for children in whom passage of a tube through the mouth, pharynx, esophagus, and cardiac sphincter of the stomach is contraindicated or impossible. It is also used to avoid the constant irritation of a gastric tube in children who require tube feeding over an extended period of time. Placement of a gastrostomy tube may be performed with the patient under **general anaesthesia** or percutaneously using an endoscope with the patient sedated and under local anaesthesia (percutaneous endoscopic gastrostomy [PEG]). The tube is inserted through the abdominal wall into the stomach about midway along the greater curvature and secured by a purse-string suture. The stomach is anchored to the peritoneum at the operative site. The tube used can be a Foley, wing-tip, or mushroom catheter. Immediately after surgery the catheter is left open and attached to gravity drainage for 24 hours or more.

Postoperative care of the wound site is directed toward prevention of infection and irritation. The area is cleansed at least daily or as often as needed to keep the area free of drainage and prevent irritation. After healing takes place, meticulous care is needed to keep the area surrounding the tube clean and dry to prevent excoriation and infection. It is important to prevent excessive pull on the catheter that might cause

widening of the opening and subsequent leakage of highly irritating gastric juices. The tube is securely taped to the abdomen, leaving a small loop of tubing at the exit site to prevent tension on the site.

Granulation tissue may grow around a gastrostomy site (Figure 44.27). This moist, beefy red tissue is not a sign of infection. However, if it continues to grow, the excess moisture can irritate the surrounding skin.

For children receiving long-term gastrostomy feeding, a skin-level device (e.g., MIC-KEY, Bard Button) offers several advantages. The small, flexible silicone device protrudes slightly from the abdomen, is more cosmetically pleasing in appearance, affords increased comfort and mobility to the child, is easy to care for, and is fully immersible in water (Figure 44.28). The one-way valve at the proximal end minimizes reflux and eliminates the need for clamping. However, the button requires a well-established gastrostomy site and is more expensive than the conventional tube. In addition, the valve may become clogged. When functioning, the valve prevents air from escaping; thus the child may require frequent burping or venting from the tube. With some devices, during feedings the child must remain fairly still because the tubing easily disconnects from the opening if the child moves. With other devices, extension tubing can be securely attached to the opening. Tubing and extension pieces need to be checked for locking devices to secure the tube in place. The feeding is instilled at the other end of the tubing in a manner similar to that for a regular gastrostomy. The extension tubing may also have a separate medication port. Both the feeding and the medication ports have plugs attached. Some skin-level devices require a special tube to decompress the stomach (to check residual or release air).

Fig. 44.27 Appearance of healthy granulation tissue around stoma.

Fig. 44.28 Child with skin-level gastrostomy device (MIC-KEY), which provides for secure attachment of extension tubing to gastrostomy opening.

Feeding of water, formula, or pureed foods is carried out in the same manner and rate as in gavage feeding. A mechanical pump may be used to regulate the volume and rate of feeding. After feedings, the infant or child is positioned on the right side or in Fowler's position, and the tube may be clamped or left open and suspended between feedings, depending on the child's condition. A clamped tube allows more mobility but is appropriate only if the child can tolerate intermittent feedings without vomiting or prolonged backup of feeding into the tube. Sometimes a Y tube is used to allow for simultaneous decompression during feeding. If a Foley catheter is used as the gastrostomy tube, very slight tension is applied. The tube is securely taped to maintain the balloon at the gastrostomy opening to prevent leakage of gastric contents and to prevent the tube's progression toward the pyloric sphincter, where it may occlude the stomach outlet. As a precaution, the length of the tube should be measured postoperatively and then remeasured each shift to be certain it has not slipped. A mark can be made above the skin level to further ensure its placement. When the gastrostomy tube is no longer needed, it is removed; the skin opening usually closes spontaneously by contracture.

Nasoduodenal and Nasojejunal Tubes

Children at high risk for regurgitation or aspiration, such as those with gastroparesis, mechanical ventilation, or brain injuries, may require placement of a postpyloric feeding tube. Insertion of a nasoduodenal or nasojejunal tube is done by a trained practitioner because of the risk of misplacement and potential for perforation in tubes requiring a stylet. Accurate placement is verified by radiography. Small-bore tubes may easily clog. The tube needs to be flushed when feeding is interrupted, before and after medication administration, and routinely every 4 hours or as directed by institutional policy. Tube replacement should be considered monthly to ensure optimal tube patency. Continuous feedings are delivered by mechanical pump to regulate volume and rate. Bolus feeds are contraindicated. Tube displacement is suspected if the child shows signs of feeding intolerance, such as vomiting. Feedings should be stopped and the primary care provider notified.

Total Parenteral Nutrition

TPN provides for the total nutritional needs of infants or children when feeding by the gastrointestinal tract is impossible, inadequate, or hazardous. Some common conditions associated with TPN include chronic intestinal obstruction, inadequate intestinal length, and prophylactically after surgery or during critical illness.

TPN therapy involves IV infusion of highly concentrated solutions of protein, glucose, and other nutrients. The solution is infused through conventional tubing with a special filter attached to remove particulate matter or microorganisms that may have contaminated the solution. The highly concentrated solutions require infusion into a vessel with sufficient volume and turbulence to allow for rapid dilution. The wide-diameter vessels selected are the superior vena cava and innominate or intrathoracic subclavian veins, approached by way of the external or internal jugular veins. The highly irritating nature of concentrated glucose precludes the use of the small peripheral veins in most instances. However, dilute glucose-protein hydrolysates that are appropriate for infusing into peripheral veins are being used with increasing frequency. When peripheral veins are used, intralipid becomes the major calorie source. For long-term alimentation CVCs are usually used.

The major nursing responsibilities are the same as for any IV therapy: control of sepsis, monitoring of the infusion rate, and assessment

of the patient. The TPN solution must be prepared under sterile conditions, by specially trained technicians. Nurses trained in TPN management should change the solution and tubing and redress the infusion using meticulous aseptic precautions. The procedure is carried out according to hospital protocol.

The infusion is maintained at a constant rate by an infusion pump to ensure the proper concentrations of glucose and amino acids. Accurate calculation of the rate is required to deliver a measured amount over a given length of time. Because alterations in flow rate are relatively common, the drip should be checked frequently to ensure an even, continuous infusion. The TPN infusion rate should not be increased or decreased without the health care provider being informed, since alterations can cause hyperglycemia or hypoglycemia.

General assessments, such as vital signs, I&O measurements, and laboratory tests, facilitate early detection of infection or fluid and electrolyte imbalance. Additional amounts of potassium and sodium chloride are often required in hyperalimentation; therefore, observation for signs of potassium or sodium deficit or excess is part of nursing care. This is rarely an issue except in children with reduced renal function or metabolic defects. **Hyperglycemia** may occur during the first day or two as the child adapts to the high-glucose load of the hyperalimentation solution. Although hyperglycemia occurs infrequently, insulin may be required to assist the body's adjustment. When this occurs, nursing responsibilities include blood glucose testing. To prevent hypoglycemia at the time the hyperalimentation is disconnected, the rate of the infusion and the amount of insulin are decreased gradually.

Family Teaching and Home Care

When alternative feedings are needed for an extended period, the family may need to learn how to feed the child with a nasogastric, gastrostomy, or TPN feeding regimen. Ample time must be allowed for the family to learn and perform the procedures under supervision before assuming full responsibility for the child's care at home (see Chapter 41 for further information on home care).

PROCEDURES RELATED TO ELIMINATION

Enema

The procedure for giving an enema to an infant or child does not differ essentially from that for an adult, except for the type and amount of fluid administered and the distance for inserting the tube into the rectum (see Guidelines box: Administration of Enemas to Children). Depending on the volume, a syringe with rubber tubing, an enema bottle, or an enema bag should be used.

GUIDELINES

Administration of Enemas to Children

Age	Amount (mL)	Insertion Distance
Infant	120–240	2.5 cm
2–4 years	240–360	5 cm
4–10 years	360–480	7.5 cm
11+ years	480–720	10 cm

An isotonic solution is used in children. Plain water is not used because, being hypotonic, it can cause rapid fluid shift and fluid overload. The Fleet enema (pediatric or adult sized) is not advised for children because of the harsh action of its ingredients (sodium biphosphate and sodium phosphate). Commercial enemas can be dangerous to patients with megacolon and to dehydrated or azotemic children. The osmotic effect of the Fleet enema may produce diarrhea, which can lead to metabolic **acidosis**. Other potential complications are extreme hyperphosphatemia, hypernatremia, and hypocalcemia, which may lead to neuromuscular irritability and coma.

Because infants and young children are unable to retain the solution after it is administered, the buttocks must be held together for a short time to retain the fluid. The enema is administered and expelled while the child is lying with the buttocks over the bedpan and with the head and back supported by pillows. Older children are usually able to hold the solution if they understand what to do and if they are not expected to hold it for too long. The nurse should have the bedpan handy or, for the ambulatory child, ensure that the bathroom is available before beginning the procedure. An enema is an intrusive procedure and thus threatening to the preschool child; a careful explanation is especially important to ease possible fear.

A preoperative bowel preparation solution given orally or through an NG tube is increasingly being used instead of an enema. The polyethylene glycol–electrolyte lavage solution (GoLYTELY) mechanically flushes the bowel without significant absorption, thereby avoiding potential fluid and electrolyte imbalance. NuLYTELY, a newer form of GoLYTELY, has the same therapeutic effect but tastes better. Magnesium citrate solution is another effective cathartic.

Ostomies

Children may require stomas for various health conditions. The most frequent causes in infants are necrotizing enterocolitis, imperforate anus, and, less often, Hirschsprung disease. In older children the most frequent causes are inflammatory bowel disease, especially Crohn disease (regional enteritis), and ureterostomies for distal ureter or bladder defects.

Care and management of ostomies (ileostomy and colostomy) in the older child differ little from the care of ostomies in the adult patient. The major emphases in pediatric care are preparing the child for the procedure and teaching care of the ostomy to the child and family. The basic principles of preparation are the same as for any procedure. Simple, straightforward language is most effective, together with the use of illustrations and a replica model, such as drawing a picture of a child with a stoma on the abdomen and explaining it as "another opening where bowel movements [or any other term the child uses] will come out." At another time the nurse can draw a pouch over the opening to demonstrate how the contents are collected. Using a doll to demonstrate the process is an excellent teaching strategy, and special books are available.

Children with ostomies are fitted immediately after surgery with an appliance to protect the skin from the proteolytic enzymes in the liquid stool. Infants may not be fitted with a pouch in the immediate postoperative period. When stomal drainage is minimal, a gauze dressing will suffice. Pediatric appliances are available in a variety of sizes to ensure an adequate fit.

Ostomy equipment consists of a one- or two-piece system with a hypoallergenic skin barrier to maintain peristomal skin integrity. The pouch should be large enough to contain a moderate amount of stool and flatus but not so large as to overwhelm the infant or child. A backing helps minimize the risk of skin breakdown from moisture trapped between the skin and pouch. Use of small clips or rubber bands should be avoided to prevent choking in the young child.

Protection of the peristomal skin is a major aspect of stoma care. Well-fitting appliances are important to prevent leakage of contents. Before the appliance is applied, the skin is prepared with a skin sealant

that is allowed to dry. Stoma paste may also be applied around the base of the stoma or the back of the wafer. The sealant and paste work together to prevent peristomal skin breakdown.

In infants with a colostomy left unpouched, skin care is similar to that of any diapered infant. However, the peristomal skin is protected with a wafer barrier, such as a hydrocolloid dressing (e.g., DuoDERM) or a barrier substance (e.g., zinc oxide ointment [Desitin], or a mixture of the zinc oxide ointment and stoma [Stomahesive] powder). A diaper larger than the one usually worn may be needed to extend upward over the stoma and absorb drainage. If the skin becomes inflamed, denuded, or infected, the care is similar to the interventions used for diaper dermatitis (see Chapter 52, Diaper Dermatitis). A zinc-based product helps protect healthy skin, heal excoriated skin, and minimize pain associated with skin breakdown. The skin protectant adheres to denuded, weeping skin. The nurse can apply zinc-based products over topical antifungal and antibacterial agents if infection is present. No-sting barrier film is a skin sealant that has no alcohol base and can be used on open skin without stinging.

Preventing young children from pulling off the pouch is also an important consideration. One-piece outfits keep exploring hands from reaching the pouch, and the loose waist prevents any pressure on the appliance. Keeping the child occupied with toys during the pouch change is also helpful. As children mature, their participation in ostomy care should be encouraged. Even preschoolers can assist by holding supplies, pulling paper backings from the appliance, and helping clean the stoma area. Toilet learning for bladder control needs to begin at the appropriate time as for any other child.

Older children and adolescents should eventually have total responsibility for ostomy care, just as they would for usual bowel function. Adolescents may have concerns about body image and the ostomy's impact on intimacy and sexuality. The nurse should stress to teenagers that the presence of a stoma need not interfere with their activities. These youngsters can choose which ostomy equipment is best suited to their needs. Attractively designed and decorated pouch covers are well liked by teenagers.

Children with familial adenomatous polyposis may require a colectomy with ileoanal reservoir to prevent or treat carcinoma of the colon. Peristomal skin care for these children is particularly challenging because of increased liquid stools, increased digestive enzymes that may cause skin breakdown, and the stoma being at skin level rather than raised. Additional care with this condition includes close monitoring of fluid and electrolyte status and for increased incidence of bowel obstruction.

An enterostomal therapy nurse specialist is an important member of the health care team for these children and will have additional suggestions and skin care information and ostomy pouching options. Further information may be obtained by contacting the Wound, Ostomy and Continence Nurses Society (see Additional Resources at the end of this chapter).

Family Teaching and Home Care

Because these children are almost always discharged with a functioning ostomy, preparation of the family should begin as early as possible in the hospital. The family needs to be instructed in application of the device (if used), care of the skin, and appropriate action in case skin conditions develop. Reviewing relevant Internet videos and resources may be helpful for some families providing hands-on care (see Additional Resources). Early evidence of skin breakdown or stomal complications, such as ribbonlike stools, excessive diarrhea, bleeding, prolapse, or failure to pass flatus or stool, should be brought to the attention of the health care provider, the nurse, or the stoma specialist. The same principles are applied for discharge planning and home care.

KEY POINTS

- Before undergoing any invasive procedure, the patient (if old enough to comprehend) and the patient's legal surrogate must receive sufficient information on which to make an informed health care decision (informed consent). In Canada there is no age of consent, except for in Québec, where it is 14 years.
- Informed consent is needed for major surgery, minor surgery, and diagnostic tests and medical treatments with an element of risk.
- The major principles in psychological preparation of the child for procedures are to establish trust, provide support, and give an explanation in easy-to-understand terms.
- Preparation for procedures should be based on developmental characteristics of the child and knowledge of the family, emphasizing the importance of the parents' role.
- Most parents and children want to be together during stressful procedures and should be offered this opportunity, along with guidance on how the parent can comfort the child.
- The use of play activities to provide teaching about necessary nursing and medical interventions is an effective aid in providing such care in children.
- In performing a procedure, the nurse should expect success, involve the child when possible in the procedure, provide distraction, and allow for expression of feelings.
- Proper positioning of infants and small children for procedures is essential to minimize movement and discomfort.
- In giving postprocedural support, the nurse should encourage children to express feelings and should give praise for completion of the procedure.
- Stressful times before and after surgery that produce anxiety in children are admission, blood tests, injection of preoperative medication (if used), transportation to the operating room, and return from the PACU.
- Knowledge of the ill child's eating habits and favourite foods can help in maintaining adequate nutrition.
- Skin care is essential to prevent skin breakdown.
- Control of fever may be accomplished by administration of antipyretics; hyperthermia is controlled by environmental means (minimum clothing, increased air circulation, hypothermia mattress, or cool compresses).
- Infection control is based on two systems. Routine practices provide protection when the infected person is undiagnosed. Additional precautions add extra interventions for patients diagnosed with or suspected of having an infection.
- Ensuring safety in the hospital setting is a major concern and can be achieved through environmental measures, limit setting, infection control, and safe transportation.
- Restraints should be used with caution and require a medical order. Use of therapeutic holding can avoid the use of restraints.
- Factors that affect medication dosage are growth and maturation, difficulty in evaluating a medication response, and BSA.
- Family teaching regarding medication administration includes teaching parents why the child is receiving the medication; its possible effects; and the amount, frequency, and length of time it is to be administered.
- The preferred sites for intramuscular injection in children are the vastus lateralis and ventrogluteal areas.
- Intermittent venous access is accomplished by means of a peripheral intermittent infusion device, a peripherally inserted central catheter, a central venous catheter, or an implanted port.
- Several safety catheters and needleless device systems are available to reduce the risk of needlestick injuries in patients and caregivers.

- Nursing assessment of fluid and electrolyte disturbances entails observation of general appearance, vital signs, and measurement of I&O.
- Oxygen can be administered by hood, mask, nasal cannula, or ventilator.
- Tracheostomy suctioning involves premeasured insertion of the catheter, application of suction for 5 seconds when withdrawing the catheter, and supplemental oxygen before and after suctioning.
- Alternative forms of feeding include gavage feeding, gastrostomy feeding, and TPN.
- In the care of children with ostomies, nurses play an important role in family support and instruction in care of the stoma site.

Respiratory Conditions

Cheryl Sams
Originating US Chapter by *Cheryl R. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify the factors leading to respiratory tract infection in the infant and young child.
2. Contrast the effects of various respiratory infections observed in infants and children.
3. Describe the postoperative nursing care of the child with an adenotonsillectomy.
4. Outline the nursing care for a child with croup.
5. Outline the nursing care for a child with acute otitis media.
6. Describe the nursing care for a child with a lower respiratory tract infection.
7. Demonstrate an understanding of the ways in which inhalation of noninfectious irritants produce pulmonary dysfunction.
8. Describe the ways in which various therapeutic measures relieve the symptoms of asthma.
9. Outline a plan for teaching home care for the child with asthma.
10. Describe the physiological effects of cystic fibrosis on the gastrointestinal, endocrine, reproductive, and pulmonary systems.
11. Outline a plan of care for the child with cystic fibrosis.
12. Describe congenital respiratory disorders and the appropriate nursing care.
13. List the major signs of respiratory distress in infants and children.
14. Describe the nursing care for a child with respiratory failure.

RESPIRATORY INFECTION

General Aspects of Respiratory Infections

Infections of the respiratory tract are described according to the anatomical area of involvement. The *upper respiratory tract*, or *upper airway*, consists of the oronasopharynx, pharynx, larynx, and upper part of the trachea. The *lower respiratory tract* consists of the lower trachea, mainstem bronchi, segmental bronchi, subsegmental bronchioles, terminal bronchioles, and alveoli. In this discussion, the trachea is considered with lower tract disorders, and infections of the epiglottis and larynx are categorized as croup syndromes. However, respiratory infections seldom fall into discrete anatomical areas. Infections often spread from one structure to another because of the adjoining nature of the mucous membrane lining the entire tract. Consequently, respiratory tract infections involve several areas, although the effect on one area may predominate in any given illness.

Etiology and Characteristics. Respiratory infections account for the majority of acute illnesses in children. The etiology and course of these infections are influenced by the age of the child, the season, living conditions, and pre-existing medical conditions.

Infectious agents. The respiratory tract is subject to a wide variety of infective organisms. Most infections are caused by viruses, particularly respiratory syncytial virus (RSV), rhinovirus, nonpolio enteroviruses A, B, C, and D (formerly coxsackieviruses A and B), adenoviruses, parainfluenza viruses, and human meta-pneumoviruses. Other agents involved in primary or secondary invasion include group A beta-hemolytic streptococci (GABHS), staphylococci, *Haemophilus influenzae*, *Haemophilus influenzae, Chlamydia trachomatis*, *Mycoplasma* organisms, and pneumococci.

Age. Healthy full-term infants younger than 3 months of age are presumed to have a lower infection rate than that of older children because of the protective function of maternal **antibodies**. However, infants may be susceptible to specific respiratory tract infections, namely pertussis, during this period. The infection rate increases between 3 and 6 months of age, the time between the disappearance of maternal antibodies and before the infant's own antibody production matures. The Canadian Paediatric Society (CPS) (2016) notes that it is not unusual for children to get as many as 8 to 10 colds each year before they turn 2 years of age. The viral infection rate remains high during the toddler and preschool years. By 5 years of age, viral respiratory infections are less frequent, but the incidence of *Mycoplasma pneumoniae*

and GABHS infections increases. The amount of lymphoid tissue increases through middle childhood, and repeated exposures to organisms increase the level of immunity as a child grows older.

Some viral or bacterial agents produce a mild illness in older children but severe lower respiratory tract illness or croup in infants. For example, pertussis causes a relatively harmless tracheobronchitis in childhood but is a serious disease in infancy.

Size. Anatomical differences influence the response to respiratory tract infections. The diameter of the airways is smaller in young children and subject to considerable narrowing from edematous mucous membranes and increased production of secretions. The distance between structures within the respiratory tract is also shorter in the young child, and organisms may move rapidly down the respiratory tract, causing more extensive involvement. The relatively short and open eustachian tube in infants and young children allows **pathogens** easy access to the middle ear.

Resistance. The ability to resist invading organisms depends on several factors. Passive immunity is passed on from the mother at birth but diminishes in the first few weeks and months after birth. Infants produce their own antibodies whenever they are exposed to a virus or bacteria, but it takes time for this immunity to fully develop. Children who are breastfed have increased resistance to infections because they are still receiving immunity from the mother through breast milk. Deficiencies of the **immune system** place the child at risk for infection. Other conditions that decrease resistance are malnutrition, anemia, and fatigue. Conditions that weaken defences of the respiratory tract and predispose children to infection include allergies (e.g., allergic rhinitis), preterm birth, bronchopulmonary dysplasia (BPD), asthma, history of RSV infection, cardiac anomalies that cause pulmonary congestion, and cystic fibrosis (CF). Day care attendance and exposure to secondhand smoke also increases the likelihood of infection.

Seasonal variations. The most common respiratory pathogens appear in epidemics during the winter and spring months. Mycoplasmal infections occur more often in autumn and early winter. Infection-related asthma (e.g., asthmatic bronchitis) occurs more frequently during cold weather, whereas winter and spring are typically the "RSV seasons."

Clinical Manifestations. Infants and young children, especially those between 6 months and 3 years of age, react more severely to acute respiratory tract infection than older children. Young children display a number of generalized signs and symptoms and local manifestations (Box 45.1).

Nursing Care. Assessment of the respiratory system follows the guidelines described in Chapter 33 (for assessment of the ear, nose, mouth and throat, chest, and lungs). The assessment should include respiratory rate, depth, and rhythm; heart rate; oxygenation; hydration status; body temperature; activity level; and level of comfort. Special attention should be given to the components and observations listed in Box 45.2. A noninvasive pulse oximeter (oxygen saturation) measurement should be performed on all children as part of the routine physical assessment. The nursing process in the case of the child with acute respiratory tract infection is outlined in the Nursing Care Plan on the Evolve site.

Easing respiratory efforts. Many acute respiratory infections are mild and cause few symptoms. Although children may feel uncomfortable and have a "stuffy" nose (congestion) and some mucosal swelling, respiratory distress occurs infrequently. Interventions delivered at home are usually sufficient to relieve minor discomfort and ease respiratory efforts. However, in some cases, the infant or child may require close observation in hospital to ensure adequate oxygenation and for maintenance of fluid and electrolyte status.

Warm or cool mist is a common therapeutic measure for symptomatic relief of respiratory discomfort. The moisture soothes inflamed membranes and is beneficial when there is hoarseness or laryngeal involvement. However, the use of hot steam vaporizers in the home is not recommended because of burn hazard and limited evidence to support their efficacy (Himdani et al., 2016). As well, cool-mist vaporizers are not recommended because of the hazard of contamination from mould and bacteria unless disinfected daily.

A time-honoured method of producing warm steam is the shower. Running a shower of hot water into the empty bathtub or open shower stall with the bathroom door closed produces a quick source of steam. Keeping a child in this environment for 10 to 15 minutes humidifies inspired air and can help relieve symptoms. A small child can be held on the lap of a caregiver. Older children can sit in the bathroom under the supervision of an adult. Maintaining a calming environment will assist in preventing increased respiratory efforts related to emotional distress of the child.

Promoting rest. Children who have an acute febrile illness usually have limited activity. One of the cardinal signs that the child is feeling better is their increase in activity; this may, however, be temporary if a high fever returns after a few hours of increased activity. Children should be encouraged to rest or play quietly to avoid exacerbating symptoms.

Promoting comfort. Older children are usually able to manage nasal secretions with little difficulty. For very young infants, who normally breathe through their noses, an infant nasal aspirator or a bulb syringe is helpful in removing nasal secretions, especially before being put to bed to sleep and before feeding. This practice, preceded by instillation of saline nose drops as needed, may clear nasal passages and promote feeding. Saline nose drops can be prepared at home by dissolving 5 mL of salt in 1 L of warm water. Two to three drops of saline can be put into the nostril, and a bulb syringe can be used to suction it out. Bottles of nose drops should be used for only one child and one illness because they are easily contaminated with bacteria.

Medicated nose drops or sprays, oral decongestants, cough medication, or other cold products should not be administered to children under 6 years of age except after discussion with the health care provider. These medications should also not be given without discussion with the primary health care provider to children over 6 years of age taking other medications or who have a chronic illness. Medicated nose drops or sprays provide only short-lived relief and should not be used for more than 2 to 3 days because they can worsen congestion with a rebound effect.

Hot or cold applications sometimes provide relief for children with painful cervical adenitis. An ice pack or heating pad applied to the neck may decrease the discomfort, but safety precautions must be observed to prevent burns and frostbite. The ice bag or heating device must be covered, and the heating pad should not be set at high settings.

Reducing the spread of infection. Thorough hand hygiene is important when caring for children with respiratory tract infections. Children and families should be taught to cough or sneeze into their arm. Remembering to cover the nose or mouth is often difficult for toddlers; they should be encouraged to wash their hands frequently to prevent the spread of infection. Used tissues should be thrown into the wastebasket immediately, and tissues should not be allowed to accumulate in a pile. Children with respiratory infections should not share drinking cups, utensils, washcloths, or towels. To decrease contamination, children need to wash their hands frequently and not touch their eyes or nose with their hands. Parents should also keep affected children out of school or day care settings to prevent the spread of infection. Well children should be taught

BOX 45.1 Signs and Symptoms Associated With Respiratory Infections in Infants and Small Children

Fever
May be absent in newborns (<28 days of age)
Greatest at ages 6 months to 3 years
Temperature may reach 39.5° to 40.5°C (103° to 105°F) even with mild infections
Often appears as first sign of infection
May appear listless and irritable with altered activity pattern
Tendency to develop high temperatures with infection in certain families
May precipitate febrile seizures (see Chapter 50)

Poor Feeding and Anorexia
Common with most childhood illnesses
Frequently the initial evidence of illness
Persists to a greater or lesser degree throughout febrile stage of illness; often extends into convalescence

Vomiting
Common in small children with illness
A clue to onset of infection
May precede other signs of infection by several hours
Usually short-lived but may persist during the illness
Frequent cause of dehydration if fluid intake is impaired

Diarrhea
Usually mild, transient diarrhea but may become severe
Often accompanies viral respiratory infections
Frequent cause of dehydration

Abdominal Pain
Common symptom
Sometimes indistinguishable from pain of appendicitis
May represent referred pain (e.g., chest pain associated with pneumonia)
May be caused by mesenteric lymphadenitis
May be linked to muscle spasms from vomiting, especially in nervous, tense child

Nasal Blockage
Small nasal passages of infants easily blocked by mucosal swelling and exudation
Can interfere with respiration and feeding in infants
May contribute to development of otitis media and sinusitis

Nasal Discharge
Frequent occurrence
May be thin and watery (rhinorrhea) or thick and purulent
Depends on type or stage of infection
Associated with itching
May irritate upper lip and skin surrounding the nose

Cough
Common feature can be either congested in nature or a dry, hacky consistency
May be evident only during acute phase
May persist several months after a disease

Respiratory Sounds
Sounds associated with respiratory disease:
- Cough
- Hoarseness
- Grunting
- Stridor
- Wheezing

Findings on auscultation:
- Wheezing
- Crackles
- Absence of breath sounds (air movement)

Sore Throat
Frequent symptom of older children
Young children (unable to describe symptoms) may not state it is sore even when highly inflamed
Often accompanied by refusal to take oral fluids or solids

Meningismus
Meningeal signs without infection of the meninges
Occurs with abrupt onset of fever
Accompanied by the following:
- Headache
- Pain and stiffness in the back and neck
- Presence of Kernig and Brudzinski signs

Signs subside as temperature decreases

to stay away from ill children, to wash their hands frequently, and to avoid eating and drinking with the same utensils or cups used by ill children.

Reducing temperature. If the child has a significantly elevated body temperature, the fever needs to be controlled. Parents need to know how to take a child's temperature and read the thermometer accurately. Nurses should not assume that all parents can read a thermometer and should provide education when needed.

If the health care provider prescribes acetaminophen or ibuprofen, parents may need instruction on how to administer the medication. Most parents can read the label and calculate the desired dose, but parents of infants and toddlers may require detailed instruction and dosing parameters. It is important to emphasize accuracy in determining both the amount of medication to be given and the time intervals for administration. The child can be given cool liquids to help reduce the core temperature and minimize the risk of dehydration (see Controlling Elevated Temperatures, Chapter 44).

! NURSING ALERT

Acetaminophen is an appropriate medication for fever, pain, and aches, and it can be given every 4 hours up to five times in 24 hours if the child is not dehydrated. Ibuprofen can be used as well if the child is over 6 months, or in younger children if approved by a health care provider, and can be given every 6 to 8 hours up to four times in a 24-hour period. Caution parents about the use of over-the-counter combination "cold" remedies, since these often include acetaminophen. Careful calculation of both the acetaminophen given separately and the acetaminophen in combination medications is necessary to avoid an overdose.

Promoting hydration. Dehydration is a potential complication when children have respiratory tract infections and are febrile or anorexic, especially when vomiting or diarrhea is present. Infants are especially prone to fluid and electrolyte deficits when they have a

BOX 45.2 Components for Assessing Respiratory Function

Pattern of Respirations

Rate—Rapid (*tachypnea*), normal, or slow (*bradypnea*) for the particular child

Depth—Normal depth, too shallow (*hypopnea*), too deep (*hyperpnea*); usually estimated from the amplitude of thoracic and abdominal excursion

Ease—Effortless; laboured (*dyspnea*); difficult breathing except in upright position (*orthopnea*); associated with intercostal or substernal retractions (inspiratory "sinking in" of soft tissues in relation to the cartilaginous and bony thorax); pulsus paradoxus (blood pressure falling with inspiration and rising with expiration); nasal flaring; head bobbing (head of sleeping child with suboccipital area supported on caregiver's forearm bobs forward in synchrony with each inspiration); grunting, wheezing, or stridor

Laboured breathing—Continuous, intermittent, becoming steadily worse, sudden onset, at rest or on exertion, associated with wheezing or grunting, can be associated with pain

Rhythm—Variation in rate and depth of respirations

Other Observations

In addition to respirations, particular attention is addressed to the following:

Evidence of infection—Check for elevated temperature; enlarged cervical lymph nodes; inflamed mucous membranes; and purulent discharges from the nose, ears, or lungs (sputum).

Cough—Observe characteristics of cough (if present): under what circumstances cough is heard (e.g., night only, on arising), nature of cough (paroxysmal with or without wheeze, "barking like a seal" or "brassy"), frequency of cough, associated with swallowing or other activity, character of cough (moist or dry), and productivity.

Wheeze—Note if expiratory or inspiratory, high-pitched or musical, prolonged, slowly progressive or sudden, associated with laboured breathing.

Stridor—A high-pitched wheezing sound; it may be present on inspiration, exhalation, or both and is a sign of upper airway edema or obstruction by mass or object.

Cyanosis—Note distribution (peripheral, circumoral, facial, trunk, and face), degree, duration, and whether associated with activity or feeding (infant).

Abdominal pain—May be a symptom in preschooler and school-age children; it probably represents referred pain from the chest; it may be a symptom in children with pneumonia.

Chest pain—May be a symptom in older children; note location and circumstances: localized or generalized, referred to base of neck or abdomen, dull or sharp, deep or superficial, associated with rapid, shallow respirations or grunting.

Sputum—Older children may provide a sputum sample by coughing, whereas young children may need bulb suction to provide a sample; note volume, colour, viscosity, and odour.

Bad breath (*halitosis*)—May be associated with some lung infections.

respiratory illness, because a rapid respiratory rate that accompanies such illnesses precludes adequate fluid intake. In addition, the presence of fever in infants increases total body fluid turnover. Nasal secretions in the infant further prevent adequate respiratory effort by blocking the narrow nasal passages; when the infant reclines to feed, the compensatory mouth breathing effort ceases, causing the child to limit intake of fluids.

Adequate fluid intake is encouraged by offering small amounts of favourite fluids (clear liquids if vomiting) at frequent intervals. Breastfeeding infants should continue to be breastfed because human milk confers some degree of protection from infection (see Chapter 27). Oral rehydration solutions, such as Infalyte, Pedialyte, or other pediatric rehydration brands, should be considered for infants, and water or a low-carbohydrate (<5 g per 240 mL) flavoured drink should be considered for older children. Intake of fluids with caffeine (tea, coffee, and cola) should be avoided because these may act as a diuretic and promote fluid loss. Sports drinks and energy drinks are not recommended for oral rehydration (Pound et al., 2017), although some sports drinks may be diluted for older children. Fluids should not be forced on children because this creates the same issue as urging unwanted food. Gentle persuasion with preferred beverages or sugar-free popsicles is usually more successful. Younger children may like to drink smaller amounts from a plastic medicine cup.

To assess their child's level of hydration, parents are advised to observe the frequency of voiding and to notify a health care provider if there is insufficient voiding (see also Chapter 46, Dehydration). Counting the number of wet diapers in a 24-hour period is a satisfactory method to assess output for infants and toddlers. In the hospital, diapers are weighed to assess output, which should be at least 1 to 2 mL/kg per hour in younger children and at least 30 mL per hour in older patients. The health care provider should be notified if the urine output is low.

Providing nutrition. Loss of appetite is characteristic of children with acute infections. In most cases children can be permitted to determine their own need for food. Many children show no decrease in appetite, and others respond well to foods such as gelatin, soup, and puddings (see Feeding the Sick Child, Chapter 44). Urging foods for children who are sick may precipitate nausea and vomiting and cause an aversion to feeding that can extend into the convalescent period and beyond.

Encouraging family support and home care. Young children with respiratory tract infections may be irritable and difficult to comfort; therefore, the family needs support, encouragement, and practical suggestions for comfort measures and administration of medication. In addition to **antipyretics** and nose drops, the child may require antibiotic therapy. Parents of children receiving oral antibiotics must understand the importance of regular administration and continuing the medication for the prescribed length of time, regardless of whether the child appears ill. Parents should be cautioned against giving their child any medications that are not approved by the health care provider and to avoid giving antibiotics left over from a previous illness or prescribed for another child. Administering unprescribed antibiotics can produce serious adverse effects and lead to the development of new antibiotic-resistant organisms (see Chapter 44 for administration of medications and related parent teaching).

UPPER RESPIRATORY TRACT INFECTIONS

Nasopharyngitis

Acute nasopharyngitis (the equivalent of the "common cold") is caused by rhinovirus, RSV, adenovirus, enterovirus, influenza virus, and parainfluenza virus. Symptoms are more severe in infants and children than in adults. Fever is common in young children, and older children have low-grade fevers, which appear early in the course of the illness. Other clinical manifestations are listed in Box 45.3. Symptoms may last up to 10 days or longer.

Therapeutic Management and Nursing Care. Children with nasopharyngitis are managed at home. There is no specific treatment, and effective vaccines are not available. Antipyretics are prescribed for

BOX 45.3 Clinical Manifestations of Nasopharyngitis and Pharyngitis

Nasopharyngitis

Younger Child

Fever
Irritability, restlessness
Poor feeding and decreased fluid intake
Sneezing
Mouth breathing from abundant nasal mucus
Nasal mucus (abundant) causing mouth breathing
Vomiting and diarrhea

Older Child

Dryness and irritation of nose and throat
Nasal discharge causing mouth breathing
Sneezing, chilling sensation
Muscular aches
Cough (productive/nonproductive), sometimes

Physical Signs

Edema and vasodilation of mucosa

Pharyngitis

Younger Child

Fever
General malaise
Anorexia
Moderate sore throat
Headache

Older Child

Fever (may reach 40°C [104°F])
Headache
Anorexia
Dysphagia
Abdominal pain
Vomiting

Physical Signs

Younger Child

Mild to moderate hyperemia

Older Child

Mild to bright red, edematous pharynx
Hyperemia of tonsils and pharynx; may extend to soft palate and uvula
Often abundant follicular exudate that spreads and coalesces to form pseudomembrane on tonsils
Cervical glands enlarged and tender

mild fever and discomfort (see Chapter 44 for management of fever). Rest is recommended.

Cough suppressants containing dextromethorphan should be used with caution (cough is a protective way of clearing secretions) but may be prescribed every 6 to 8 hours for a dry, hacking cough, especially at night. However, some preparations contain 22% alcohol and can cause adverse effects such as confusion, hyperexcitability, dizziness, nausea, and sedation. Parents should monitor the child carefully for potential adverse effects. Despite the widespread use of over-the-counter (OTC) cough and cold medications, the effectiveness of most of these medications has not been proven in children and they are potentially harmful (Goldman & Canadian Paediatric Society [CPS], Drug Therapy and Hazardous Substances Committee, 2011/2019). Several alternatives, such as fluids, humidified air, nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines, echinacea, zinc and vitamin C, have been investigated and show little benefit in the pediatric population. Honey may have beneficial effects, but dosing is yet to be determined (Goldman & CPS, Drug Therapy and Hazardous Substances Committee, 2011/2019).

Antihistamines are largely ineffective in treatment of nasopharyngitis. These medications have a weak atropine-like effect that dries secretions, but they can cause drowsiness or, paradoxically, have a stimulatory effect on children. Second-generation antihistamines such as loratadine or cetirizine are nonsedating but also have not been shown to be effective in relieving the symptoms of the common cold in small children and are not recommended. There is no support for the usefulness of expectorants, and antibiotics are usually not indicated because most infections are viral.

Most discomfort of nasopharyngitis is related to the nasal obstruction, especially in small infants. Elevating the head of the bed or crib mattress assists with drainage of secretions. Suctioning and vaporization may also provide relief. Saline nose drops and gentle suction with a bulb syringe before feeding and sleep time may be useful. Maintaining adequate fluid intake is essential. Although a child's appetite for solid foods is usually diminished for several days, it is important to offer appropriate fluids to prevent dehydration. The combination of supportive treatment with antipyretics, nasal saline irrigation, elevating the head of bed to promote drainage of secretions, and adequate fluid hydration is still the safest and most often recommended therapy for infants and small children with the common cold. Parents should know the signs of respiratory complications (Box 45.4) and should notify a health care provider if complications occur. Because nasopharyngitis is spread from secretions, the best means of prevention is avoiding contact with affected people (see Reducing the Spread of Infection above).

BOX 45.4 Early Evidence of Respiratory Complications

Parents should be instructed to notify their primary health care provider if any of the following are noted:

If child is less than 3 months of age:

- Is having trouble breathing,
- Is not eating or is vomiting, or
- Has a fever (temperature of 38.5°C or higher)

In children of all ages:

- Is breathing rapidly or seems to be working hard to breathe,
- Has blue lips,
- Is coughing so bad that they are choking or vomiting,
- Wakes in the morning with one or both eyes stuck shut with dried yellow pus,
- Is much sleepier than usual, doesn't want to feed or play, or is very fussy and cannot be comforted, or
- Has thick or coloured (yellow, green) discharge from the nose for more than 10 to 14 days.

Adapted from Caring for Kids (2016). *Colds in children.* https://www.caringforkids.cps.ca/handouts/colds_in_children.

Acute Streptococcal Pharyngitis

Acute infectious pharyngitis can be caused by many bacteria or viruses. GABHS infection is the most common causative organism for this infection. Children who experience GABHS infection of the upper airway (strep throat) are at risk for *rheumatic fever* (RF), an inflammatory disease of the heart, joints, and central nervous system (CNS) (see Chapter 47), and *acute glomerulonephritis* (AGN), an acute kidney infection (see Chapter 49). Permanent damage can result from these sequelae, especially with RF. GABHS may also cause skin manifestations, including impetigo or pyoderma.

Clinical Manifestations. GABHS is generally a relatively brief illness that varies in severity from subclinical (no symptoms) to severe toxicity. The onset is often abrupt and characterized by pharyngitis, headache, fever, and abdominal pain (especially in small children). The tonsils and pharynx may be inflamed and covered with exudate (Figure 45.1), which usually appears by the second day of illness. However, streptococcal infections should be suspected in children older than 2 years of age who have pharyngitis without exudate or nasal symptoms. The tongue may appear edematous and red ("strawberry tongue"), and the child may have a fine sandpaper rash on the trunk, axillae, elbows, and groin, seen in scarlet fever (caused by a strain of group A streptococcus). The uvula is edematous and red. Anterior cervical lymphadenopathy (in about 30 to 50% of cases) usually occurs early, and the nodes are often tender. Pain can be relatively mild to severe enough to make swallowing difficult. Clinical manifestations usually subside in 3 to 5 days unless complicated by sinusitis or parapharyngeal, peritonsillar, or retropharyngeal abscesses. Nonsuppurative complications may appear after the onset of GABHS (i.e., AGN in about 10 days and RF in an average of 18 days).

Children who are GABHS carriers may have a positive throat culture but often experience a coincidental viral illness.

Diagnostic Evaluation. Although 80 to 90% of all cases of acute pharyngitis are viral, a throat culture or rapid streptococcal identification test should be performed to rule out GABHS. A throat culture or rapid test should not be done if the child has cold symptoms (rhinorrhea, cough, or hoarseness of voice) as that indicates that the child is likely a carrier, does not have an acute infection, and will not benefit from taking antibiotics (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2014/2020). Most streptococcal infections are short-term illnesses; antibody responses appear later than symptoms and are useful only for retrospective diagnosis.

Fig. 45.1 Tonsillitis and pharyngitis. (Courtesy Dr. Edward L. Applebaum, Head, Department of Otolaryngology, University of Illinois Medical Center.)

Rapid identification of GABHS with diagnostic test kits (rapid antigen detection test) is possible in the office or clinic setting. Because of the high specificity of these rapid tests, a positive test result generally does not require throat culture confirmation. However, the sensitivities of these kits vary considerably, and a confirmatory throat culture is recommended in patients who have a negative test result (Healthlink BC, 2019).

Therapeutic Management. If streptococcal sore throat infection is present, oral penicillin is prescribed in a dose sufficient to control the acute local manifestations and maintain an adequate level for at least 10 days to eliminate any organisms that might remain to initiate RF symptoms. Penicillin does not prevent the development of AGN in susceptible children; however, it may prevent the spread of a nephrogenic strain of GABHS to others in the family. Penicillin usually produces a prompt response within 24 hours. Patients who have a history of RF or who remain symptomatic after a full course of antibiotics may require a follow-up throat swab. Parents who have allergies to penicillin or other antibiotics can be advised to have their children allergy tested in case their children have the allergies as well.

Intramuscular (IM) benzathine penicillin G is an appropriate therapy, but it is painful and is not the first choice for children. Oral erythromycin is indicated for children allergic to penicillin. Other antibiotics used to treat GABHS are azithromycin, clarithromycin, oral cephalosporins, amoxicillin, and amoxicillin with clavulanic acid (American Academy of Pediatrics [AAP], Committee on Infectious Diseases, et al., 2018).

Nursing Care. Often, the nurse obtains a throat swab for culture or rapid antigen testing and instructs the parents about administering oral antibiotics and analgesics as prescribed. Cold or warm compresses to the neck may provide relief. In children who can gargle, warm salt gargles offer relief of throat discomfort. Acetaminophen and ibuprofen may be effective in decreasing throat pain; liquid preparations or chewable forms may be preferable because of the pain associated with swallowing. While pain may interfere with oral intake, fluid intake is essential. Cool liquids or ice chips may be tolerated better than solids.

Special emphasis should be placed on correct administration of oral medication and completing the course of antibiotic therapy (see Administration of Medication, Chapter 44). If injections are required, they must be administered deep into a large muscle mass (e.g., vastus lateralis or ventrogluteal muscle). To prevent pain, application of a topical anesthetic cream, such as LMX4 (4% lidocaine) or eutectic mixture of lidocaine and prilocaine (EMLA) over the injection site before the injection is helpful (see Administration of Medication: Intramuscular Administration, Chapter 44). The injection site may be tender for 1 to 2 days. Local application of heat can help relieve this discomfort.

Children are considered infectious to others at the onset of symptoms and up to 24 hours after initiation of antibiotic therapy, and they should not return to school or day care until after this period of time. Nurses should remind the family to discard the child's toothbrush and replace it with a new one after they have been taking antibiotics for 24 hours. Orthodontic appliances should be washed thoroughly because they may harbour the infectious organisms. Parents should be cautioned to prevent other household members, especially if immunocompromised, from having close contact with the sick child and to avoid sharing drinking or eating items.

If the child continues to have a high fever that does not respond to antipyretics, has an extremely sore throat, refuses liquids, and appears extremely ill 24 to 48 hours after starting an antibiotic, further evaluation by a health care provider is recommended.

Tonsillitis

The *tonsils* are masses of lymphoid tissue located in the pharyngeal cavity. They filter and protect the respiratory and alimentary tracts from invasion by pathogenic organisms and play a role in antibody formation. Although their size varies, children generally have much larger tonsils than those of adolescents or adults. This difference is thought to be a protective mechanism because young children are especially susceptible to upper respiratory infections.

Pathophysiology. Several pairs of tonsils are part of a mass of lymphoid tissue encircling the nasal and oral pharynx, known as the *Waldeyer tonsillar ring* (Figure 45.2). The *palatine*, also known as *faucial*, *tonsils* are located on either side of the oropharynx, behind and below the pillars of the fauces (opening from the mouth). A surface of the palatine tonsils is usually visible during oral examination. The palatine tonsils are those removed during tonsillectomy. The *pharyngeal tonsils*, also known as the *adenoids*, are located above the palatine tonsils on the posterior wall of the nasopharynx. Their proximity to the nares and eustachian tubes can cause difficulties in instances of **inflammation**. The *lingual tonsils* are located at the base of the tongue. The *tubal tonsils*, found near the posterior nasopharyngeal opening of the eustachian tubes, are not part of the Waldeyer tonsillar ring.

Etiology. Tonsillitis often occurs with pharyngitis. The causative agent may be viral or bacterial. Because of the abundant lymphoid tissue and the frequency of upper respiratory infections, tonsillitis is a common cause of illness in young children. The causative agent may be viral or bacterial.

Clinical Manifestations. The manifestations of tonsillitis are caused by inflammation. As the palatine tonsils enlarge from edema, they may meet in the midline (kissing tonsils), obstructing the passage of air or food. The child has difficulty swallowing and breathing. When the adenoids enlarge, the space behind the posterior nares becomes blocked, making it difficult or impossible for air to pass from the nose to the throat. As a result, the child breathes through the mouth.

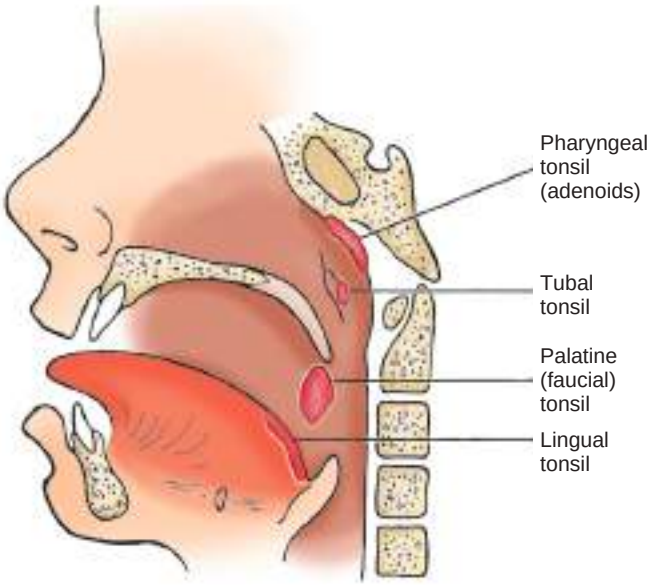

Fig. 45.2 Location of various tonsillar masses.

Therapeutic Management. Because tonsillitis is self-limiting, treatment of viral pharyngitis is symptomatic. Throat cultures positive for GABHS infection warrant antibiotic treatment. It is important to differentiate between viral and streptococcal infection in febrile exudative tonsillitis. Because most infections are of viral origin, early rapid tests can eliminate unnecessary antibiotic administration.

Tonsillectomy is the surgical removal of the palatine tonsils. Indications for a tonsillectomy are recurrent peritonsillar abscess (six episodes per year causing a child to miss 20 days of school), airway obstruction that leads to obstructive sleep apnea, and tonsils requiring tissue pathology (Canadian Society of Otolaryngology, 2017b).

Adenoidectomy (the surgical removal of the adenoids) is recommended for children who have hypertrophied adenoids that obstruct nasal breathing; additional indications for adenoidectomy include recurrent adenoiditis and sinusitis, otitis media with effusion, airway obstruction and subsequent sleep-disordered breathing, and recurrent rhinorrhea (Canadian Society of Otolaryngology, 2017a). For some children the effectiveness of tonsillectomy or adenoidectomy is modest and may not justify the risk of surgery. In practice, many physicians rely on individualized decision making and do not subscribe to an absolute set of eligibility criteria for these surgical procedures. Contraindications to either tonsillectomy or adenoidectomy are (1) cleft palate, because tonsils help minimize the escape of air during speech; (2) acute infections at the time of surgery, because locally inflamed tissues increase the risk of bleeding; (3) uncontrolled systemic diseases or blood dyscrasias; and (4) poor anaesthetic risk.

Nursing Care. Nursing care of children with a tonsillectomy involves providing comfort and minimizing activities or interventions that could precipitate bleeding. A soft to liquid diet is preferred. Patients with sleep-disordered breathing require close monitoring of airway and breathing postoperatively. A cool-mist vaporizer keeps the mucous membranes moist during periods of mouth breathing. Warm salt-water gargles, warm fluids, and analgesic-antipyretic medications such as acetaminophen or ibuprofen can be used to promote comfort. In the past, opioids were often administered to children to reduce the pain after tonsillectomy so the child could drink. Current research recommends the combined use of ibuprofen and acetaminophen to provide safe and effective post-tonsillectomy pain relief in most children (Ministry of Health and Long-Term Care & Provincial Council for Maternal & Child Health, 2016). Post-tonsillectomy morphine should be used with caution because it may be unsafe for specific children, and codeine should never be used in children under 12 years of age (Government of Canada, 2016a). The use of ibuprofen does not increase the risk of postsurgical bleeding (Kelly et al., 2015).

Children who have an adenoidectomy will experience mild to moderate discomfort for a couple of days and usually return to normal activity within a few days, although many surgeons will restrict swimming and major physical activity for a week or more.

! NURSING ALERT

After tonsillectomy and adenoidectomy surgery, children with sleeping disorders need to be monitored carefully for any sign of respiratory distress.

If surgery is required, the child needs the same psychological preparation and physical care as for any other surgical procedure (see Chapters 43 and 44). Most tonsillectomy and adenoidectomy (T&A) surgeries now take place in outpatient settings; however, the priorities of preoperative and postoperative care remain the same. The following discussion focuses on postoperative nursing care for T&A, although both procedures may not be performed.

Until they are fully awake, children are placed on their abdomen or side to facilitate drainage of secretions. Routine suctioning is avoided, and, when performed, it is done carefully to avoid trauma to the oropharynx. When alert, children may prefer sitting up. They should be discouraged from coughing frequently, clearing their throat, blowing their nose, or any other activity that may aggravate the operative site. Raising the head of the bed helps to reduce edema.

Some secretions are common, particularly dried blood from surgery. All secretions and vomitus need to be inspected for evidence of fresh bleeding (some blood-tinged mucus is expected). Dark brown (old) blood is usually present in the emesis, in the nose, and between the teeth. If parents do not expect this, they often become frightened at a time when they need to be calm and reassuring.

The throat is sore after surgery. An ice collar provides relief, but many children find it bothersome and may refuse to use it. Most children experience moderate pain after a T&A and need pain medication regularly for at least the first few days. Analgesics may be given rectally or intravenously to avoid the oral route. Because pain is continuous, analgesics should be administered at regular intervals. An antiemetic such as ondansetron (Zofran) may be administered postoperatively if nausea or vomiting is present (see Pain Management, Chapter 34).

Food and fluids should be restricted until children are fully alert and there are no signs of hemorrhage. Cool water, crushed ice, flavoured ice pops, or diluted fruit juice may be given, but fluids with a red or brown colour should be avoided so that fresh or old blood in emesis can be differentiated from the ingested liquid. Citrus juice may cause discomfort and is usually poorly tolerated. Soft foods, particularly gelatin, cooked fruits, sherbet, soup, and mashed potatoes, are started on the first or second postoperative day or as the child tolerates feeding. The pain from surgery often inhibits fluid intake, reinforcing the need for adequate pain control. Milk, ice cream, and pudding are usually not offered, since milk products coat the mouth and throat and may cause the child to clear the throat, which can initiate bleeding.

Postoperative hemorrhage is uncommon but can occur in up to 5% of patients up to 14 days after surgery. The nurse needs to observe the throat directly for evidence of bleeding, using a good source of light and, if necessary, carefully inserting a tongue depressor. Other signs of hemorrhage are tachycardia, pallor, frequent clearing of the throat or swallowing, particularly in a younger child, and vomiting of bright red blood. Restlessness, an indication of hemorrhage, may be difficult to differentiate from general discomfort after surgery. Decreasing blood pressure is a late sign of shock.

Surgery may be required to cauterize or ligate a bleeding vessel. Airway obstruction may also occur as a result of edema or accumulated secretions and is indicated by signs of respiratory distress, such as stridor, drooling, restlessness, agitation, increasing respiratory rate, and progressive cyanosis. Suction equipment and oxygen should be easily available after tonsillectomy.

! NURSING ALERT

The most obvious early sign of bleeding is the child's continuous swallowing of the trickling blood. While the child is sleeping, note the frequency of swallowing. If continuous bleeding is suspected, notify the surgeon immediately.

Providing family support and home care. Most children are ready to be discharged from the hospital in 6 to 8 hours after surgery. Discharge instructions include (1) avoiding intake of irritating or highly seasoned foods; (2) avoiding gargles or vigorous tooth brushing; (3) avoiding coughing, clearing the throat, or putting objects in the mouth such as a straw; the child should sneeze with an open mouth; (4) using analgesics or an ice collar for pain; and (5) limiting activity to decrease the potential for bleeding. Chewing gum may prevent throat and ear pain in older children. Objectionable mouth odour and slight ear pain with a low-grade fever are common for 5 to 10 days postoperatively. However, persistent severe earache, fever, very stiff neck, or cough requires immediate medical evaluation. Most children are ready to resume normal activity within 1 to 2 weeks after the operation. Children who live far away from a pediatric centre or a pediatric ear, nose, and throat specialist need to stay close to the hospital for the first 7 to 14 days. The child's voice may sound different postoperatively, especially if the tonsils were large.

Hemorrhage may occur up to 14 days after surgery as a result of tissue sloughing from the healing process. Any sign of bleeding warrants immediate medical attention.

Influenza

Influenza, or flu, is caused by three orthomyxoviruses which are antigenically distinct: types A and B, which cause epidemic disease, and type C, which is antigenically stable and causes milder disease. Influenza is spread from one individual to another by direct contact (large-droplet infection) or by articles recently contaminated by nasopharyngeal secretions. The rates for occurrence of seasonal influenza in healthy children vary. In 2020, the largest proportion of hospitalizations in children were among those under 5 years of age (Government of Canada, 2020c). Attack rates are highest in young children who have had no previous contact with a strain. Influenza is frequently most severe in infants. During epidemics, infection among school-age children is believed to be a major source of transmission in a community. There is a higher risk of influenza-related complications and/or hospitalization among Indigenous people (Government of Canada, 2020b). Multiple factors play a role here, including a high occurrence of chronic health conditions, reduced access to health care, and other social and environmental issues such as inadequate access to health care, food insecurity, unsafe drinking water, poor housing, poverty, and overcrowding. New immigrant children and those living in poverty are also at risk, for similar reasons.

The disease is more common during the winter months and has a 1- to 3-day incubation period. Affected persons are most infectious for 24 hours before and after the onset of symptoms. The virus has a peculiar affinity for epithelial cells of the respiratory tract mucosa, where it destroys ciliated epithelium with metaplastic hyperplasia of the tracheal and bronchial epithelium with associated edema. The alveoli may also become distended with a hyaline-like material. The viruses can be isolated from nasopharyngeal secretions early after the onset of infection, and serological tests can be used to identify the type by complement fixation or the subgroups by hemagglutination inhibition.

Clinical Manifestations. The manifestations of influenza may be subclinical, mild, moderate, or severe. Most patients have a dry throat and nasal mucosa, a dry cough, and a tendency toward hoarseness. A flushed face, photophobia, myalgia, hyperesthesia, and sometimes exhaustion and lack of energy accompany a sudden onset of fever and chills. Subglottal croup is common, especially in infants. The symptoms of influenza last for 4 or 5 days. Complications include severe viral pneumonia (often hemorrhagic), encephalitis, and secondary bacterial infections, such as sinusitis or pneumonia.

Therapeutic Management. Uncomplicated influenza in children usually requires only symptomatic treatment: acetaminophen or ibuprofen for fever and sufficient fluids to maintain hydration. Currently, the neuraminidase inhibitors zanamivir and oseltamivir (Tamiflu) are stored in many countries to treat and prevent pandemic and seasonal influenza outbreaks before an influenza vaccine that matches the

influenza strain is available. Neuraminidase inhibitors help prevent influenza A and B viruses from multiplying, by interfering with the production and release of viruses from cells that line the respiratory tract. This process may slow the spread of infection within the airways and from the cells that line the respiratory tract.

While amantadine, zanamivir, and oseltamivir have been approved for the treatment of flu symptoms in children (Aoki et al., 2019), amantadine is generally not used because of resistance that has developed to the medication. Zanamivir and oseltamivir must be started within 2 days of symptom onset. Zanamivir is an inhaled medication effective for types A and B influenza and is taken twice daily for 5 days; it is administered by a specially designed oral inhaler (Diskhaler). Zanamivir cannot be used in children younger than 7 years of age. Zanamivir has also caused bronchospasm in some patients with asthma; these children need to have a short-acting bronchodilator available (Aoki et al., 2019). Oseltamivir (Tamiflu) is given orally for 5 days to children over 1 year of age to decrease flu symptoms. It is reported to be effective for types A and B influenza and has decreased hospitalizations and mortality. Antivirals can be used with caution in younger children although require a health care provider's supervision.

Prevention. The National Advisory Committee on Immunizations (NACI) in Canada is the national surveillance program that provides information on which viral strains are put into each year's influenza vaccines. FluWatch is part of Canada's national surveillance system that provides information on the spread of influenza and influenza-like illnesses on an ongoing basis. Specific information is provided weekly on influenza viruses that are circulating across Canada (see Additional Resources at the end of this chapter). Each province or territory advises which vaccines will be made available for the publicly funded program in that jurisdiction.

The most important method to prevent influenza is proper hand hygiene. Parents also need to be encouraged to keep children home from day care or school when they are ill. These strategies have been shown to dramatically decrease influenza rates during the COVID-19 pandemic.

The CPS recommends annual influenza vaccination for all children age 6 months or older, particularly in high-risk populations such as Indigenous people, persons who are immunocompromised, and chronically ill populations (Moore & CPS, Infectious Diseases and Immunization Committee, 2020/2021). In addition, the NACI has made some significant changes to their recommendations, which include the following:

- Children and adolescents with neurological or neurodevelopmental disorders have been added to the list of individuals considered to be at high risk for severe influenza.
- Two types of influenza vaccines are licensed in Canada: inactivated influenza vaccines (IIV) for IM injection and an intranasal, live attenuated influenza vaccine (LAIV).
- In recent years, trivalent vaccines are now being replaced by quadrivalent vaccines containing two strains of influenza A and both lineages of influenza B. The NACI recommends preferential use of quadrivalent vaccines for children and adolescents because influenza B causes more mortality and morbidity in children than in adults.

Children and adults who have been previously immunized with seasonal influenza vaccine should receive one dose of influenza vaccine each year, preferably before the start of the flu season. Children 6 months to 8 years of age receiving seasonal influenza vaccine for the first time should be given two doses, with a minimum interval of 4 weeks between doses.

Any individual who developed an anaphylactic reaction to a previous dose of influenza vaccine or to any of the vaccine components (with the exception of egg) or who developed Guillain-Barré syndrome (GBS) within 6 weeks of vaccination should not receive a further dose. The NACI recommends that individuals who are allergic to eggs be vaccinated against influenza. All influenza vaccines should be given in a facility that can manage anaphylaxis, should it occur (Moore & CPS, Infectious Diseases and Immunization Committee, 2020/2021). LAIV is contraindicated in individuals with immunocompromising conditions (except for well-controlled HIV), individuals with severe asthma (defined as current active wheezing or currently on oral or high-dose inhaled glucocorticosteroids, or medically attended wheezing within the previous 7 days), and during pregnancy. LAIV is also contraindicated in children and adolescents 2 to 17 years of age who are receiving chronic acetylsalicylic acid–containing therapy, because of the association of Reye syndrome with acetylsalicylic acid given during influenza infection (Moore & CPS, Infectious Diseases and Immunization Committee, 2020/2021).

Nursing Care. Nursing care is the same as that for any child with an upper respiratory infection, including implementing measures to relieve symptoms. The greatest danger to affected children is development of a secondary infection. Prolonged fever or appearance of fever during early convalescence is a sign of secondary bacterial infection and should be reported to the health care provider for antibiotic therapy.

Otitis Media (OM)

OM is the presence of fluid in the middle ear along with acute signs of illness and symptoms of middle ear inflammation. The standard terminology used to define OM is outlined in Box 45.5. OM is one of the most prevalent diseases of early childhood. Its incidence is highest in the winter months. The majority of cases of bacterial OM are preceded by a viral respiratory infection. The two viruses most likely to precipitate OM are RSV and influenza. Most episodes of acute otitis media (AOM) occur in the first 24 months of life, but the incidence decreases with age, except for a small increase at age 5 or 6 years when children enter school. OM occurs infrequently in children older than 7 years of age. Preschool-age boys are affected more frequently than preschool-age girls. Children who have sibling or parents with a history of chronic OM have a higher incidence of OM. Children who live in households with many members (especially smokers) are more likely to have OM than those living with fewer persons.

Exposure to passive cigarette smoke increases the risk of persistent middle ear effusion by enhancing attachment of the pathogens that cause otitis to the respiratory epithelium in the middle ear space, prolonging the inflammatory response, and impeding drainage through the eustachian tube (Le Saux et al., 2016/2021). Other risk factors include orofacial abnormalities, premature birth, a shorter duration of breastfeeding, prolonged bottle-feeding while lying down, and **immunodeficiency** (Le Saux et al., 2016/2021). The high rate of chronic

BOX 45.5 Standard Terminology for Otitis Media

Otitis media (OM)—An inflammation of the middle ear without reference to etiology or pathogenesis

Acute otitis media (AOM)—An inflammation of the middle ear with a rapid onset of the signs and symptoms of acute infection (i.e., fever and otalgia [ear pain])

Otitis media with effusion (OME)—Inflammation and fluid in the middle ear without symptoms of acute infection

Middle ear effusion (MEE)—Fluid in the middle ear without reference to etiology, pathogenesis, pathology, or duration

suppurative OM among Indigenous children is likely due to the fact that Indigenous peoples have three times the smoking rate of that for the general Canadian population. An additional factor may be that a small number of Indigenous children have lower levels of secretory immunoglobulin A or persistent biofilms in the middle ear, which may play a part in increasing the risk for recurrent AOM (Le Saux et al., 2016/2021).

Etiology. *Streptococcus pneumoniae*, *H. influenzae*, and *Moraxella catarrhalis* are the three most common bacteria causing AOM. The etiology of noninfectious OM is unknown, although OM may occur because of a blocked eustachian tube, which results in negative ear pressure. Fluid is pulled from the mucosal lining, which accumulates and becomes colonized by infectious organisms. Predisposing factors include upper respiratory infections, allergies, Down syndrome, cleft palate, day care attendance, exposure to secondhand smoke, and bottle propping during feeding.

Breastfed infants have a lower incidence of OM than formula-fed infants. Breastfeeding may protect infants against respiratory viruses and allergy because it contains secretory immune globulin A, which limits the exposure of the eustachian tube and middle ear mucosa to microbial pathogens and foreign proteins. Prolonged breastfeeding shows a protective effect for prevention of OM and recurrent AOM (Le Saux et al., 2016/2021). Reflux of milk up the eustachian tubes is less likely in breastfed infants because of the semivertical positioning during breastfeeding compared with positioning during bottle-feeding.

Pathophysiology. OM is primarily a result of malfunctioning eustachian tubes. Eustachian tubes have three functions relative to the middle ear: (1) protection of the middle ear from nasopharyngeal secretions, (2) drainage of secretions produced in the middle ear into the nasopharynx, and (3) ventilation of the middle ear to equalize air pressure within the middle ear and atmospheric pressure in the external ear canal and to replenish oxygen that has been absorbed.

Mechanical or functional obstruction of the eustachian tube causes accumulation of secretions in the middle ear. Intrinsic obstruction can be caused by infection or allergy; extrinsic obstruction is usually a result of enlarged adenoids or nasopharyngeal tumours. When the passage is not totally obstructed, contamination of the middle ear can take place by reflux, aspiration, or insufflation during crying, sneezing, nose-blowing, and swallowing when the nose is obstructed.

Diagnostic Evaluation. Careful assessment of the tympanic membrane with a pneumatic otoscope to see if it is immobile is essential to differentiate AOM from OM with effusion (OME). A diagnosis of AOM is made if visual inspection of the tympanic membrane reveals a purulent discoloured effusion and a bulging or full, opacified, or reddened immobile membrane, as well as an acute onset of ear pain. An immobile tympanic membrane or an orange-coloured membrane indicates OME. Clinical symptoms of OM are also helpful in making the diagnosis (Box 45.6). In OME, these symptoms may be absent, and other nonspecific symptoms such as rhinitis, cough, or diarrhea are often present (Le Saux et al., 2016/2021). OME may precede AOM or predispose to its development, but OME does not represent an acute infectious process that requires antibiotic therapy.

Therapeutic Management. Treatment for AOM is one of the most common reasons for antibiotic use in the ambulatory setting. However, concerns about antibiotic-resistant *S. pneumoniae* and other medication resistances have led infectious disease authorities to recommend careful and judicious use of antibiotics for treatment of this illness. Current recommendations regarding antibiotic administration to children with AOM are as follows (Le Saux et al., 2016/2021):

- Prescribe antibiotics for children 6 months of age and older who have severe signs or symptoms of AOM (moderate or severe otalgia for at least 48 hours or temperature equal to or greater than 39°C).
- Prescribe antibiotics for bilateral AOM in children younger than 24 months of age who do not have severe signs or symptoms (moderate or severe otalgia for at least 48 hours or temperature equal to or greater than 39°C).
- Either prescribe antibiotics *or* offer observation with close follow-up (based on joint decision making with the parent or caregiver) for unilateral AOM in children 6 months to 23 months of age who do not have severe signs or symptoms (moderate or severe otalgia for at least 48 hours or temperature equal to or greater than 39°C); if the child does not improve within 48 hours, begin antibiotic therapy.
- Either prescribe antibiotics *or* offer observation with close follow-up (based on joint decision making with the parent or caregiver) for unilateral or bilateral AOM in children 24 months of age or older who do not have severe signs and symptoms (moderate or severe otalgia for at least 48 hours or temperature equal to or greater than 39°C).

It is essential that children who are on observation have medical follow-up and that parents be able to recognize a lack of improvement and to treat symptoms with analgesics. The parents should be given a deferred prescription for antimicrobials if there is no improvement in the condition. Some reviews of the treatment of AOM show no clear evidence that antibiotics improve outcomes in children younger than 2 years of age with uncomplicated AOM. In addition, all cases of AOM in infants younger than 6 months of age should be treated with

BOX 45.6 Clinical Manifestations of Otitis Media

Acute Otitis Media (AOM)

Follows an upper respiratory infection
Otalgia (earache)
Fever
Purulent discharge (otorrhea) may or may not be present

Infant or Very Young Child

Crying, fussiness, restlessness, irritability, especially on lying down
Tendency to rub, hold, or pull affected ear
Rolls head from side to side
Difficulty comforting child
Loss of appetite, refusal to feed

Older Child

Crying or expressing feelings of discomfort
Irritability
Lethargy
Loss of appetite

Chronic Otitis Media

Hearing impairment
Difficulty communicating
Possible feeling of fullness, tinnitus, or vertigo

antibiotics because of the infant's immature immune system and the potential for infection with bacteria other than the three most common organisms found in older infants and children with AOM.

When antibiotics are warranted, oral amoxicillin in high doses (75 to 90 mg/kg/day, divided twice daily) is the treatment of choice for initial episodes of AOM in children who have not received amoxicillin within the past month. The recommendation for the duration of antibiotic therapy in severe AOM is 10 days. A 5-day course may be sufficient in children 6 years of age and older with uncomplicated mild or moderate AOM. For children with penicillin allergies, first-line antibiotics include cefuroxime-axetil 30 mg/kg/day divided twice or three times per day as tablets or suspension or ceftriaxone 50 mg/kg intramuscularly (or intravenously) daily for 3 days (Le Saux et al., 2016/2021).

Second-line antibiotics used to treat OM include amoxicillin-clavulanate and IM or intravenous (IV) ceftriaxone if the causative organism is a highly resistant pneumococcus or if the parents have difficulty ensuring that the child receives the therapy. An important consideration with the use of single-dose IM injections is the pain involved in this therapy. One strategy to minimize pain at the injection site is to reconstitute the cephalosporin with 1% lidocaine. A topical analgesic cream such as EMLA or LMX4 can also be applied to the site beforehand to reduce pain. Alternatively, the IV route can be used. The use of steroids, decongestants, and antihistamines to treat AOM is not recommended (Le Saux et al., 2016/2021).

Myringotomy, a surgical incision of the eardrum, may be necessary to alleviate the severe pain of AOM. A myringotomy is also performed to provide drainage of infected middle ear fluid in the presence of complications (mastoiditis, labyrinthitis, or facial paralysis) or to allow purulent middle ear fluid to drain into the ear canal for culture. A minimally invasive laser-assisted myringotomy procedure may be performed in outpatient settings.

Tympanostomy tube (t-tube) placement and adenoidectomy are surgical procedures that may be done to treat recurrent chronic AOM (defined as three bouts in 6 months, six in 12 months, or six by 6 years of age). Tympanostomy tubes or pressure-equalizer (PE) tubes are grommets that facilitate continued drainage of fluid and allow ventilation of the middle ear. They are inserted to treat severe eustachian tube dysfunction, OM with effusion, or complications of OM (mastoiditis, facial nerve paralysis, brain abscess, labyrinthitis). Adenoidectomy is not recommended for treatment of AOM and is performed only in children with recurrent AOM or chronic OME with postnasal obstruction, adenoiditis, or chronic sinusitis.

In some children residual middle ear effusions remain after episodes of AOM. Some children have fluid that persists in the middle ear for weeks or months. Antibiotics are not required for initial treatment of OME but may be indicated for children with persistent effusion for more than 3 months (Le Saux et al., 2016/2021). Placement of tympanostomy tubes is recommended after a total of 4 to 6 months of bilateral effusion with a bilateral hearing deficit (Kerschner & Preciado, 2020). This therapy allows for mechanical drainage of the fluid, which promotes healing of the membrane and prevents scar formation and loss of elasticity. Myringotomy with or without insertion of PE tubes should not be performed for initial management of OME but may be recommended for children who have recurrent episodes of OME with a long cumulative duration (Kerschner & Preciado, 2020).

OME is frequently associated with mild to moderate impairment of hearing. A hearing test should be performed if OME persists for 3 months or more or if there is evidence of language or learning delays. Follow-up examinations of children with chronic OME should be maintained on a 3- to 6-month basis until the OME is resolved, a significant hearing impairment is identified, or a structural defect of the tympanic membrane or middle ear is identified (Kerschner & Preciado, 2020). Children with hearing impairment should be referred to an otolaryngologist and should receive a speech and language evaluation as necessary.

Prevention. In Canada, the pneumococcal 13-valent conjugate vaccines have been developed and approved to help prevent OM from pneumococci and nontypeable *H. influenza.* There has been a significant decline in the number of AOM cases since the introduction of the pneumococcal vaccine. In Canada, AOM incidence has been reduced by 13 to 19% because the nasopharyngeal colonization with vaccine-type *S. pneumoniae* in children has been significantly decreased, particularly among children under 2 years of age (Le Saux et al., 2016/2021). All children are recommended to receive the 13-valent vaccine starting at 2 months in a three- to four-dose schedule (Government of Canada, 2016b).

Nursing Care. Nursing objectives for the child with AOM include (1) relieving pain, (2) facilitating drainage when possible, (3) preventing complications or recurrence, (4) educating the family in care of the child, and (5) providing emotional support to the child and family.

Children with AOM require comprehensive assessment and management of pain. Analgesic medications such as acetaminophen and ibuprofen (6 months of age and older) are used to treat mild pain as well as fever. For more severe pain, a stronger analgesic may be prescribed. The health care provider may prescribe topical pain relief drops such as benzocaine or lidocaine.

If the ear is draining, the external canal may be cleaned with sterile cotton swabs or cotton balls, coupled with topical antibiotic treatment. If ear wicks or lightly rolled sterile gauze packs are placed in the ear after surgical treatment, they should be loose enough to allow accumulated drainage to flow out of the ear; otherwise, infection may be transferred to the mastoid process. The wicks need to stay dry during shampoos or baths. Occasionally, drainage is so profuse that the auricle and the skin surrounding the ear become excoriated from the exudate. This is usually prevented by frequent cleansing and application of various moisture barriers (e.g., Proshield Plus) or petrolatum jelly (e.g., Vaseline).

No routine precautions are necessary for water-related activities; earplugs, headbands, or the avoidance of swimming or water sports are not recommended (Rosenfeld et al., 2013). Parents should be aware of the appearance of a grommet (usually a tiny, white, plastic spool-shaped tube) so that they can recognize if it falls out. They need to be reassured that this is normal and requires no immediate intervention, although they should notify the health care provider.

Prevention of recurrence requires adequate education regarding antibiotic therapy. The symptoms of pain and fever usually subside within 24 to 48 hours, but nurses need to emphasize that all of the prescribed medication must be taken. Parents should be aware that potential complications of OM, such as hearing impairment, can be prevented with adequate treatment and follow-up care.

Parents also need anticipatory guidance regarding methods to reduce the risks of OM, especially in children younger than 2 years. Reducing the occurrence of OM is possible with simple measures, such as sitting or holding an infant upright for feedings, maintaining routine childhood immunizations, and exclusively breastfeeding until at least 6 months of age. Propping of bottles is discouraged to avoid pooling of milk while the child is in the supine position and to encourage human contact during feeding. Eliminating tobacco smoke and known allergens from the environment is also recommended. Early detection of middle ear effusion is essential to prevent complications. Infants and preschool children should be screened for effusion, and all schoolchildren, especially those with learning disabilities, should be tested for hearing deficits related to a middle ear effusion.

Infectious Mononucleosis

Infectious mononucleosis is an acute, self-limiting infectious disease that is common among people younger than 25 years of age. Symptoms include fever, exudative pharyngitis, lymphadenopathy, hepatosplenomegaly, and an increase in atypical lymphocytes. The course is usually mild but occasionally can be severe or, rarely, accompanied by serious complications.

Etiology and Pathophysiology. The Epstein-Barr virus (EBV) is the principal cause of infectious mononucleosis. It appears in both sporadic and epidemic forms, but sporadic cases are more common. The mechanism of spread has not been proven, but it is believed to be transmitted in saliva by direct intimate contact, although it survives in saliva for many hours outside of the body. It is mildly contagious; the period of communicability is unknown. The incubation period following exposure is approximately 30 to 50 days (AAP, Committee on Infectious Diseases et al., 2018).

Diagnostic Tests. The onset of symptoms may be acute or insidious and may appear anywhere from 10 days to 6 weeks after exposure. The presenting symptoms vary greatly in type, severity, and duration (Box 45.7). The clinical manifestations of infectious mononucleosis are usually less severe (often subclinical or unapparent), and the convalescent phase is shorter in younger children than in older children and young adults. Heterophil antibody tests (Paul-Bunnell or Monospot) determine the extent to which the patient's serum will agglutinate sheep red blood cells; the response in these tests is primarily to immunoglobulin M, which is present in the first 2 weeks of the illness and may last up to 1 year (AAP, Committee on Infectious Diseases et al., 2018). The *spot test (Monospot)* is a slide test of venous blood that has high specificity. It is rapid, sensitive, inexpensive, and easy to perform and has an advantage over the heterophil antibody test (i.e., it can detect significant agglutinins at lower levels, thus allowing earlier diagnosis). Blood is usually obtained for the test by finger puncture or venous sampling and is placed on special paper. If the blood agglutinates, forming fragments or clumps, the test is positive for the infection.

BOX 45.7 Clinical Manifestations of Infectious Mononucleosis

Early Signs
Headache
Malaise
Fatigue
Chills
Low-grade fever
Loss of appetite
Puffy eyes

Acute Disease
Cardinal Features
Fever
Sore throat
Cervical adenopathy

Common Features
Splenomegaly (may persist for several months)
Palatine petechiae
Macular eruption (especially on trunk)
Exudative pharyngitis or tonsillitis
Hepatic involvement to some degree, often associated with jaundice

Therapeutic Management. No specific treatment exists for infectious mononucleosis. The course of this disease is usually self-limiting and uncomplicated. Acute symptoms often disappear within 7 to 10 days, and persistent fatigue subsides within 2 to 4 weeks. Some children may need to restrict vigorous activities for 2 to 3 months, but the disease rarely extends for longer periods. Affected persons are instructed to regulate activities according to their own tolerance unless complicating factors are present. Contact sports are discouraged in the presence of splenomegaly. Simple remedies ordinarily relieve the symptoms.

Antibiotics are contraindicated unless beta-hemolytic streptococci are present (amoxicillin or ampicillin can cause a rash in patients with EBV infection). If sore throat is severe, effective therapies include gargles, hot drinks, anaesthetic lozenges, or analgesics, including opioids. Corticosteroids have been used to treat respiratory distress from significant tonsillar inflammation, hemolytic anemia, thrombocytopenia, and neurological complications; however, routine use of steroids is not recommended (AAP, Committee on Infectious Diseases et al., 2018).

Nursing Care. Nursing responsibilities are directed toward providing comfort measures to relieve symptoms. The child should be advised to limit exposure to persons outside the family, especially during the acute phase of illness. A mild analgesic is often sufficient to relieve the headache, fever, and malaise. It may be more comfortable to limit intake to liquids during the acute phase; milkshakes are a good alternative to solid foods on a temporary basis. Careful nursing assessment of swallowing ability is essential because the edema may cause serious airway compromise.

! NURSING ALERT

Advise the family to seek medical evaluation of the child or adolescent with infectious mononucleosis has any of the following symptoms:
- Breathing becomes difficult.
- Severe abdominal pain develops.
- Sore throat pain is so severe that the child is unable to drink liquids.
- Respiratory stridor is observed.

CROUP SYNDROMES

The term *croup* refers to a heterogeneous group of mainly acute and infectious processes that are characterized by a bark-like or brassy cough and may be associated with hoarseness, inspiratory stridor, and varying degrees of respiratory distress resulting from swelling or obstruction in the region of the larynx (Rodrigues & Roosevelt, 2020). Acute infections of the larynx are important to address in infants and small children because of their increased incidence in these age groups and because the small diameter of the airway in infants and children places them at risk for significant narrowing with inflammation.

Croup syndromes can affect the larynx, trachea, and bronchi. However, laryngeal involvement often dominates the clinical picture because of the severe effects on the voice and breathing. Croup syndromes are described according to the primary anatomical area affected (i.e., epiglottitis [or supraglottitis], laryngitis, laryngotracheobronchitis [LTB], and tracheitis). In general, LTB occurs in very young children, and epiglottitis is more common in older children. A comparison of croup syndromes is provided in Table 45.1.

With widespread immunization programs aimed at preventing *H. influenzae* type B, the cause of most cases of croup syndrome in Canada is now attributed to viruses (i.e., parainfluenza virus, human metapneumovirus, influenza types A and B, adenovirus, and measles).

TABLE 45.1 Comparison of Croup Syndromes

	Acute Epiglottitis	Acute LTB	Acute Spasmodic Laryngitis	Acute Tracheitis
Age group affected	2–5 years but varies	Infant or child under 5 years	1–3 years	5–7 years
Etiological agent	Bacterial	Viral	Viral with allergic component	Viral or bacterial with allergic component
Onset	Rapidly progressive	Slowly progressive	Sudden; at night	Moderately progressive
Major symptoms	Dysphagia Stridor aggravated when supine Drooling High fever Toxic appearance Rapid pulse and respirations	URI Stridor Brassy cough Hoarseness Dyspnea Restlessness Irritability Low-grade fever Nontoxic appearance	URI Croupy cough Stridor Hoarseness Dyspnea Restlessness Symptoms awakening child but disappearing during day Tendency to recur	URI Croupy cough Purulent secretions High fever No response to LTB therapy
Treatment	Airway protection Antibiotics Fluids Reassurance	Humidified oxygen if needed Corticosteroids Fluids Reassurance	Corticosteroids Reassurance	Corticosteroid Antibiotics Fluids

LTB, Laryngotracheobronchitis; *URI,* upper respiratory infection.
Source: Ortiz-Alvarez, O., & Canadian Paediatric Society, Acute Care Committee. (2017). Acute management of croup in the emergency department. *Paediatrics & Child Health, 22*(3), 166–169. Updated 2019. https://www.cps.ca/en/documents/position/acute-management-of-croup.

Acute Epiglottitis

Acute epiglottitis, or *acute supraglottitis*, is a medical emergency. It is a serious obstructive inflammatory process that occurs predominately in children ages 2 to 5 years but can occur from infancy to adulthood. The obstruction is supraglottic as opposed to the subglottic obstruction of laryngitis. The responsible organism is usually *H. influenzae*. LTB and epiglottitis do not occur together.

Clinical Manifestations. The onset of epiglottitis is abrupt, and it can rapidly progress to severe respiratory distress. The child usually goes to bed asymptomatic to awaken later with a sore throat and pain on swallowing. The child will have a fever, appear sicker than clinical findings suggest, and insist on sitting upright and leaning forward with the chin thrust out, mouth open, and tongue protruding (*tripod position*). Drooling of saliva is common because of the difficulty or pain on swallowing and excessive secretions.

! NURSING ALERT

Three clinical observations found to be predictive of epiglottitis are absence of spontaneous cough, presence of drooling, and agitation.

The child tends to be irritable and extremely restless and have an anxious, apprehensive, and frightened expression. The voice is thick and muffled, with a froglike croaking sound on inspiration, but the child is not hoarse. Suprasternal and substernal retractions may be visible. The child will seldom struggle to breathe, and slow, quiet breathing provides better air exchange. The throat will appear red and inflamed, and a distinctive large, cherry-red, edematous epiglottis will be visible on careful throat inspection.

! NURSING ALERT

Throat inspection should be attempted only by experienced personnel when equipment is available to proceed with immediate endotracheal intubation or tracheostomy.

Therapeutic Management. The course of epiglottitis may be fulminant, with respiratory obstruction appearing suddenly. Progressive obstruction leads to hypoxia, **hypercapnia**, and **acidosis** followed by decreased muscle tone; reduced level of consciousness; and, when obstruction becomes more or less complete, a sudden death.

The child who is suspected of having epiglottitis should be examined in a setting where emergency personnel are ready to intubate and airway equipment is readily available. Examination of the throat with a tongue depressor is contraindicated until experienced personnel and equipment are available to proceed with immediate intubation or tracheostomy in the event that the examination precipitates further or complete obstruction (see Clinical Reasoning Case Study: Croup Syndrome).

Nasotracheal intubation or tracheostomy is usually considered for the child with epiglottitis with severe respiratory distress. It is recommended that the intubation or tracheostomy and any invasive procedure, such as starting an IV infusion, be performed in an area where emergency airway management can be easily and quickly accomplished. Humidified oxygen is administered as necessary either via mask in older children or blow-by in younger children, to avoid further agitation. Regardless of whether or not there is an artificial airway, the child requires intensive observation by experienced personnel. The epiglottal swelling usually decreases after 24 hours of antibiotic therapy (ceftriaxone sodium or alternate cephalosporin), and the epiglottis is near normal by the third day. Intubated children are generally extubated at this time.

Nebulized epinephrine is recommended for moderate to severe croup (Ortiz-Alverez & CPS, Acute Care Committee, 2017/2021).

Children with suspected bacterial epiglottitis are given antibiotics intravenously, followed by oral administration, to complete a 7- to 10-day course. Family contacts with children younger than 4 years of age are treated with rifampin for 4 days (Rodrigues & Roosevelt, 2020).

CLINICAL REASONING CASE STUDY

Croup Syndrome

Kim, a 5-year-old patient, is admitted to the emergency department in the early evening hours with a sore throat, pain on swallowing, drooling, and a fever of 39°C (102.2°F). She looks ill; her skin is flushed; she is agitated; and she prefers to sit up leaning on her arms. According to Kim's mother, she has not had anything to eat or drink since this morning.

Questions

1. Evidence—Is there sufficient evidence to draw any conclusions about Kim's condition at this time?
2. Assumptions—Describe some underlying assumptions about each of the following:
   a. Epiglottitis in children
   b. Symptoms of epiglottitis
   c. Precautions to be taken when a child has suspected epiglottitis
   d. Immediate nursing interventions when caring for a child with epiglottitis
3. What priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Kim's care.

Nursing Care. Epiglottitis is a serious and frightening disease for the child and family. It is important to act quickly but calmly and to provide support without increasing anxiety. The child should be allowed to remain in the position that provides the most comfort and security, and parents need to be reassured that everything possible is being done to provide relief for their child.

NURSING ALERT

When epiglottitis is suspected, the nurse should not attempt to visualize the epiglottis directly with a tongue depressor or take a throat culture but instead refer the child for medical evaluation immediately.

Acute care of the child is the same as that described later for the child with LTB. Continuous monitoring of respiratory status, including pulse oximetry (and blood gases if the patient is intubated), is an important part of nursing observations, and the IV infusion is maintained as described in Chapter 44.

Laryngotracheobronchitis

LTB is the most common croup syndrome. It affects primarily children younger than 5 years of age, and the causative organisms are viral agents, particularly the parainfluenza virus types 1, 2, and 3, adenovirus, enterovirus, RSV, rhinovirus, and influenza A and B. Bacterial organisms are rarely a causative organism but can include *M. pneumoniae* and diphtheria. The disease is usually preceded by an upper respiratory infection, which gradually descends to adjacent structures. It is characterized by gradual onset of low-grade fever, and the parents often report that the child went to bed and later awoke with a barky, brassy cough. Inflammation of the mucosa lining the larynx and trachea causes a narrowing of the airway. When the airway is significantly narrowed, the child inspires air past the obstruction and into the lungs, producing the characteristic inspiratory stridor and suprasternal retractions. Other classic manifestations include cough and hoarseness. Respiratory distress in infants and toddlers may be manifested by nasal flaring, intercostal retractions, tachypnea, and continuous stridor. The typical child with LTB develops the classic barking or seal-like cough and acute stridor after several days of rhinitis. When the child is unable to inhale a sufficient volume of air, symptoms of hypoxia become evident. Obstruction that is severe enough to prevent adequate ventilation and exhalation of carbon dioxide can cause respiratory acidosis and eventually respiratory failure.

Therapeutic Management. The major objective in medical management is maintaining the airway and providing adequate respiratory exchange. Children with mild croup (no stridor at rest) can be managed at home. Parents should be taught the signs of respiratory distress and instructed to summon professional help early if needed. Children with laboured respirations and stridor or other respiratory symptoms should receive medical attention.

Despite the observation that cold night air is beneficial, there is no evidence supporting the use of cool mist in the emergency department for the treatment of croup (Rodrigues & Roosevelt, 2020). A ride in the car with the windows down may help relieve symptoms.

Oral steroids (dexamethasone) have proven effective in the treatment of croup (often as a single dose) and are considered standard treatment for this condition. IM dexamethasone may be given to children who are unable to tolerate oral dosing (Ortiz-Alverez & CPS, Acute Care Committee, 2017/2021).

Nebulized epinephrine is often used in children with severe disease, stridor at rest, retractions, or difficulty breathing. The beta-adrenergic effects cause mucosal vasoconstriction and subsequently decrease subglottic edema. The onset of action is rapid, and the peak effect is observed in 2 hours. Children may be discharged home following nebulized epinephrine after a 2- to 3-hour period of observation for return of acute symptoms. When children with severe croup are given epinephrine, they are less likely to require intubation or tracheotomy (Ortiz-Alvarez & CPS, Acute Care Committee, 2017/2021).

In severe cases of LTB, the administration of heliox (a mixture of 70 to 80% helium and 20 to 30% oxygen) may be used to reduce the work of breathing and relieve airway obstruction. It reduces airway turbulence but is not recommended as a standard treatment of croup. On occasion, intubation and ventilation may be required when airway obstruction becomes more severe.

Nursing Care. The most important nursing function in the care of children with LTB is continuous, vigilant observation and accurate assessment of respiratory status. Cardiac, respiratory, and pulse oximetry monitoring supplement visual observation. Changes in therapy are frequently based on the nurse's observations and assessments and the child's response to therapy and tolerance of procedures. The trend away from early intubation of children with LTB emphasizes the importance of nursing observations and the ability to recognize impending respiratory failure so that intubation can be implemented without delay.

NURSING ALERT

Early signs of impending airway obstruction include increased pulse and respiratory rate; substernal, suprasternal, and intercostal retractions; nasal flaring; and increased restlessness.

In most acute care facilities, the infant with LTB is allowed to be held by the parent. If oxygen is used in the treatment, it can be administered through a tube held in front of the patient while the child is held on the

parent's lap. Children need the security of the parent's presence, because crying increases respiratory distress and hypoxia.

Children with mild croup are allowed to drink beverages they like as long as respiratory status is stable, and caregivers should be encouraged to try whatever comforting measures work best (e.g., holding the child, rocking, singing). If the child is unable to take oral fluids, IV fluids may be required, and steroids may need to be given intravenously. The use of antipyretics is beneficial for reducing fever and discomfort.

The rapid progression of croup, the alarming sound of the cough and stridor, and the child's apprehensive behaviour and ill appearance combine to create a frightening experience for the parents. The family should be allowed to remain with their child as much as possible. Parents need frequent reassurance provided in a calm, quiet manner and education regarding what they can do to make their child more comfortable. Fortunately, as the crisis subsides and the child responds to therapy, breathing becomes easier and the recovery is generally prompt. Home care includes monitoring for worsening symptoms, continued humidity, adequate hydration, and nourishment.

Acute Spasmodic Laryngitis

Acute spasmodic laryngitis (spasmodic croup) is distinct from laryngitis and LTB and is characterized by paroxysmal attacks of laryngeal obstruction that occur chiefly at night. Signs of inflammation are absent or mild, and it is followed by an uneventful recovery. The child usually feels well the next day. Some children appear to be predisposed to the condition; allergies or hypersensitivities may be implicated in some cases. Management is the same as for infectious croup.

Bacterial Tracheitis

Bacterial tracheitis, an infection of the mucosa of the upper trachea, is a distinct entity with features of both croup and epiglottitis. The disease occurs typically between 5 and 7 years of age and may cause severe airway obstruction (Rodrigues & Roosevelt, 2020). It is believed to be a complication of LTB, and although *Staphylococcus aureus* is the most frequent organism responsible, *M. catarrhalis, S. pneumonia,* and *H. influenzae* have also been implicated.

Many of the manifestations of bacterial tracheitis are similar to those of LTB but are unresponsive to LTB therapy. There is a history of previous viral upper respiratory infection with croupy cough, stridor unaffected by position, toxicity, absence of drooling, absence of dysphagia, and high fever. A prominent manifestation is the production of thick, purulent tracheal secretions. Respiratory difficulties are secondary to these copious secretions and mucosal edema at the level of the cricoid cartilage. The child's white cell count will be elevated.

Therapeutic Management and Nursing Care. Bacterial tracheitis requires vigorous management with antipyretics and antibiotics. Some younger children require endotracheal intubation and mechanical ventilation. Patients are closely monitored for impending respiratory failure if not intubated. Supplemental oxygen may be necessary. Early recognition to prevent life-threatening airway obstruction is essential.

INFECTIONS OF THE LOWER AIRWAYS

The *reactive portion* of the lower respiratory tract includes the bronchi and bronchioles in children. Cartilaginous support of the large airways is not fully developed until adolescence. Consequently, the smooth muscle in these structures represents a major factor in the constriction of the airway, particularly in the *bronchioles*, the portion that extends from the bronchi to the alveoli. Table 45.2 compares some of the major features of bronchial and bronchiolar infections.

Bronchitis

Bronchitis (sometimes referred to as *tracheobronchitis*) is inflammation of the large airways (trachea and bronchi), which is frequently associated with an upper respiratory infection. See Table 45.2 for the etiological agents and predominant characteristics.

TABLE 45.2 Comparison of Conditions Affecting the Bronchi

	Asthma*	Bronchitis	Bronchiolitis
Description	Exaggerated response of bronchi to a trigger such as URI, dander, cold air, exercise Bronchospasm, exudation, and edema of bronchi, airway obstruction Inflammatory response	Usually occurs in association with URI Seldom an isolated entity	Most common infectious disease of lower airways Maximum obstructive impact at bronchiolar level
Age group affected	Infancy to adolescence	First 4 years of life	Usually children 2–12 months of age; rare after age 2 years Peak incidence approximately age 6 months
Etiological agents	Most often viruses such as RSV in infants but may be any of a variety of URI pathogens	Usually viral Other agents (e.g., bacteria, fungi, allergic disorders, airborne irritants) can trigger symptoms	Viruses, predominantly RSVs; also adenoviruses, parainfluenza viruses, human meta-pneumovirus, and *Mycoplasma pneumonia*
Predominant characteristics	Wheezing, cough, laboured respirations	Persistent dry, hacking cough (worse at night) becoming productive in 2–3 days	Laboured respirations, poor feeding, cough, tachypnea, retractions and flaring nares, emphysema, increased nasal mucus, wheezing, may have fever
Treatment	Inhaled corticosteroids, bronchodilators, leukotriene modifiers, allergen and "trigger" control, long-term anti-inflammatory medications	Cough suppressants if needed	Provide supplemental oxygen if saturations $\leq$90%; bronchodilators (optional) Suction nasopharynx Ensure adequate fluid intake Maintain adequate oxygenation

RSV, Respiratory syncytial virus; *URI,* upper respiratory infection.
*See discussion on Asthma later in chapter.

Bronchitis is a mild, self-limiting disease that requires only symptomatic treatment, including analgesics, antipyretics, and humidity. Cough suppressants in older children and adolescents may be useful to allow rest but can interfere with clearance of secretions; parents should discuss use of these with their health care provider before administering them. Most patients recover uneventfully in 5 to 10 days. It can be associated with underlying conditions such as CF and bronchiectasis and can become chronic in nature with a cough over 3 months. Adolescents with bronchitis should be screened for tobacco or marijuana use.

Respiratory Syncytial Virus and Bronchiolitis

Bronchiolitis is a common acute viral infection with upper respiratory symptoms and lower respiratory infection of the bronchioles due to inflammation. By age 3, most children have been infected at least once. In Canada, RSV infection is the most frequent cause of hospitalization in children less than 2 years of age with bronchiolitis. In northern Canada, Indigenous children have one of the highest rates of RSV bronchiolitis hospitalizations in the world, with a 1% mortality rate and a 3% mortality rate for children with underlying cardiac or respiratory disease, respectively. Inuit children have a bronchiolitis RSV rate up to 484 per 1 000 infants in the first year of life versus 27 per 1 000 infants in temperate Canada and the United States (Kovesi, 2012). The Canadian RSV season usually starts in November or December and lasts for 4 to 5 months (Robinson et al., 2015/2020). RSV infection may also occur in children older than 1 year who have a chronic or serious disabling illness. Occasionally, infants with RSV may have a concurrent viral or bacterial infection (e.g., otitis media, pertussis) (Crowe, 2020). Many older children who are diagnosed with asthma have a history of severe bronchiolitis in infancy (Crowe, 2020).

Risk factors for infants developing severe RSV are being less than 6 weeks old, prematurity and under 6 months of age with no chronic lung disease, underlying cardiac or respiratory conditions, Down syndrome, and immunocompromised children (particularly transplant patients) (Robinson et al., 2015/2020). A study in Nunavut revealed additional factors: maternal smoking during pregnancy, residing in communities outside Iqaluit, being of full Inuit lineage, and overcrowding (Banerji et al., 2009).

Although most cases of bronchiolitis are caused by RSV, adenoviruses and parainfluenza viruses are also implicated; human metapneumovirus has also been associated with bronchiolitis in children. It can also rarely be caused by *M. pneumoniae.*

RSV is transmitted from exposure to contaminated secretions. RSV can live on fomites for several hours and on hands for 30 minutes (AAP, Committee on Infectious Diseases et al., 2018).

Pathophysiology. RSV affects the epithelial cells of the respiratory tract. The ciliated cells swell, protrude into the lumen, and lose their cilia. The walls of the bronchi and bronchioles are infiltrated with inflammatory cells, and varying degrees of intraluminal obstruction lead to hyperinflation, obstructive emphysema resulting from partial obstruction, and patchy areas of atelectasis. Dilation of bronchial passages on inspiration allows sufficient space for intake of air, but narrowing of the passages on expiration prevents air from leaving the lungs. As a result, the air is trapped distal to the obstruction and causes progressive overinflation (emphysema).

Clinical Manifestations. The illness usually begins with an upper respiratory infection after an incubation of about 5 to 8 days. Symptoms such as rhinorrhea and low-grade fever often appear first. OM and conjunctivitis may also be present. In time, a cough may develop. If the disease progresses, it becomes a lower respiratory tract infection and manifests typical symptoms (Box 45.8). Infants may have several days of upper respiratory infection symptoms or no symptoms except slight lethargy, poor feeding, or irritability. Children who are infected with RSV are usually contagious for 3 to 8 days, but some infants and patients with weakened immune systems can be contagious for as long as 4 weeks (AAP, Committee on Infectious Diseases et al., 2018).

BOX 45.8 Signs and Symptoms of Respiratory Syncytial Virus

Initial
Rhinorrhea
Pharyngitis
Coughing/sneezing
Wheezing
Possible ear or eye drainage
Intermittent fever

With Progression of Illness
Increased coughing and wheezing
Tachypnea and retractions
Cyanosis

Severe Illness
Tachypnea greater than 70 breaths/min
Listlessness
Apneic spells
Poor air exchange; decreased breath sounds

Once the lower airway is involved, classic manifestations include signs of altered air exchange, such as wheezing, retractions, crackles, dyspnea, tachypnea, and diminished breath sounds. Apnea may be the first recognized indicator of RSV infection in very young infants (younger than 1 month).

Diagnostic Evaluation. Identification has been simplified by the development of tests done on nasal or nasopharyngeal secretions, using either rapid immunofluorescent antibody–direct fluorescent antibody (DFA) staining or enzyme-linked immunosorbent assay (ELISA) techniques for RSV antigen detection (see Respiratory Secretion Specimens, Chapter 44). Hyperinflation of the lungs is generally seen on the chest X-ray.

Therapeutic Management. Children with bronchiolitis are treated at home if they are maintaining hydration, do not have respiratory distress, and do not need oxygen therapy. Hospitalization is usually recommended for children with respiratory distress or those who cannot maintain adequate hydration. Other reasons for hospitalization include complicating conditions, such as underlying lung or heart disease or associated debilitated states, or a home environment where adequate management is questionable. An infant who is tachypneic or apneic, has marked retractions, seems listless, or has a history of poor fluid intake or is dehydrated should be closely observed for respiratory failure.

Humidified oxygen is administered via mask or hood, in concentrations sufficient to maintain adequate oxygenation (Spo_2) at or above 90% as measured by pulse oximetry. An alternative oxygen delivery system is humidified high-flow nasal cannula therapy, which may be better tolerated and potentially decrease the need for mechanical ventilation but still needs further research on efficacy. Infants with abundant nasal secretions may benefit from periodic superficial suctioning. Deep suctioning is not recommended (Friedman et al., 2014/2018).

Management of hydration is an important aspect of care. Frequent feeds should be encouraged and breastfeeding supported; both may be facilitated by providing supplemental oxygen. Fluids by mouth may be contraindicated because of tachypnea or nasal congestion may not be able to safely feed orally. When supplemental fluids are required, a recent randomized trial found nasogastric (NG) and IV routes to be equally effective, with no difference in length of hospital stay (Friedman et al., 2014/2018).

Clinical assessments, noninvasive oxygen monitoring, and blood gas values may guide therapy. Medical therapy for bronchiolitis is primarily supportive and aimed at decreasing airway hyperresonance and inflammation and promoting adequate fluid intake. Epinephrine may produce modest improvement in ventilation status. However, the evidence remains insufficient to support routine use of epinephrine in the emergency department. It may be reasonable to administer a dose of epinephrine and carefully monitor clinical response; however, unless there is clear evidence of improvement, continued use is not appropriate (Friedman et al., 2014/2018).

Corticosteroids (inhaled or systemic) and antihistamines have not been shown to be effective and are not recommended for routine use. Antibiotics are not part of the treatment of RSV unless there is a coexisting bacterial infection such as OM (Friedman, et al., 2014/2018). Additional recommendations include encouraging breastfeeding, avoiding passive tobacco smoke exposure, and promoting preventive measures, including hand hygiene.

Prevention of respiratory syncytial virus infection. The only product available in Canada for prevention of RSV is palivizumab, a monoclonal antibody, which is given monthly in an IM injection every 30 days during RSV season (November to April) for a maximum of five doses (Robinson et al., 2015/2021). Palivizumab use is managed by individual provinces and territories and the health care providers must apply to see if their patients qualify. According to the CPS, a reduction in hospitalization has been shown in the following children: infants at highest risk for a severe RSV infection; children with chronic lung disease of prematurity who require ongoing medical therapy; children with hemodynamically significant congenital heart disease who are younger than 24 months of age at the start of RSV season; and infants born before 32 weeks' gestational age and who are younger than 6 months at the start of the RSV season (Robinson et al., 2015/2021). At the present time, the CPS recommends palivizumab to prevent RSV in these high-risk populations (Robinson et al., 2015/2021).

MEDICATION ALERT

The lyophilized powder form of palivizumab should be administered within 6 hours of being reconstituted with sterile water because it is preservative free.

Nursing Care. Children admitted to the hospital with suspected RSV infection may be assigned separate rooms or grouped with other RSV-infected children. Droplet, contact, and routine precautions should be used, including hand hygiene, not touching one's nasal mucosa or conjunctiva, and using gloves, mask, and gowns when entering the patient's room. Other isolation procedures of potential benefit are those aimed at diminishing the number of hospital personnel, visitors, and uninfected children in contact with the child. Another measure is to make patient assignments so that nurses assigned to children with RSV are not caring for other patients who are considered high risk.

Infants with RSV often have copious nasal secretions, making breathing and feeding difficult. The child may lose weight or stop feeding altogether. If the child is breastfeeding, the mother should be encouraged to continue feeding the infant, or if feedings are contraindicated because of the acuity of the illness, the mother should pump milk and store it appropriately for later use (see Chapter 27). Parents should be taught how to instill normal saline drops into the nares and suction the mucus with a bulb syringe before feedings and before bedtime so that the child can eat and rest better. Unfortunately, no medications appropriate for infants can help with these symptoms. To address the issue of decreased fluid intake, parents may offer small amounts of clear fluids, 5 to 10 mL at a time, with a medication syringe every 5 to 10 minutes or so to maintain adequate hydration. Infants may cough or vomit as the secretions settle in the stomach; this may make them prone to emesis of such secretions.

Additional nursing care is aimed at monitoring oxygenation with pulse oximetry and providing information for the parent regarding the infant's status. For the most part, infants recover quickly from the disease and resume normal daily activities, including fluid intake. These infants are at risk for further episodes of wheezing that may or may not involve another RSV infection; parents, however, may be concerned that the infant has another serious case of RSV infection.

Pneumonias

Pneumonia, inflammation of the pulmonary parenchyma, is common in childhood but occurs more frequently in infancy and early childhood. Clinically, pneumonia may occur either as a primary disease or as a complication of another illness. The causative agent is either inhaled into the lungs directly or comes from the bloodstream.

The most useful classification of pneumonia is based on the etiological agent (i.e., viral, bacterial, mycoplasmal, or aspiration of foreign substances) (see the Aspiration Pneumonia section later in this chapter). Many organisms can cause pneumonia, and the causative organisms vary according to the child's age (Le Saux et al., 2018/2021). *Streptococcus pneumoniae* (pneumococcus) is the most common bacterial pathogen in children of all ages, whereas *Mycoplasma pneumoniae* and *Chlamydophila pneumoniae* are also frequent bacterial pathogens in children older than 5 years. Histomycosis, coccidioidomycosis, and other fungi can also cause pneumonia. *Pneumonitis* is a localized acute inflammation of the lung without the toxemia associated with lobar pneumonia.

The clinical manifestations of pneumonia vary depending on the etiological agent, the child's age, the child's systemic reaction to the infection, the extent of the lesions, and the degree of bronchial and bronchiolar obstruction (Box 45.9). The causative agent is identified from the clinical history, the child's age, the general health history, the physical examination, radiography, and the laboratory examination.

BOX 45.9 General Signs of Pneumonia

Fever—Usually quite high (≥39.5°C [103°F])
Respiratory
- Cough—nonproductive to productive with whitish sputum
- Tachypnea
- Breath sounds—crackles, decreased breath sounds
- Dullness with percussion
- Chest pain; abdominal pain with lower lobe involvement
- Retractions
- Nasal flaring
- Pallor to cyanosis (depends on severity)

Chest X-ray film—diffuse or patchy infiltration with peribronchial distribution
Behaviour—irritable, restless, lethargic
Gastrointestinal—anorexia, vomiting, diarrhea, abdominal pain

Viral Pneumonia. Viral pneumonias, which occur more frequently than bacterial pneumonias, are seen in children of all ages and are often associated with viral upper respiratory infections. Viruses that cause pneumonia include RSV in infants, and parainfluenza, influenza, human meta-pneumovirus, enterovirus, and adenovirus in older children. Differentiation between viruses is usually made by clinical features, such as the child's age, past medical history, season of the year, and radiographic and laboratory examination.

Viral infections of the respiratory tract render the affected child more susceptible to secondary bacterial invasion, especially when there is denuded bronchial mucosa. Treatment is symptomatic and includes measures to promote oxygenation, rehydration, and comfort, such as oxygen administration, antipyretics for fever management, monitoring fluid intake, and family support. Antimicrobial therapy is usually reserved for children in whom a bacterial infection is demonstrated by appropriate cultures.

Primary Atypical Pneumonia. *Atypical pneumonia* refers to pneumonia that is caused by pathogens other than the traditionally most common and readily cultured bacteria (e.g., *S. pneumoniae*). *M. pneumoniae* and *Chlamydia pneumoniae* are the most common causes of community-acquired pneumonia in children age 5 years or older (Kelly & Sandora, 2020; Le Saux et al., 2018/2021). It occurs in the fall and winter months and is more prevalent in crowded living conditions. Most affected persons recover from acute illness at home in 7 to 10 days with symptomatic treatment followed by a week of convalescence. The incubation period is 2 to 3 weeks, but the cough may last several weeks.

Chlamydial pneumonia, caused by *C. trachomatis,* can also occur in infants and generally appears between 1 and 3 months of age. The newborn contracts this from the infected genital tract of the mother at birth and more than half of these infants have chlamydial conjunctivitis first.

Erythromycin (for those younger than 9 years), azithromycin, and clarithromycin are the primary medications used for treating atypical pneumonia.

Bacterial Pneumonia. *S. pneumoniae* is the most common bacterial pathogen responsible for community-acquired pneumonia in children aged 3 weeks to 4 years (Kelly & Sandora, 2020). Other bacteria that cause pneumonia in children are group A streptococcus, *S. aureus*, *M. catarrhalis*, *M. pneumoniae*, and *C. pneumoniae*.

Beyond the newborn period, bacterial pneumonias display distinct clinical patterns that facilitate their differentiation from other forms of pneumonia. The onset of illness is abrupt and generally follows a viral infection that disturbs the natural defence mechanisms of the upper respiratory tract.

The child with bacterial pneumonia usually appears ill. Symptoms include fever, malaise, rapid and shallow respirations, cough, and chest pain. The pain of pneumonia may be referred to the abdomen in young children. Chills and meningeal symptoms (meningism) without meningitis are common.

Most older children with pneumonia can be treated at home if the condition is recognized and treatment is initiated early. Antibiotic therapy, rest, liberal oral intake of fluid, and administration of an antipyretic for fever are the principal therapeutic measures. Follow-up examination is recommended for small infants and toddlers. Hospitalization is indicated when pleural effusion or empyema accompanies the disease, when moderate or severe respiratory distress or deoxygenation occurs, in situations in which adherence to therapy is difficult, in infants younger than 6 months of age, and when there are chronic illnesses such as congenital heart disease or BPD (Chibuk et al., 2011/2018; Kelly & Sandora, 2020). IV fluids may be necessary to ensure adequate hydration, and oxygen is required if the child is in respiratory distress; some children may require initial therapy with parenteral antibiotics because of the severity of illness.

Complications. At present, the classic features and clinical course of pneumonia are seen infrequently because of early and vigorous antibiotic and supportive therapy. However, some children, especially infants, with staphylococcal or GABHS pneumonia develop empyema, pyopneumothorax, or tension pneumothorax. AOM and pleural effusion are common in children with pneumococcal pneumonia. Box 45.10 describes pneumothorax and plural effusion.

Continuous closed-chest drainage may be instituted when purulent fluid is aspirated. If a large amount of purulent drainage is obtained, an appropriate antibiotic is instilled into the pleural space, and active chest drainage is discontinued for approximately 1 hour after the instillation. Closed drainage is continued until drainage fluid is free of pathogens, which rarely requires more than 5 to 7 days. Sometimes, repeated pleural taps are sufficient to remove fluid; however, if the purulent drainage accumulates rapidly and is highly viscous, continuous chest drainage is preferred. Rarely thoracotomy with open debridement of the infected lung tissue may be required. If empyema and pneumothorax tend to recur, a partial thoracoscopic lobectomy may be performed. Alternatively, video-assisted thoroscopy (VATS) or insertion of a small-bore percutaneous chest tube with instillation of fibrinolytics are the best current options for and may preclude the use of open debridement and thoracotomy (Chibuk et al., 2011/2018).

Prevention. Currently, the use of the heptavalent pneumococcal conjugate vaccine (PCV-13) is recommended for infants and children (see vaccination schedule in Additional Resources at the end of this chapter). This addition has nearly eradicated invasive pneumococcal disease in children and adults. This vaccine has also decreased the rates of lobar pneumonia, pneumococcal meningitis, and OM. There has been a relatively small increase in an antibiotic-resistant strain of pneumococcal pneumonia (serotype-19) that has developed as result of the vaccine. In Quebec, in the under-5-year age group, there was a 72% drop in hospital admissions for lobar pneumonia and a 13% decline in admissions for all-cause pneumonia after the universal pneumococcal vaccine was introduced (De Wals et al., 2008).

Nursing and Interprofessional Care. Care of the hospitalized child with pneumonia is primarily supportive and symptomatic but requires thorough respiratory assessment and administration of fluids and antibiotics. The respiratory therapist is involved in the child's care if supplemental oxygen is needed. For some children, a pulmonologist may

BOX 45.10 Pneumothorax and Pleural Effusion

Pneumothorax occurs when there is an accumulation of air in the pleural space; this air increases intrapleural pressure, making it more difficult to expand the affected lung. This leads to the clinical manifestations of dyspnea, chest pain and often back pain, laboured respirations, tachycardia, and decreased oxygen saturation. In newborns and infants on mechanical ventilation, the first clinical signs of pneumothorax are oxygen desaturation and hypotension. The three major types of pneumothorax are tension, spontaneous, and traumatic. The definitive diagnosis of pneumothorax is a chest X-ray. The emergent treatment involves needle aspiration of the air within the pleural space; subsequently a chest tube to closed drainage is usually inserted to prevent the reaccumulation of air. *Pleural effusion* occurs when there is an excessive accumulation of fluid in the pleural space. The diagnosis is made by chest X-ray, and the treatment involves evacuation of the fluid by needle aspiration, followed by insertion of a chest tube to closed drainage.

be consulted. The child's respiratory rate and oxygenation status, as well as vital signs, pain level, and general disposition and level of activity, are frequently assessed. To prevent dehydration, fluids may need to be administered intravenously during the acute phase. If the child is ill, solid foods may be rejected; fluid intake is encouraged until the child feels well enough to eat solids. Dietitians can perform a nutritional assessment and provide nutritional interventions if indicated.

Nursing care of the child with a chest tube requires close attention to respiratory status, as noted previously; the chest tube and drainage device used should be monitored for proper function (i.e., drainage is not impeded, vacuum setting is correct, tubing is free of kinks, dressing covering chest tube insertion site is intact, water seal is maintained [if used], and chest tube remains in place). Movement in bed and ambulation with a chest tube should be encouraged according to the child's respiratory status; children often require a mild analgesic such as acetaminophen.

If needed, supplemental oxygen may be administered by nasal cannula, face mask, or blow-by (which is the process of wafting or blowing oxygen past a child's face). Children are usually more comfortable in a semierect position (Figure 45.3) but should be allowed to determine the position of comfort. Lying on the affected side if pneumonia is unilateral (good lung up) splints the chest on that side and can reduce the pleural rubbing that often causes discomfort. Fever is controlled by ensuring adequate fluid intake and administration of antipyretic medications.

Children, especially infants, with ineffectual cough or difficulty handling secretions require suctioning to maintain a patent airway. A simple bulb suction syringe is usually sufficient for clearing the nares and nasopharynx of infants, but mechanical suction should be readily available if needed. A noninvasive suction device may be used to suction the infant's nares without the danger of causing nasal trauma; the device may be connected to mechanical suction for best results. Older children can usually handle secretions without assistance. Incentive spirometer and nebulized bronchodilator treatments may be prescribed, depending on the child's condition.

The presence of a caregiver often provides the child with a source of comfort and support. It is important to involve the entire family in the child's care, as appropriate, and to encourage questions and facilitate effective communication. Allowing the child to be involved in regular activities, such as quiet play, may help reduce the anxiety and fears of hospitalization.

Fig. 45.3 A child placed in a semierect position is often more comfortable, and this position enhances diaphragmatic expansion.

For the child being cared for at home, the nurse needs to educate the parents regarding observation for worsening symptoms, antibiotic and antipyretic administration, and encouragement of oral fluid intake. Return to school or day care is usually permitted according to the type of pneumonia, severity of illness, and health care provider's recommendation. It should be emphasized that the infection may be transmitted to other children through close contact.

OTHER RESPIRATORY TRACT INFECTIONS

Pertussis (Whooping Cough)

Pertussis, or *whooping cough*, is an acute respiratory tract infection caused by *Bordetella pertussis* that in the past occurred primarily in children younger than 4 years of age who were not immunized. It is highly contagious and is particularly threatening in young infants, who have a higher morbidity and mortality rate. Complications in adolescents commonly include syncope, rib fractures, insomnia, and weight loss, whereas in younger children pneumonia, atelectasis, seizures, encephalopathy, hernias, and death can occur (Government of Canada, 2020d; Kilgore et al., 2016). Infants younger than 3 months of age may not come to the health care provider with the typical cough; in this age group, apnea is a common presenting manifestation (Souder & Long, 2020). Likewise, older children are known to manifest the disease with a persistent cough and the absence of the characteristic whoop (see Table 35.7 for signs, symptoms, and management of pertussis). Diagnosis is obtained via culture or *B. pertussis* polymerase chain reaction (PCR) test on specimens obtained with a nasopharyngeal swab.

Most children with pertussis can be managed at home. Care is supportive and includes encouraging adequate hydration and administering antipyretics. When coughing spasms occur in small children, they can be frightening for the parents and family. Admission to the hospital is required if respiratory symptoms are severe or if apnea occurs. Treatment with antibiotics (erythromycin, clarithromycin, or azithromycin) in the catarrhal stage may result in a milder form of the infection, but treatment also prevents spread to others (Kilgore et al., 2016). Family contacts may also be treated. Pertussis symptoms usually last for 6 to 10 weeks but may persist longer.

Children with pertussis who are symptomatic and are confirmed by laboratory or are linked to an individual with a laboratory positive test need to be reported to their local public health department. Pertussis is a nationally reportable disease and surveillance of pertussis is conducted by public health professionals in provinces and territories who report cases to the Public Health Agency of Canada through the Canadian Notifiable Disease Surveillance System (CNDSS).

In Canada, one to four deaths each year are related to pertussis, usually in infants who are too young to be immunized or only partly immunized (Government of Canada, 2020d). The incidence is highest in the spring and summer months, and a single attack confers lifetime immunity. The resurgence of pertussis in Canada, particularly among older children and adults, is due to weakening immunity from vaccines produced in the mid-1990s as well as some parents opting not to immunize their children. See Chapter 35 for discussion of vaccination schedule recommendations for children. Initial immunization for all children is recommended at 2, 4, and 6 months of age with additional boosters given at specified times (see Figure 35.16). In order to decrease transmission to newborns prior to their being adequately immunized, it is recommended that all pregnant patients be offered the pertussis vaccine during the second or third trimester, preferably between 21 and 32 weeks' gestation, during every pregnancy, irrespective of immunization history (Castillo & Poliquin, 2018; Government of Canada, 2020d).

Tuberculosis

Worldwide, tuberculosis (TB) is one of the most widespread infectious diseases and among one of the 10 leading causes of death. The WHO estimates that there were 10 million new TB cases in the world in 2019 with 1.2 million deaths (WHO, 2020). Canada has one of the lowest TB rates in the world; in 2017, there were 1 796 cases of TB reported, which is a 2.6% increase compared to 2016 (Government of Canada, 2019c). The majority (71.8%) of cases were foreign-born and the incidence rate remained highest among Canadian-born Indigenous people (17.4% of all cases) (Government of Canada, 2019c). Rates are high among Indigenous children and young adults. Although the TB rates in Canada are still very low, the rates may continue to rise, with potential increases in immigration and in young Indigenous people (LaFreniere et al., 2019). Risk factors for developing TB include the following: those who reside in crowded and poorly ventilated housing, those with human immunodeficiency virus (HIV) or acquired immune deficiency syndrome (AIDS); those who come in close contact with individuals with known or suspected active TB, or who have a past history of TB but did not receive adequate treatment; individuals living in Indigenous communities with high rates of TB; poor, particularly urban homeless individuals; heavy alcohol drinkers; residents of long-term care and correctional facilities; individuals with transplants, diabetes mellitus, or cancer of the head and neck; those with chronic kidney disease who are on dialysis; those who have been infected by TB bacteria within the past 2 years; individuals who have undergone steroid treatments or treatment for **autoimmune disorders**; those who are underweight; individuals who smoke 1 pack of cigarettes a day or more; and individuals working with any of these groups. When children under age 5 are infected with TB it can advance to a severe level of disease (Government of Canada, 2019d; Kitai & Demers, 2014).

TB is caused by *Mycobacterium tuberculosis*. Children are susceptible to the human (*M. tuberculosis*) and the bovine (*Mycobacterium bovis*) organisms. In parts of the world where TB in cattle is not controlled or milk is not pasteurized, the bovine type is a common source of infection.

The source of TB infection in children is usually an infected member of the household or a frequent visitor to the home. The airway is the usual portal of entry for the organism. In the lungs, a proliferation of epithelial cells surrounds and encapsulates the multiplying bacilli in an attempt to wall it off, thus forming the typical tubercle. Extension of the primary lesion at the original site causes progressive tissue destruction as it spreads within the lung, discharges material from foci to other areas of the lungs (e.g., bronchi, pleura), or produces pneumonia. Erosion of blood vessels by the primary lesion can cause widespread dissemination of the tubercle bacillus to near and distant sites (miliary TB). Extrapulmonary (miliary) TB may manifest as superior lymphadenitis, meningitis, and osteoarthritis and may appear in the middle ear and mastoid and on the skin (AAP, Committee on Infectious Diseases et al., 2018). With the exception of meningitis, treatment for extrapulmonary TB may be with the same medication regimen as for pulmonary TB. Infants and children younger than 3 years of age are more likely to develop miliary TB.

Diagnostic Evaluation. Diagnosis is based on information derived from physical examination, history, tuberculin skin testing, radiographic examinations, and cultures of the organism. The clinical manifestations of the disease are extremely variable (Box 45.11).

The *tuberculin skin test (TST)* is the most important indicator of whether a child has been infected with the tubercle bacillus. The standard dose of purified protein derivative (PPD) is 5 tuberculin units, which is administered using a 27-gauge needle and a 1-mL syringe intradermally into the volar aspect of the forearm. Creation of a visible wheal is crucial to accurate testing and is repeated if the wheal does not form (Figure 45.4). The size of the transverse diameter of induration, not the erythema, is measured (Figure 45.5). In Canada, the current recommendations are to screen only children who are at high risk for TB infections or who are progressing from latent to active TB disease (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2019).

A *positive reaction* indicates that the individual has been infected and has developed sensitivity to the tubercle bacillus. However, it does not confirm the presence of active disease. The test is usually positive 2 to 10 weeks after initial infection with the organism. Once a child reacts positively, then the child will always react positively. A previously negative reaction that becomes positive indicates that the person has been infected since the last test. Guidelines for interpreting the TST are listed

BOX 45.11 Clinical Manifestations of Tuberculosis

May be asymptomatic or produce a broad range of symptoms:
- Fever
- Malaise
- Anorexia
- Weight loss (or failure to grow in child)
- Cough (may or may not be present; progresses slowly over weeks to months)
- Aching pain and tightness in the chest
- Hemoptysis (rare)

With progression:
- Increased respiratory rate
- Poor expansion of lung on the affected side
- Diminished breath sounds and crackles
- Dullness on percussion
- Persistent fever
- Pallor, anemia, weakness, and weight loss

Fig. 45.4 Administration of TST. While holding the skin of the inner aspect of the forearm taut, insert the needle at a 5- to 15-degree angle to the skin without aspirating. The tip of the needle will be visible just below the surface of the skin. The needle is inserted until the entire bevel is covered. (Source: Government of Canada. [2014]. *Chapter 4: Canadian tuberculosis standards 7th edition: 2014—Diagnosis of latent tuberculosis infection.* https://www.canada.ca/en/public-health/services/infectious-diseases/canadian-tuberculosis-standards-7th-edition/edition-16.html#a5_0).

Fig. 45.5 Reading of induration should be performed 48 to 72 hours after TST administration, as maximum induration can take up to 48 hours to develop, but after 72 hours it is difficult to interpret a reaction. (Source: Government of Canada. [2014]. *Chapter 4: Canadian tuberculosis standards 7th edition: 2014 – Diagnosis of latent tuberculosis infection.* https://www.canada.ca/en/public-health/services/infectious-diseases/canadian-tuberculosis-standards-7th-edition/edition-16.html#a5_0).

in Box 45.12. Prompt radiographic evaluation of all children with a positive TST reaction is recommended.

The term *latent tuberculosis infection* (LTBI) is used to indicate infection in a person who has a positive TST, no physical findings of disease, and normal chest X-ray findings. The majority of children are asymptomatic when a positive skin test result is found, and most of them do not go on to develop the disease.

The term *tuberculosis disease* or *clinically active TB* is used when a child has clinical symptoms or radiographic manifestations caused by the *M. tuberculosis* organism. A diagnosis of TB disease represents recent transmission of the *M. tuberculosis* organism and is an urgent event for public health. Prompt evaluation, treatment, and identification and treatment of contacts are key components to managing TB.

Blood tests have been developed to help diagnose LTBI. The CPS recommends that the IGRA (interferon-gamma-release-assay) be used as a diagnostic aid in combination with the Spot-TB test and other radiological and sputum or gastric washings culture tests to help diagnose active TB (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2019).

Therapeutic Management. Medical management of TB disease in children consists of adequate nutrition, pharmacotherapy, general supportive measures, prevention of unnecessary exposure to other infections that would further compromise the body's defences, prevention of reinfection, and sometimes surgical procedures. Family members and other contacts should also be assessed for symptoms by public health providers and treated accordingly.

The recommended medication regimen for LTBI in children and adolescents includes a 6- or 9-month course of isoniazid (INH) in either a daily dose or divided into two doses per week, with direct observation of therapy (DOT). DOT means that a health care worker or other responsible, mutually agreed-on individual is present when medications are administered to the patient. DOT decreases the rates of relapse, treatment failures, and drug resistance. Rifampin (daily for 6 months; alternatively, DOT twice weekly for 6 months) may be used to treat the child or adolescent who is INH resistant (Kitai & Demers, 2014).

For the child with clinically active TB, the goal is to achieve sterilization of the tuberculous lesion. Recommended medication therapy for treating TB disease includes combinations of INH, rifampin, and pyrazinamide (PZA) and ethambutol. The Public Health Agency of Canada recommends a 6-month regimen consisting of INH, rifampin, ethambutol, and PZA given daily for the first 2 months, followed by INH and rifampin given two or three times a week by DOT for the remaining 4 months (Kitai & Demers, 2014).

In Canada, it is recommended that previously treated patients have access to drug-susceptibility testing and culture at the beginning of treatment to identify possible multidrug–TB resistance. The optimal treatment of pulmonary TB in children and adolescents with HIV infection is unknown and advice from a TB expert should be sought (Kitai & Demers, 2014).

Surgical procedures may be required to remove the source of infection in tissues that are inaccessible to pharmacotherapy or that are destroyed by the disease. Orthopedic procedures may be performed for correction of bone deformities, and bronchoscopy may be done for removal of a tuberculous granulomatous polyp.

BOX 45.12 Definition of Positive Tuberculin Skin Test (TST) Results in Infants, Children, and Adolescents*

Induration 5 mm or Greater

Children in close contact with known or suspected contagious cases of tuberculosis (TB) disease

Children suspected of having TB disease:

- Findings on chest X-ray film consistent with active or previously active TB
- Clinical evidence of TB disease†

Children receiving immune suppressive therapy‡ or who have immunosuppressive conditions, including HIV infection

Induration 10 mm or Greater

Children at increased risk of disseminated disease:

- Those younger than 4 years of age
- Those with other medical risk conditions, including Hodgkin disease, lymphoma, diabetes mellitus, chronic renal failure, or malnutrition

Children at increased risk of exposure to TB disease:

- Those born, or whose parents were born, in high-prevalence TB regions of the world
- Those frequently exposed to adults who are HIV infected, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized, or migrant farm workers
- Those who travel to high-prevalence TB regions of the world

Induration 15 mm or Greater

Children 4 years of age or older without any risk factors

From Pai, M., Kunimoto, D., Jamieson, F., & Menzies, D. (2014). *Chapter 4: Canadian tuberculosis standards 7th edition: 2014—Diagnosis of latent tuberculosis infection.* https://www.canada.ca/en/public-health/services/infectious-diseases/canadian-tuberculosis-standards-7th-edition/edition-16.html.

*These definitions apply regardless of previous Bacille Calmette-Guérin (BCG) immunization; erythema at tuberculin skin test (TST) site does not indicate a positive test result. TSTs should be read at 48 to 72 hours after placement.

†Evidence by physical examination or laboratory assessment that would include TB in the working differential diagnosis (e.g., meningitis).

‡Including immunosuppressive doses of corticosteroids.

Prognosis. Most children recover from primary TB infection and are often unaware of its presence. However, very young children have a higher incidence of disseminated disease. TB is a serious disease during the first 2 years of life, during adolescence, and in children who are HIV positive. Except in cases of tuberculous meningitis, death seldom occurs in treated children. Antibiotic therapy has decreased the death rate and the hematogenous spread from primary lesions.

Prevention. The only definite means of preventing TB is to avoid contact with the tubercle bacillus. Maintaining an optimal state of health with adequate nutrition and avoiding fatigue and debilitating infections promote natural resistance but do not prevent infection. Pasteurization and routine testing of milk and elimination of diseased cattle have reduced the incidence of bovine TB.

Limited immunity can be produced by the administration of *Bacille Calmette-Guérin* (BCG), a live vaccine containing bovine bacilli with reduced **virulence** (attenuated). In most instances, positive tuberculin reactions develop after inoculation with BCG. Currently, the NACI does not recommend BCG vaccination for all Canadians. However, it allows that, in some settings, consideration of local TB epidemiology and access to diagnostic services may lead to the decision to offer BCG. BCG vaccination may be considered in exceptional circumstances, such as for infants in high-risk communities, persons at high risk of repeated exposure, certain long-term travellers to high-prevalence countries, and infants born to mothers with infectious TB disease (Government of Canada, 2020a).

Nursing Care. Most hospitalized children with TB are not contagious and require only routine precautions. Children with no cough and negative sputum smears can be hospitalized in a regular patient room. However, airborne precautions and a negative-pressure room are required for children who are contagious and hospitalized with active TB disease. Infection control for hospital personnel in contagious cases should include the use of a personally fitted air-purifying N95 or N100 (powered air-purifying respirator [PAPR]) respirator for all patient contacts.

Asymptomatic children with TB can attend school or day care facilities if they are receiving pharmacotherapy. They can return to regular activities as soon as effective therapy has been instituted, adherence to therapy has been documented, and clinical symptoms have diminished. Children receiving pharmacotherapy for TB can receive measles and other age-appropriate live virus vaccines unless they are receiving high-dose corticosteroids, are severely ill, or have specific contraindications to immunization. Children with TB should also receive optimal nutrition and adequate rest.

Sputum specimens are either difficult or impossible to obtain from an infant or young child, because they swallow any mucus coughed from the lower respiratory tract. The best means of obtaining material for smears or culture is by gastric washing (i.e., aspiration of lavaged contents from the fasting stomach). The procedure is carried out and the specimen obtained early in the morning before the customary breakfast time. In some cases, an induced sputum specimen may be obtained by administering aerosolized normal saline for 10 to 15 minutes, followed by chest percussion and postural drainage and suctioning of the nasopharynx for sputum collection.

Because the success of therapy depends on adherence to the medication regimen, parents need to be instructed about the importance of and rationale for DOT. Case finding in the community and follow-up of known contacts—individuals from whom the affected child may have acquired the disease and persons who may have been exposed to the child with the disease—are essential control measures.

PULMONARY DYSFUNCTION CAUSED BY NONINFECTIOUS IRRITANTS

Foreign Body Aspiration

Small children characteristically explore matter with their mouths and are prone to aspirate a foreign body (FB). They also place objects such as beads, paper clips, small magnets, or food items in the nose, which can easily be aspirated into the trachea. While FB aspiration can occur at any age, it is most common in children 1 to 3 years of age. Severity is determined by the location, type of object aspirated, and extent of obstruction. For example, dry vegetable matter, such as a seed, nut, or piece of carrot or popcorn, that does not dissolve and that may swell when wet creates a particularly difficult challenge. The high fat content of potato chips and peanuts may cause the added risk of lipoid pneumonia. "Fun foods" are the worst offenders in terms of potential for aspiration. Offending foods in the order of frequency of aspiration are hot dog, round candy, peanut or other nut, grape, cookie or biscuit, other meat, carrot, peas, apple, and peanut butter. Other items that can present a danger include burst latex balloons, plastic or glass beads, marbles, pen or marker caps, button or disc batteries, and coins. Objects such as small lithium or cadmium batteries may cause esophageal or tracheal corrosion.

Diagnostic Evaluation. The diagnosis of FB aspiration is suspected on the basis of the history and physical signs. Initially, a FB in the air passages produces choking, gagging, wheezing, or coughing. Laryngotracheal obstruction most commonly causes dyspnea, cough, stridor, and hoarseness because of decreased air entry. Up to one half of all children with FB ingestion may be asymptomatic. Cyanosis may occur if the obstruction becomes worse. Bronchial obstruction usually produces cough (frequently paroxysmal), wheezing, asymmetrical breath sounds, decreased airway entry, and dyspnea. When an object is lodged in the larynx, the child is unable to speak or breathe. If the obstruction progresses, the child's face may become livid; if the obstruction is total, the child can become unconscious and die of **asphyxiation**. If obstruction is partial, hours, days, or even weeks may pass without symptoms after the initial period. Secondary symptoms are related to the anatomical area in which the object is lodged and are usually caused by a persistent respiratory tract infection distal to the obstruction. FB aspiration should also be suspected in the presence of acute or chronic pulmonary lesions. Often, by the time secondary symptoms appear, the parents have forgotten the initial episode of coughing and gagging. Nasal FB cases are often symptomatic with unilateral purulent drainage that does not improve over time.

Radiographic examination can reveal opaque FBs but is of limited use in localizing nonradiographic matter. Bronchoscopy is required for a definitive diagnosis of objects in the larynx and trachea. Fluoroscopic examination is valuable in detecting FBs in the bronchi. The mainstay of diagnosis and management of FBs is endoscopy. If there is doubt about the presence of an FB, endoscopy can be diagnostic and therapeutic.

Therapeutic Management. FB aspiration may result in life-threatening airway obstruction, especially in infants because of the small diameter of their airways. Current recommendations for emergency treatment of the choking child include the use of abdominal thrusts for children older than 1 year of age and back blows and chest thrusts for those younger than 1 year of age (see Airway Obstruction).

An FB is rarely coughed up spontaneously. Most frequently, it must be removed instrumentally by endoscopy. Endoscopy and bronchoscopy require sedation with an agent such as IV propofol or midazolam.

The procedure is carried out as quickly as possible because the progressive local inflammatory process triggered by the foreign material hampers removal. A chemical pneumonia soon develops, and vegetable matter begins to macerate within a few days, making it even more difficult to remove. After removal of the FB, the child is usually observed for any complications, such as laryngeal edema, and discharged home within a matter of hours if vital signs are stable and recovery is satisfactory.

Prevention. Nurses are in a position to teach prevention of FB aspiration, in a variety of settings. They can educate parents singly or in groups about hazards of aspiration in relation to the developmental level of their children and encourage them to teach their children safety. Parents should be cautioned about behaviours that their children might imitate (e.g., holding foreign objects, such as pins, nails, and toothpicks, in their lips or mouth). Parents should be educated on access to age-appropriate toys and how older siblings' toys could be hazardous for younger siblings (see Chapter 35). Magnets must be kept away from younger children.

Nursing Care. A major role of nurses caring for a child who has aspirated an FB is to recognize the signs of FB aspiration, observe for worsening respiratory symptoms, and implement immediate measures to relieve an emergency obstruction. Choking on food or other material should not be fatal. Back blows and chest thrusts in infants and abdominal thrusts in children are simple procedures that can be used by both health care providers and laypersons to save lives. To aid a child who is choking, nurses must recognize the signs of distress. A blind sweep of the child's mouth should never be performed because it may lodge the agent farther into the airway. Not every child who gags or coughs while eating is truly choking.

! NURSING ALERT

The child in severe distress (1) cannot speak, (2) becomes cyanotic, and (3) collapses. These three signs indicate that the child is truly choking and requires immediate action. The child can die within 4 minutes.

Aspiration Pneumonia

Aspiration pneumonia occurs when food, secretions, inert materials, volatile compounds, or liquids enter the lung and cause inflammation and a chemical pneumonitis. Aspiration of fluid or foods is a particular hazard in the child who has difficulty swallowing; is unable to swallow because of paralysis, weakness, debility, congenital anomalies, or absent cough reflex; or is force-fed, especially while crying or breathing rapidly.

Clinical signs of the aspiration of oral secretions may not be distinguishable from those of other forms of acute bacterial pneumonia. For example, if vegetable matter has been aspirated, manifestations may not appear for several weeks after the event. Classic symptoms include an increasing cough or fever with foul-smelling sputum, deteriorating chest radiographs, and other signs of lower airway involvement. These deviations may persist for weeks while the child starts to feel better. Rarely, aspiration causes immediate death from asphyxia; more often the irritated mucous membrane becomes a site for secondary bacterial infection. In addition to fluids, food, vomitus, and nasopharyngeal secretions, other substances that may cause pneumonia are hydrocarbons, lipids, powder, and contrast dye or barium. The severity of the lung injury depends on the pH of the aspirated material.

Nursing Care. Care of the child with aspiration pneumonia is the same as that described for the child with pneumonia from other causes. However, the major focus of nursing care is on the prevention of aspiration. Proper feeding techniques should be carried out for weak and debilitated children and those who cannot assist in feeding, and preventive measures should be used to prevent aspiration of any material that might enter the nasopharynx. The presence of an NG feeding tube or a history of gastroesophageal reflux disease places the child at risk for aspiration. NG tubes used for feedings should be checked before the initiation of bolus feedings; continuous NG tube feedings also need to be evaluated periodically for proper tube placement.

Children who are at risk for swallowing difficulties as a result of illness, physical debilitation, anaesthesia, or sedation should be kept NPO (nothing by mouth) until they can properly swallow fluids effectively. Nurses can request a formal evaluation by a speech therapist or occupational therapist of a child's ability to swallow in patients who are at risk for aspiration. The child may receive nutrition by alternate means (such as an enteral feeding tube), and a dietitian can determine the best nutrition. The child who is at risk for vomiting and incapable of protecting the airway should be positioned in a side-lying recovery position. In addition to nursing care of the child, nurses can help prevent aspiration pneumonia by educating parents in measures that prevent aspiration.

Pulmonary Edema

Pulmonary edema is the movement of fluid into the alveoli and interstitium of the lungs that is caused by extravasation of fluid from the pulmonary vasculature (Woods & Mazor, 2020). There are two main types of pulmonary edema—cardiogenic and noncardiogenic.

Cardiogenic (hydrostatic, hemodynamic) pulmonary edema is caused by an increase in pulmonary capillary pressure because of an increase in pulmonary venous pressure. It can be caused by excessive IV fluid administration, left ventricular failure, heart valve disorder (aortic regurgitation, aortic stenosis, mitral regurgitation), myocardial ischemia, myocarditis, sepsis, acute tachydysrhythmia, or coronary arteriosclerosis (Pinto & Garon, 2019).

Noncardiogenic pulmonary edema is caused by various conditions that result in increased pulmonary capillary permeability. Some subtypes of noncardiogenic pulmonary edema include permeability pulmonary edema (caused by acute respiratory distress syndrome [ARDS] or acute lung injury [ALI]), high-altitude pulmonary edema (caused by rapid ascension to heights above 3 600 metres), and neurogenic pulmonary edema (after CNS insult, such as seizures, head injury, or cerebral hemorrhage). Some less common forms of pulmonary edema are reperfusion pulmonary edema (after removal of thromboemboli from the lung or a lung transplant), re-expansion pulmonary edema (caused by rapid re-expansion of a collapsed lung), and pulmonary edema that results from opiate overdose (methadone or heroin), salicylate toxicity (chronic), aspiration (FB inhalation), inhalation injuries, near submersion injury, pulmonary embolism, viral infections, or pulmonary venoocclusive disease. Other causes include traumatic injury, organ dysfunction caused by sepsis, multiorgan failure, alcoholism or substance use, pregnancy (eclampsia), chronic renal impairment, malnutrition, hypertension, or a blood transfusion (transfusion-related ALI).

Pathophysiology. Fluid flows from the pulmonary vasculature into the alveolar interstitial space and then returns to the systemic circulation in a normal lung. Movement of this fluid is controlled by the net difference between hydrostatic and osmotic pressures and the permeability of the capillary membrane. Increased pulmonary hydrostatic pressure or increased permeability of the vascular membrane results in movement of fluid into the alveoli and interstitium of the lung. The pulmonary lymph system normally drains away any fluid from

the alveoli, but when the amount of fluid present in the alveoli exceeds lymph drainage, pulmonary edema occurs.

Symptoms include extreme shortness of breath, cyanosis, tachypnea, diminished breath sounds, anxiety, agitation, confusion, diaphoresis, orthopnea, respiratory crackles, expiratory wheezing (in young infants), heart murmur, third heart sound (S_3) gallop, cool extremities, jugular venous distention, nocturnal dyspnea, cough, pink frothy sputum (if severe), tachycardia, hypertension, and hypotension (if caused by left ventricle dysfunction).

Therapeutic Management. Management of pulmonary edema depends on the cause but can include oxygen therapy, positive end-expiratory pressure (PEEP) via continuous positive airway pressure (CPAP), and intubation with ventilatory support if respiratory failure occurs. If ventricular failure is the cause, medications such as diuretics, digoxin, positive inotropes, and vasodilators (nitroglycerin) may be started and the child may be placed on fluid and sodium restriction. Morphine may be prescribed to relieve dyspnea. The primary goal of management is to determine why pulmonary edema occurred and to treat the underlying condition.

Nursing Care. Nursing care of the child with pulmonary edema is similar to that for any other acute respiratory condition. Pulse oximetry is monitored, and vital signs are observed closely for any deterioration. The nurse should note changes in oxygen saturation (Sao_2), end-tidal carbon dioxide ($ETCO_2$), and arterial blood gas (ABG) values. An ongoing assessment of the child's cardiopulmonary status is needed by checking lung sounds and observing respiratory rate, rhythm, depth, and effort. Oxygen, medications, and other respiratory treatments are administered as prescribed. Close monitoring of intake and output, electrolytes, and comfort is important. The child should be monitored for restlessness, anxiety, and air hunger. Placing the child in a high Fowler position may help with lung expansion. Because this position places pressure on bony prominences in the sacrum and hips, pressure areas must be relieved at intervals. Most of the care of pulmonary edema occurs in the critical care unit, which can be anxiety provoking for the child and family. They should be given the opportunity to express their fears and anxieties and to ask questions. (For other nursing care activities, see the following section on ARDS and ALI.)

Acute Respiratory Distress Syndrome (ARDS)/Acute Lung Injury (ALI)

ARDS and ALI are potentially life-threatening inflammatory lung conditions that may occur in both children and adults. The syndromes may be caused by direct injury to the lungs or by systemic insults that lead indirectly to lung injury with subsequent hypoxemia and respiratory failure due to noncardiogenic pulmonary edema. Sepsis, **trauma**, viral pneumonia, aspiration, fat emboli, drug overdose, reperfusion injury after lung transplantation, smoke inhalation, and submersion injury, among others, have been associated with ALI and ARDS. Both conditions are characterized by respiratory distress and hypoxemia that occur within 72 hours of a serious injury or surgery in a person with previously normal lungs. Acute pulmonary inflammation with alveolar capillary membrane destruction results in significant hypoxemia, and mechanical ventilation is often required. ARDS is most severe in the spectrum of illnesses in relation to the degree of hypoxemia. Mechanical ventilation is often required.

Diagnostic criteria include radiographic evidence of bilateral alveolar infiltrates, the absence of left-sided heart failure, and hypoxemia. ALI is differentiated from the more severe syndrome of ARDS by the severity of hypoxemia. In ALI, the P/F ratio is less than or equal to 300; in ARDS, the P/F ratio is less than or equal to 200 (Sarnaik et al., 2020). Children with ARDS have been previously been diagnosed using the Berlin definition for adults even though the pathophysiology is different between children and adults. The current pediatric definition (PARDS) differs in chest imaging findings, definition of oxygenation, consideration of both noninvasive and invasive mechanical ventilation, and consideration of special populations (Sarnaik et al., 2020).

Pathologically, the hallmark of ARDS is increased permeability of the alveolar-capillary membrane that results in pulmonary edema. During the acute phase of ARDS, the alveolocapillary membrane is damaged, with an increasing pulmonary capillary permeability and resulting interstitial edema. Later stages are characterized by pneumocyte and fibrin infiltration of the alveoli, with the start of either the healing process or fibrosis. When fibrosis occurs, the child may demonstrate respiratory distress and the need for mechanical ventilation. In ARDS, the lungs become stiff as a result of surfactant inactivation, gas diffusion is impaired, and eventually bronchiolar mucosal swelling and congestive atelectasis occur. The net effect is decreased functional residual capacity, pulmonary hypertension, and increased intrapulmonary right-to-left shunting of pulmonary blood flow. Surfactant secretion is reduced, and the atelectasis and fluid-filled alveoli provide an excellent medium for bacterial growth. Hypoxemia or increased work of breathing may require ventilator support.

Therapeutic Management. The child with ARDS may first demonstrate only symptoms caused by an injury or infection, but as the condition deteriorates, hyperventilation, tachypnea, increasing respiratory effort, cyanosis, and decreasing oxygen saturation occur. At times, the developing hypoxemia is not responsive to oxygen administration.

Treatment involves supportive measures such as maintenance of adequate oxygenation, administration of heliox, and pulmonary perfusion and maintenance of adequate cardiac output and vascular volume. After the underlying cause has been identified, specific treatment (e.g., antibiotics for infection) is initiated. Many patients require mechanical ventilatory support. This is usually achieved invasively (i.e., after endotracheal intubation), but occasionally noninvasive ventilation is used in milder cases. Patients requiring invasive mechanical ventilation usually require sedation, at least initially, to allow for ventilatory synchrony. Fluid administration to maintain adequate intravascular volume and end-organ perfusion must be balanced against the desire to decrease lung fluid to improve oxygenation. The provision of adequate nutrition, maintenance of patient comfort, and prevention of complications such as gastrointestinal ulceration are essential. Psychological support of the patient and family is also important.

Inappropriate use of mechanical ventilatory support may worsen the lung injury by causing volutrauma, barotrauma, atelectrauma, and biotrauma to the injured lungs. Protective ventilatory strategies using low tidal volumes (6 mL/kg ideal body weight) have been demonstrated to improve outcomes in adults and theoretically are also appropriate in children. PEEP is applied to decrease atelectasis and maintain an "open" lung. Permissive hypercapnia may also be used. Other strategies used in the support of patients with ARDS include maintaining them in the prone position, inhaled nitric oxide, inhaled prostaglandins, high-frequency oscillatory ventilation (HFOV), and extracorporeal membrane oxygenation (ECMO), although evidence to support these therapies is scant.

Prognosis. The prognosis for patients with ARDS is improving. Nonetheless, the mortality rate remains high, and in children ranges from 50% for severe pediatric ARDS at onset, 33.3% for moderate cases, and 30.5% for mild cases (Killien et al., 2020). The precipitating

disorder influences the outcome; the worst prognosis is associated with uncontrolled sepsis, bone marrow transplantation, cancer, and multisystem involvement with hepatic failure. Children who recover may have persistent cough and exertional dyspnea.

Nursing and Interprofessional Care. The child with ARDS is cared for in a critical care unit during the acute stages of illness. Care of the patient involves close monitoring of oxygenation and respiratory status as well as assessment of cardiac output, perfusion, fluid and electrolyte balance, and renal function (urinary output). Blood gas analysis, acid–base status, and pulse oximetry are important evaluation tools. Diuretics may be administered to reduce pulmonary fluid, and vasodilators may be administered to decrease pulmonary vascular pressure. Nutritional support is often required because of the prolonged acute phase of the illness. Intensivists, pulmonologists, dietitians, respiratory therapists, and often cardiologists and nephrologists are involved in the child's care.

Nursing care also includes managing pain, assessing the effects of the numerous parenteral fluids and medications used to stabilize the child, and monitoring for changes in the child's hemodynamic status. Most children with ARDS require invasive monitoring via a central venous line and possibly a pulmonary artery catheter to monitor oxygenation and administer medications. Nurses need to observe the child's skin condition and use measures to prevent skin breakdown such as pressure area relief and passive range-of-motion exercises. Physiotherapists can assist with care to prevent muscle atrophy and contractures.

Respiratory distress is a frightening situation for both the child and the parents, and attention to their psychological needs is a major element in the care of these children. The child is often sedated during the acute phase of the illness, and weaning from sedation requires close monitoring for anxiety reduction and comfort. Social workers and child life specialists can assist the patient and family with coping.

Smoke Inhalation Injury

A number of noxious substances that may be inhaled are toxic to humans. They are primarily products of incomplete combustion and cause more deaths from fires than flame injuries. The severity of the injury depends on the nature of the substances generated by the material burned, whether the victim is confined in a closed space, and the duration of contact with the smoke.

Three distinct syndromes of pulmonary complications may occur in children with inhalation injury: (1) early carbon monoxide (CO) poisoning, airway obstruction, and pulmonary edema; (2) ARDS occurring at 24 to 48 hours or later in some cases; and (3) late complications of bronchopneumonia and pulmonary emboli (Antoon, 2020).

Smoke inhalation results in three types of injury: heat, chemical, and systemic. *Heat injury* involves thermal injury to the upper airway. Air has low specific heat; thus the injury goes no farther than the upper airway. Reflex closure of the glottis prevents injury to the lower airway.

Chemical injury involves gases that may be generated during the combustion of materials such as clothing, furniture, and floor coverings. Acids, alkalis, and their precursors in smoke can produce chemical burns. These substances can be carried deep into the respiratory tract, including the lower respiratory tract, in the form of insoluble gases. Soluble gases tend to dissolve in the upper respiratory tract. Chemical burns to the airways are similar to burns on the skin, except they are painless because the tracheobronchial tree is relatively insensitive to pain.

Inhalation of small amounts of noxious irritants produces alveolar and bronchiolar damage that can lead to obstructive bronchiolitis. Severe exposure causes further injury, including alveolocapillary damage with hemorrhage, necrotizing bronchiolitis, inhibited secretion of surfactant, and formation of hyaline membranes—manifestations of ARDS.

Systemic injury occurs from gases that are nontoxic to the airways (e.g., CO, hydrogen cyanide). However, these gases cause injury and death by interfering with or inhibiting cellular respiration. CO is the leading cause of accidental poisonings in Canada. An estimated 4 990 deaths were associated with CO poisoning in Canada between 2000 and 2013 (Cohen et al., 2017). CO is a colourless, odourless gas with an affinity for hemoglobin 230 times greater than that of oxygen. When it enters the bloodstream, CO combines readily with hemoglobin to form carboxyhemoglobin (COHb). Because it is released less readily, tissue hypoxia reaches dangerous levels before oxygen is available to meet tissue needs.

! NURSING ALERT

The oxygen saturation (Sa_{O_2}) obtained by pulse oximetry will be normal because the device measures only oxygenated and deoxygenated hemoglobin; it does not measure dysfunctional hemoglobin such as COHb.

Accidental CO poisoning is most often a result of exposure to fumes of heaters or smoke from structural fires, although poorly ventilated recreational vehicles with improperly operated or maintained gas lamps or stoves and cooking in underventilated areas with charcoal grills are also frequent causes. CO is produced by incomplete combustion of carbon or carbonaceous material such as wood or charcoal.

The signs and symptoms of CO poisoning are secondary to tissue hypoxia and vary with the level of COHb. Mild manifestations include headache, visual disturbances, irritability, and nausea, whereas more severe intoxication causes confusion, hallucinations, ataxia, and coma. The bright, cherry-red lips and skin often described are less often observed; pallor and cyanosis are seen more frequently.

Therapeutic Management. Treatment of children with smoke inhalation injury is largely symptomatic. The most widely accepted treatment is placing the child on humidified 100% oxygen as quickly as possible (assuming no previous medical conditions exist contraindicating this) to rapidly reverse tissue hypoxia and to displace CO and cyanide from protein binding sites. The child is monitored for signs of respiratory distress and impending failure, and intubation may be required. A laryngoscopy or bronchoscopy evaluation may be done to assess for airway damage. Baseline ABG values and COHb levels are obtained. PaO_2 may be within normal limits unless there is marked respiratory depression. If CO poisoning is confirmed, 100% oxygen is continued until COHb levels fall to the nontoxic range of about 10%. If CO poisoning is severe, the patient may benefit from hyperbaric oxygen therapy. This therapy may be useful in the treatment of neurological complications related to CO poisoning. Pulmonary care may be facilitated by bronchodilators, inhaled corticosteroids, humidification, and chest percussion and postural drainage to enhance the removal of necrotic material, minimize bronchoconstriction, and avoid atelectasis. Bronchoscopy may be needed to clear heavy secretions.

Respiratory distress may occur early in the course of smoke inhalation as a result of hypoxia, or patients who are breathing well on admission may suddenly develop respiratory distress. Therefore, intubation equipment should be readily available. Transient edema of the airways can occur at any level in the tracheobronchial tree. Assessment and localization of the obstruction should be accomplished before severe swelling of the head, neck, or oropharynx occurs. Intubation is often necessary when (1) severe burns in the area of the nose, mouth, and face increase the likelihood of developing oropharyngeal edema and

obstruction; (2) vocal cord edema causes obstruction; (3) the patient has difficulty handling secretions; and (4) progressive respiratory distress requires artificial ventilation. Controversy surrounds the use of tracheostomy in this context, but many prefer this procedure when the obstruction is proximal to the larynx and reserve nasotracheal intubation for lower tract involvement.

Nursing Care. Nursing care of the child with inhalation injury is the same as that for any child with respiratory distress. The initial goal is to maintain a patent airway and effective ventilation status. Vital signs and other respiratory assessments (oxygenation, work of breathing, acid–base status) are performed frequently, and the pulmonary status is carefully observed and maintained. The administration of nebulized bronchodilators, humidified oxygen, and inhaled corticosteroids is often part of the child's care. Chest physiotherapy is often part of the treatment, as well as mechanical ventilation if needed. Fluid requirements for children experiencing inhalation injury are greater than for those with surface burns alone; however, one concern is the development of pulmonary edema. Thus accurate monitoring of intake and output is essential.

In addition to observation and management of the physical aspects of inhalation injury, the nurse must also address the psychological needs of a frightened child and distraught parents. As with any accidental injury, the parents may feel overwhelming guilt, even when the injury occurred through no fault of their own. Parents need support, reassurance, and information regarding the child's condition, treatment, and progress.

The nurse can provide anticipatory guidance and educate families on prevention of inhalation injuries and the importance of CO detectors in the home.

Environmental Tobacco, Cannabis Smoke Exposure, and Vaping

Numerous investigations indicate that parental smoking is an important cause of morbidity in children. Children exposed to (secondhand) passive or environmental tobacco smoke have an increased number of respiratory illnesses, increased respiratory symptoms (e.g., cough, sputum, and wheezing), and reduced performance on pulmonary function tests. The incidence of AOM and OME is also increased in children who have parents who smoke (see Otitis Media, earlier in the chapter). Maternal cigarette smoking while pregnant is associated with increased respiratory symptoms and illnesses in children; decreased fetal growth; increased births of low-birth-weight, preterm, and stillborn infants; and a greater incidence of sudden infant death syndrome (SIDS) (Government of Canada, 2015). The risk for diagnosis of early-onset asthma is associated with in utero exposure to maternal smoking. Exposure to passive smoking increases the incidence of wheezing and asthma in children and young people by at least 20%. Among children with asthma, there is an association between parental cigarette smoking and trips to the emergency department and medication use for asthma exacerbations, and impaired recovery after hospitalization for acute asthma. Exposure to tobacco smoke during childhood may contribute to the development of chronic lung disease in the adult.

Cannabis smoke comprises many of the same harmful chemicals found in tobacco smoke and children need to be protected from exposure. Some researchers have discovered that the use of cannabis during pregnancy, and while breastfeeding, may be associated with increased risk for the following issues: low birth rate; preterm labour; long-term health conditions related to mental health and cardiovascular issues; and short- and long-term learning, developmental, and behavioural issues, including low IQ scores, impulsivity, and hyperactivity in childhood, some of which may persist into adulthood (Society of Obstetricians and Gynecologists of Canada, 2019).

Another concern is the recent increase in the use of vaping. *Vaping* is an electronic aerosol cigarette that may contain nicotine, cannabis oil, and dozens of chemicals. Most vaping substances available are flavoured and contain nicotine and other chemicals that require the same level of avoidance for children as tobacco and cannabis secondhand smoke. Recently, there has been an increase in serious pulmonary illnesses that appear to be related to vaping (Government of Canada, 2020e). More research is needed to determine the effects of secondhand exposure to cannabis smoke and the use of vaping.

Nursing Care. Nurses must provide information about the hazards of environmental smoke and vapour exposure in all their interactions with children and their family members. This information is especially important for children with respiratory and allergic illnesses. In families in which smokers refuse to or cannot quit smoking, appropriate guidance should be provided for reducing exposure to smoke in the child's environment (see Family-Centred Care box: Decreasing Childhood Exposure to Environmental Tobacco, Vaping, Vapours, and Cannabis Smoke). Nurses should set an example for children and families and become advocates for "no smoking" ordinances in public places, prohibition of advertising tobacco products in the media, and inclusion of health warnings on tobacco products packaging (see Additional Resources section at the end of this chapter). Nurses also have an important role in providing parents and adolescents with affordable smoking-cessation education resources, including the appropriate use of smoking-cessation pharmacological aids.

FAMILY-CENTRED CARE

Decreasing Childhood Exposure to Environmental Tobacco, Vaping, Vapours, and Cannabis Smoke

- Maintain a smoke-free home.
- Avoid exposing infants and children to any environmental smoke.
- Use an air-purifying filter in the home where smoking is unavoidable.
- Encourage exclusive breastfeeding for the first 6 months.
- Change clothing after smoking and before breastfeeding or holding an infant in close proximity.
- Restrict smoking to outside the home.
- Do not smoke in motor vehicles with children.
- Keep vaping equipment out of reach of children who can be poisoned by liquid nicotine.

LONG-TERM RESPIRATORY DYSFUNCTION

Asthma

Asthma is a chronic inflammatory disorder of the airways characterized by recurring symptoms, airway obstruction, bronchial hyperresponsiveness, and an underlying inflammation process. In susceptible children, inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, especially at night or in the early morning. The airflow limitation or obstruction is reversible either spontaneously or with treatment. Inflammation causes an increase in bronchial hyperresponsiveness to a variety of stimuli. Recognition of the key role of inflammation has made the use of anti-inflammatory agents, especially inhaled corticosteroids, a key component in the treatment of asthma.

Asthma is the most common chronic illness in childhood and is a serious disease worldwide. The WHO (2021) reported that globally in 2019, there were over 262 million people with asthma, and it is

estimated that over 3.8 million Canadians, including 850 000 children under the age of 14, have asthma (Asthma Canada, 2021c). Fortunately, in Canada the prevalence of asthma has declined among children. Rates may be decreasing because of reduced exposure to cigarette smoke, including that at home (Thomas & Statistics Canada, 2015). In 2018, 16% of Canadians aged 12 and older smoked cigarettes either daily or occasionally. Asthma appears to be more prevalent in groups with low socioeconomic status, obesity, and low levels of physical activity (Philpott et al., 2010/2016).

In Canada, Indigenous children are affected disproportionately by respiratory infections such as viral bronchiolitis, pneumonia, and tuberculosis. However, their rates of asthma may be somewhat less than those among other Canadian children. Even so, there is a higher rate of poor asthma control in the Indigenous population (Kovesi, 2012).

Asthma is a predominant cause of hospitalization for Canadian children, with children under 5 years of age having the highest rates of more than 6 000 hospitalizations in 2015–2016 (Canadian Institute for Health Information [CIHI], 2020). Emergency department visits for asthma peak during the third week in September; occurrence of respiratory tract infections that can trigger asthma peaks in mid-winter. On average, asthma hospitalization rates for children in Canada have declined by 50% over the past 10 years. However, children living in lower-income neighbourhoods continue to have significantly higher rates of hospitalization than those in higher-income neighbourhoods (CIHI, 2018).

Asthma continues to be a very serious condition and can be life-threatening if not controlled. In Canada, approximately 6 out of 10 people with asthma do not have control of their disease. Poorly controlled asthma may lead to a severe, life-threatening asthma attack and permanent lung damage. Every year, 250 Canadians die from asthma (Asthma Canada, 2021c).

Etiology. Studies of children with asthma indicate that allergies influence both the persistence and the severity of the disease. In fact, *atopy*, or the genetic predisposition for the development of an immune globulin E (IgE)–mediated response to common aeroallergens, is the strongest identifiable predisposing factor for developing asthma. However, 20 to 40% of children with asthma have no evidence of allergic disease. In addition to allergens, other substances and conditions can serve as triggers that may exacerbate asthma (Box 45.13). Evidence shows that viral respiratory infections, including RSV infection, may have a significant role in the development and expression of asthma (Asthma Canada, 2021c).

Pathophysiology. There is general agreement that inflammation contributes to heightened airway reactivity in asthma. It is unlikely that asthma is caused by either a single cell or a single inflammatory mediator; rather, it appears that asthma results from complex interactions among inflammatory cells, mediators, and the cells and tissues present in the airways. Allergens occur when the immune system becomes sensitive and reacts to elements in the environment. Allergens cause allergic reactions. When allergens come in contact with mast cells that originate in the lining of the nose, lungs, skin and intestinal tract, the immune system produces the antibody IgE. IgE attaches to the mast cells, causing the release of many chemicals, including histamine, into the bloodstream. Histamine reacts on the eyes, nose, throat, lungs, skin, or the intestinal tract, leading to inflammation and symptoms of an allergic reaction. Repeated exposure to the allergen will trigger the same antibody response and cause an allergic reaction, which can trigger an asthma attack. Recognition of the importance of inflammation has made the use of anti-inflammatory agents a key component of asthma therapy.

BOX 45.13 Triggers Tending to Precipitate or Aggravate Asthmatic Exacerbations

Allergens
- Outdoor—trees, shrubs, weeds, grasses, moulds, pollens, air pollution, spores
- Indoor—dust or dust mites, mould, cockroach antigen

Irritants—tobacco smoke, wood smoke, odours, sprays
Exposure to occupational chemicals
Exercise
Cold air
Changes in weather or temperature
Environmental change—e.g., moving to new home, starting new school
Colds and infections
Animals—cats, dogs, rodents, horses
Medications—Aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, beta blockers
Strong emotions—fear, anger, laughing, crying
Conditions—gastroesophageal reflux, tracheoesophageal fistula
Food additives—sulphite preservatives
Foods—nuts, milk, or dairy products
Endocrine factors—menses, pregnancy, thyroid disease

Another important component of asthma is bronchospasm and airflow obstruction. The mechanisms responsible for the obstructive symptoms in asthma (Figure 45.6) include (1) inflammatory response to stimuli; (2) airway edema and accumulation and secretion of mucus; (3) spasm of the smooth muscle of the bronchi and bronchioles, which decreases the calibre of the bronchioles; and (4) airway remodelling, which causes permanent cellular changes.

Airflow is determined by the size of the airway lumen, degree of bronchial wall edema, mucus production, smooth muscle contraction, and muscle hypertrophy. Bronchial constriction is a normal reaction to foreign stimuli, but in the child with asthma it is abnormally severe, producing impaired respiratory function. Because the bronchi normally dilate and elongate during inspiration and contract and shorten on expiration, the respiratory difficulty is more pronounced during the expiratory phase of respiration.

Increased resistance in the airway causes forced expiration through the narrowed lumen. The volume of air trapped in the lungs increases as airways are functionally closed at a point between the alveoli and the lobar bronchi. This trapping of gas forces the individual to breathe at higher and higher lung volumes. Consequently, the person with asthma fights to inspire sufficient air. This expenditure of effort for breathing causes fatigue, decreased respiratory effectiveness, and increased oxygen consumption. The inspiration occurring at higher lung volumes hyperinflates the alveoli and reduces the effectiveness of the cough. As the severity of obstruction increases, there is reduced alveolar ventilation with carbon dioxide retention, hypoxemia, respiratory acidosis, and, eventually, respiratory failure.

Chronic inflammation may also cause permanent damage (airway remodelling) to airway structures; this remodelling cannot be prevented by and is not responsive to current treatments.

Diagnostic Evaluation. The classic manifestations of asthma are dyspnea, wheezing, and coughing (Box 45.14). An attack may develop gradually or appear abruptly and may be preceded by an upper respiratory tract infection. The age of the child is often a significant factor, since the first attack frequently occurs before the age of 5 years, with some children manifesting clinical signs and symptoms in infancy. In infancy an attack usually follows a respiratory infection. Some

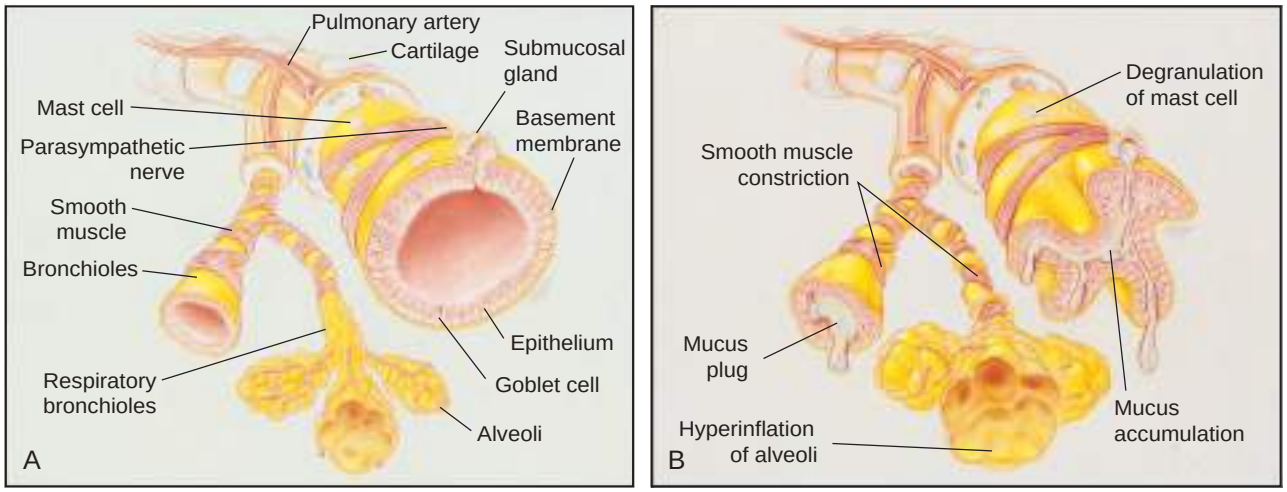

Fig. 45.6 Airway obstruction caused by asthma. **A,** A normal lung. **B,** Bronchial asthma: thick mucus, mucosal edema, and smooth muscle spasm causing obstruction of small airways; breathing becomes laboured, and expiration is difficult. (Adapted from Des Jardins, T., & Burton, G. G. [1995]. *Clinical manifestations and assessment of respiratory disease* [3rd ed.]. Mosby.)

BOX 45.14 Clinical Manifestations of Asthma

Cough
Hacking, paroxysmal, irritative, and nonproductive
Becomes rattling and productive of frothy, clear, gelatinous sputum

Respiratory-Related Signs
Shortness of breath
Prolonged expiratory phase
Audible wheeze
May have a malar flush and red ears
Lips deep, dark red colour
Possible progression to cyanosis of nail beds or circumoral cyanosis
Restlessness
Apprehension
Sweating may be prominent as the attack progresses
Posture—Older children may sit upright with shoulders in a hunched-over position, hands on the bed or chair, and arms braced (tripod position)
Speech—May speak in short, panting, broken phrases

Chest
Hyperresonance on percussion
Coarse, loud breath sounds
Wheezes throughout the lung fields
Prolonged expiration
Crackles
Generalized inspiratory and expiratory wheezing; increasingly high pitched

With Repeated Episodes
Barrel chest
Elevated shoulders
Use of accessory muscles of respiration
Facial appearance: flattened malar bones, dark circles beneath the eyes, narrow nose, prominent upper teeth

children may experience a **prodromal** itching at the front of the neck or over the upper part of the back just before an attack, especially if the attack is related to allergies.

! NURSING ALERT

Shortness of breath with air movement in the chest restricted to the point of absent breath sounds accompanied by a sudden rise in respiratory rate is an ominous sign indicating ventilatory failure and imminent respiratory arrest.

The diagnosis is determined primarily on the basis of clinical manifestations, history, physical examination, and, to a lesser extent, laboratory tests. Generally, chronic cough in the absence of infection or diffuse wheezing during the expiratory phase of respiration is sufficient to establish a diagnosis. The CPS classifies asthma severity as mild, moderate, severe, or impending respiratory failure (Ortiz-Alvarez et al., 2012/2019) (Table 45.3).

Pulmonary function tests (PFTs) provide an objective method of evaluating the presence and degree of lung disease, as well as the response to therapy. Spirometry can generally be performed reliably on children by the age of 5 or 6 years. Asthma Canada (2021c) recommends that spirometry testing be done at the time of initial assessment of asthma, after treatment is initiated and symptoms have stabilized, and at least every 1 to 2 years to assess the maintenance of airway function.

Another measurement to consider is the *peak expiratory flow rate (PEFR)*, which measures the maximum flow of air that can be forcefully exhaled in 1 second. PEFR is measured in litres per minute using a *peak expiratory flow meter (PEFM)*. Three zones of measurement are typically used to interpret PEFR. The zone system is patterned after a traffic light to make the categories easy to understand and remember (see Guidelines box: Interpreting Peak Expiratory Flow Rates). The reliability of the PEFM is controversial because it relies on the child's ability to use the PEFM and willingness to participate. The child's technique in

TABLE 45.3 Classification of Asthma Severity*

Clinical Features	Mild	Moderate	Severe	Impending Respiratory Failure
Mental status	Normal	Might look agitated	Usually look agitated	Drowsy or confused
Activity Normal	Normal activity and exertional dyspnea	Decreased activity or feeding (infant)	Decreased activity in infant, stops feeding	Unable to eat
Speech	Normal	Speaks in phrases	Speaks in words	Unable to speak
Work of breathing	Minimal intercostal retractions	Intercostal and substernal retractions	Significant respiratory distress Usually all accessory muscles involved, and may display nasal flaring and paradoxical thoraco-abdominal movement	Work of breathing Marked respiratory distress at rest All accessory muscles involved, including nasal flaring and paradoxical thoraco-abdominal movement
Chest auscultation	Moderate wheeze	Loud pan-expiratory and inspiratory wheeze	Wheezes might be audible without stethoscope	Chest is silent (absence of wheeze)
SpO_2 on room air	>94%	91–94%		<90%
Peak flow versus personal best	>80%	60–80%	Best <60%	Unable to perform the task

*Definitions are not absolute and can overlap. The presence of several parameters indicates the classification of the exacerbation.
Source: Ortiz-Alvarez, O., Mikrogianakis, A., & Canadian Paediatric Society, Acute Care Committee. (2012). Managing the paediatric patient with an acute asthma exacerbation. *Paediatrics & Child Health, 17*(5), 251–255. Updated 2019.

doing the PEFR should be examined on an ongoing basis and re-education provided when needed. Families are encouraged to record PEFM at regular intervals and to bring a record of this to any medical appointments for health care providers to review trends. Each child needs to establish their personal best value during a 2- to 3-week period when the child's asthma is stable. During this period, the child records the PEFR at least twice a day. After the personal best value has been established, the child's current PEFR on any occasion can be compared with the personal best value. In some cases, a low PEFR may not truly mean that the child's asthma is poorly controlled. Each individual child's PEFR varies according to age, height, sex, and ethnicity.

GUIDELINES

*Interpreting Peak Expiratory Flow Rates**

- Green (80 to 100% of personal best) signals all clear. Asthma is under reasonably good control. No symptoms are present, and the routine treatment plan for maintaining control can be followed.
- Yellow (50 to 79% of personal best) signals caution. Asthma is not well controlled. An acute exacerbation may be present. Maintenance therapy may need to be increased. Call the health care provider if the child stays in this zone.
- Red (below 50% of personal best) signals a medical alert. Severe airway narrowing may be occurring. A short-acting bronchodilator should be administered. Notify the health care provider if the peak expiratory flow rate does not return immediately and stay in the yellow or green zones.

*These zones are guidelines only. Specific zones and management should be individualized for each child.

Bronchoprovocation testing (i.e., direct exposure of the mucous membranes to a suspected antigen in increasing concentrations) helps to identify inhaled allergens. Exposure to methacholine, histamine, or cold or dry air may be performed to assess airway responsiveness or reactivity. Exercise challenges may be used to identify children with exercise-induced bronchospasm. Although these tests are highly specific and sensitive, they place the child at risk for an asthmatic episode and should be done under close observation in a qualified laboratory or clinic.

Skin prick testing (SPT) and serological testing (with quantification of sIgE) for allergen-specific immunoglobulin E (sIgE) may be used to identify environmental allergens that trigger asthma. It is recommended that all patients with year-round asthma symptoms be tested with skin tests or laboratory blood analysis to determine sensitization to perennial allergens (e.g., house dust mites, cats, dogs, cockroaches, moulds, and fungus) (Ortiz-Alvarez et al., 2012/2019).

In addition to these tests, other important tests include laboratory tests (complete blood count [CBC] with differential) and chest radiographs. The CBC may show a slight elevation in the white blood cell count during acute asthma episodes, but elevations of more than 12×10^9/L or an increased percentage of band cells may indicate respiratory tract infection. The presence of eosinophilia greater than 0.5×10^9/L tends to suggest an allergic or inflammatory disorder.

Frontal and lateral X-rays show infiltrates and hyperexpansion of the airways, with the anteroposterior diameter on physical examination indicating an increased diameter (suggestive of barrel chest). Additional diagnostic tests for conditions such as gastroesophageal reflux may be carried out to determine whether they may contribute to asthma symptoms. Radiography may assist in ruling out a respiratory tract infection.

Therapeutic Management. The overall goals of asthma management are to maintain normal activity levels, maintain normal pulmonary function, prevent chronic symptoms and recurrent exacerbations, provide optimum medication therapy with minimal or no adverse effects, and assist the child in living as normal a life as possible. This includes facilitating the child's social adjustments in the family, school, and community and in participation in recreational activities and sports. To accomplish these goals, several treatment principles need to be followed (Asthma Canada, 2021a):

- A continuous care approach with regular visits (at least every 1 to 6 months) to the health care provider is necessary to control symptoms and prevent exacerbations.

- Prevention of exacerbations includes avoiding triggers, avoiding allergens, and using medications as needed.
- Therapy includes efforts to reduce underlying inflammation and relieve or prevent symptomatic airway narrowing.
- Therapy includes patient education, environmental control, pharmacological management, and the use of objective measures to monitor the severity of disease and guide the course of therapy.
- Managing asthma should be fostered in the child as the child increases in age and maturity.

Asthma Canada (2021a) has provided guidelines to help children and their families with an action plan to help manage their asthma (Figure 45.7). The plan is divided into different zones similar to those used to interpret PEFR. The green zone is when the child is free of asthma symptoms. The yellow zone is when the child has asthma symptoms. When the child is in the red zone they are in danger with an asthmatic attack and need help. The action plan is modified with the health care provider and is based on frequency and severity of symptoms and/or results of peak flow monitoring. The plan sets out how the child should adjust the medication depending on how controlled the asthma is.

Allergen control. Nonpharmacological therapy is aimed at the prevention and reduction of exposure to airborne allergens and irritants. House dust mites and other components of house dust are frequent agents identified in children allergic to inhalants. The cockroach, another common household inhabitant, is a common allergen in many locations. Exterminating live cockroaches, carefully cleaning kitchen floors and cabinets, putting food away after eating, and taking garbage out are essential measures to control cockroach infestation. The mouse allergen is the most recent allergen to be identified in the homes of urban children with asthma. Although some studies suggest that sensitized persons should carefully evaluate having such pets in the household, the overall data are inconsistent on the effect of cat or dog exposure and subsequent asthma development (Ownby & Johnson, 2016). Additional sources of pollutants include tobacco, wood, and coal smoke, dusts, strong odours, and noxious air pollutants (e.g., nitrogen dioxide from inadequately vented gas stoves and furnaces); these are believed to contribute to asthma morbidity in children and should be avoided or minimized (Liu et al., 2020).

Living in homes close to busy roads and in damp homes with mould, and exposure to tobacco and other sources of smoke are significant contributing factors in the development of asthma in infants and small children. Recommendations for controlling allergens are found in the Family-Centred Care box: "Allergy-Proofing" the Home and Community.

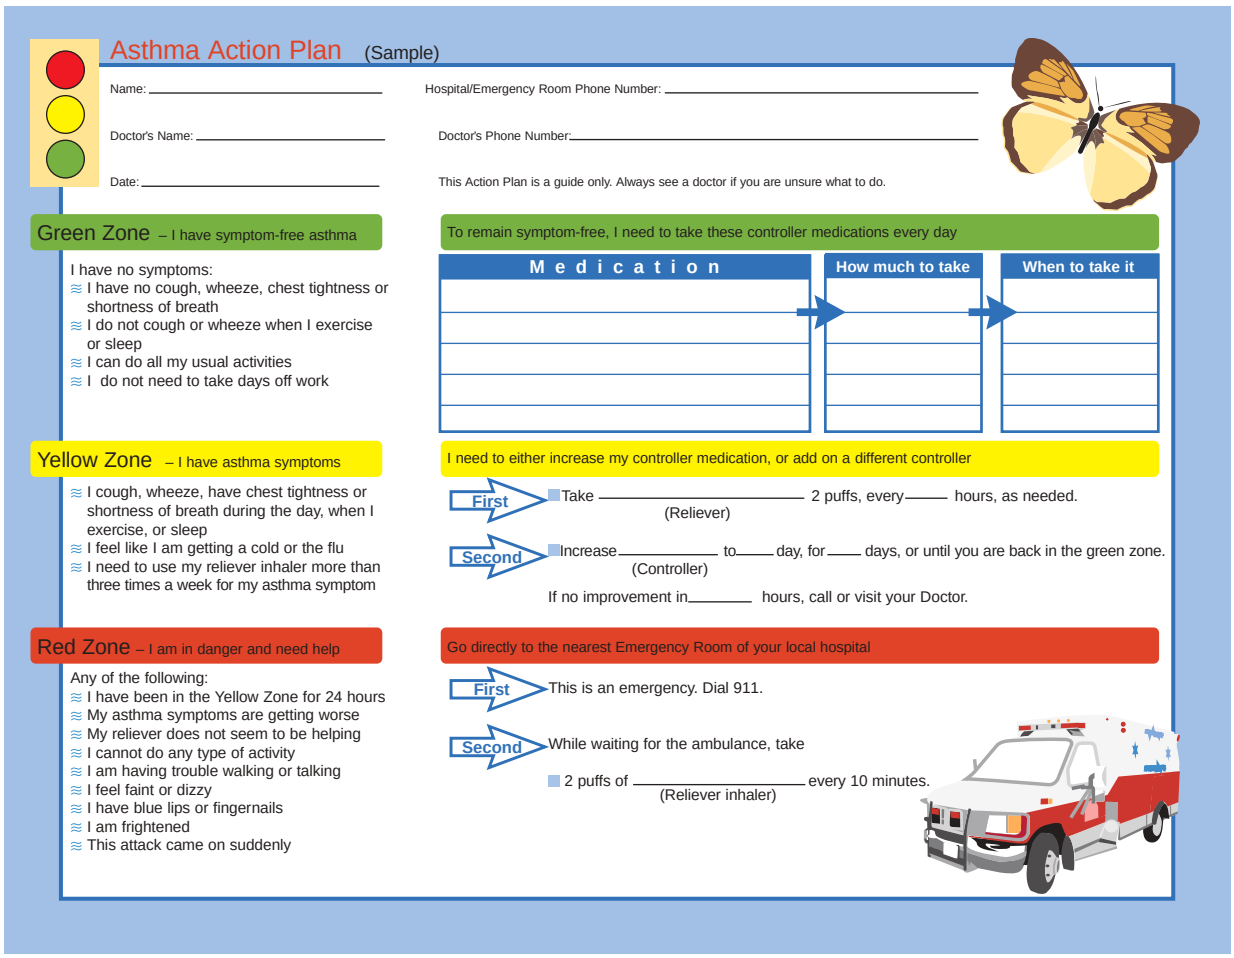

Fig. 45.7 A sample of the Asthma Canada action plan. An asthma action plan is an individualized series of steps a child can take to manage asthma when it gets out of control. (Source: Asthma Canada [2019]. *My asthma action plan*. https://asthma.ca/wp-content/uploads/2019/08/Kids-Action-Plan-FINAL.pdf.)

FAMILY-CENTRED CARE

"Allergy-Proofing" the Home and Community

- Keep humidity between 30 and 50%; use a dehumidifier or air conditioner if available; keep air conditioners clean and free of mould; do not use vaporizers or humidifiers.
- Encase pillows in zippered allergen-impermeable covers or wash pillows in hot water (at least 54.4°C) every week.
- Encase mattress and box springs in a zippered allergen-impermeable cover.
- Use foam rubber mattress and pillows or Dacron pillows and synthetic blankets.
- Wash bed linens every 7 to 10 days in hot water (at least 54.4°C).
- Encase polyester comforters in allergen-impermeable covers or wash in hot water (at least 54.4°C) every week; if possible, do not use a comforter; use cotton blankets instead.
- Store nothing under the bed; keep clothing in a closet with the door shut.
- Use washable window shades; avoid using heavy curtains; if curtains are used, launder them frequently.
- Remove all carpeting if possible; if not possible, vacuum the carpet once or twice a week while the child wears a mask; have the child remain out of the room while vacuuming and for 30 minutes after vacuuming.
- If possible, use a central vacuum cleaner with a collecting bag outside of the home or use cleaner filters (e.g., high-efficiency particulate air [HEPA] filters).
- Have air and heating ducts cleaned annually; change or clean filters monthly; cover heating vents with filter material (e.g., cheesecloth) to prevent circulation of dust, especially when heat is turned on after summer.
- Use wipeable furniture (wood, plastic, vinyl, or leather) in place of upholstered furniture; avoid rattan or wicker furniture.
- Keep the child indoors while the lawn is being mowed, bushes or trees are being trimmed, or pollen count is high.
- Keep windows and doors closed during pollen season; use an air conditioner if possible or go to places that are air conditioned, such as libraries and shopping malls, when the weather is hot.
- Wet-mop bare floors weekly; wet-dust and clean the child's room weekly; the child should not be present during cleaning activities.
- Limit or avoid child's exposure to tobacco and wood smoke; do not allow cigarette smoking in the house or car; select day care centres, play areas, and shopping malls that are smoke free.
- Avoid using the cellar (basement) as a play area if it is damp; use a dehumidifier in a damp basement.
- Use pesticide sprays, roach bait traps, and boric acid powder to kill cockroaches; if living in an apartment or adjacent housing, encourage neighbours to work together to get rid of cockroaches and mice.
- Decrease the child's exposure to air pollution from vehicle exhaust, outdoor grills, and environmental tobacco. Limit outside play on air-quality health alert days (Asthma Canada, 2021b).

Skin testing is used to identify specific allergens so steps can be taken to eliminate or avoid them. Often, simply removing the offending environmental allergens or irritants (e.g., removing carpeting from the home of a child sensitive to mould and dust particles) decreases the frequency of asthma episodes. Dehumidifiers or air conditioners may control nonspecific factors that trigger an episode, such as extremes of temperature.

Medication therapy. Pharmacological therapy is used to prevent and control asthma symptoms, reduce the frequency and severity of asthma exacerbations, and reverse airflow obstruction. A stepwise approach is recommended based on the severity of the child's asthma. Because inflammation is considered an early and persistent feature of asthma, therapy is directed toward long-term suppression of inflammation.

Asthma medications are categorized into two general classes: *long-term control medications (controllers or preventer medications)* that decrease airway swelling and prevent asthma episodes to achieve and maintain control of inflammation, and *quick-relief medications (reliever medications)* to treat symptoms and exacerbations quickly

Quick-relief and long-term medications are often used in combination. Inhaled corticosteroids, cromolyn sodium and nedocromil, long-acting β_2-agonists, methylxanthines, and leukotriene modifiers are used as long-term control medications. Short-acting β_2-agonists, anticholinergics, and systemic corticosteroids are used as quick-relief or rescue medications. Bronchodilators that relax bronchial smooth muscle and dilate the airways include β_2-agonists, methylxanthines, and anticholinergics that can be used as both quick-relief and long-term medications.

Many asthma medications are given by inhalation with a nebulizer or a **metered-dose inhaler** (MDI). All age groups should use an MDI that is attached to a spacer in order to provide the accurate dosage and to decrease adverse effects. The spacer and holder can be equipped with a mask or a mouthpiece. Several currently available MDI devices use dry powder (called *dry powder inhalers [DPIs]*); these include the Diskus inhaler and the Turbuhaler. These devices are breath activated, and the child needs to inhale as quickly and deeply as possible to use them effectively. The Diskhaler and Aerosolizer are similar, but with the Aerosolizer the medication must be loaded into the inhaler before use. Infants and very young children who have difficulty using MDIs or other inhalers can receive their asthma medications via a nebulizer, which administers the medication via compressed air or oxygen. Children are instructed to breathe normally with the mouth open to provide a direct route to the trachea. Spacers are gradually replacing nebulizers as the mechanism to deliver inhaled medications as they provide an effective way to deliver the medication.

Corticosteroids are anti-inflammatory medications used to treat reversible airflow obstruction and control symptoms and reduce bronchial hyperresponsiveness in chronic asthma. It is recommended that inhaled corticosteroids be used as first-line therapy in children over 5 years of age. Clinical studies of corticosteroids have indicated significant improvement of all asthma parameters, including decreases in symptoms, emergency department visits, and medication requirements (Ortiz-Alvarez et al., 2012/2019).

Corticosteroids may be administered parenterally, orally, or by inhalation. Oral medications are metabolized slowly, with an onset of action up to 3 hours after administration and peak effectiveness occurring within 6 to 12 hours. Oral systemic steroids may be given for short periods of time (e.g., 3- or 10-day "bursts") to gain prompt control of inadequately controlled persistent asthma or to manage severe persistent asthma. These medications should be given in the lowest effective dose. They have few adverse effects (cough, dysphonia, and oral thrush), and there is strong evidence that they improve the long-term outcomes for children of all ages with mild or moderate persistent asthma. Evidence from clinical trials that monitored children for 6 years indicates that the use of inhaled corticosteroids at recommended doses does not have long-term significant effects on growth, bone mineral density, ocular toxicity, or suppression of the adrenal–pituitary axis (Liu et al., 2020; Ortiz-Alvarez et al., 2012/2019). However, primary care providers should frequently monitor (at least every 3 to 6 months) the growth of children and adolescents taking corticosteroids to assess the systemic effects of these medications and make appropriate reductions in dosages or changes to other types of asthma therapy when necessary. The inhaled corticosteroids include budesonide and fluticasone (Flovent).

Beta-adrenergic agonists (short acting) (primarily albuterol [Ventolin], levalbuterol [Xopenex], and terbutaline) are used for treatment of acute exacerbations and for the prevention of exercise-induced bronchospasm. These medications bind with the beta receptors on the smooth muscle of airways, where they activate adenylate cyclase and convert adenosine monophosphate (AMP) to cyclic AMP (cAMP). The increased cAMP enhances binding of intracellular calcium to the cell membrane, reducing the availability of calcium and thus allowing smooth muscle to relax. Other effects of these medications help stabilize mast cells to prevent the release of mediators. Most beta-adrenergics used in asthma therapy affect predominantly the β_2-receptors, which help eliminate bronchospasm and minimize effects such as increased heart rate and gastrointestinal disturbances. These medications can be given via inhalation or as oral or parenteral preparations. The inhaled medication has a more rapid onset of action than the oral form. Inhalation also reduces troublesome systemic adverse effects: irritability, tremor, nervousness, and insomnia. Inhaled beta-adrenergic agents should not be taken more than three or four times daily for acute symptoms.

Salmeterol (Serevent) is a long-acting β_2-agonist (LABA) (bronchodilator) that is used twice a day (no more frequently than every 12 hours). This medication is added to anti-inflammatory therapy and used for long-term prevention of symptoms, especially nighttime symptoms, and exercise-induced bronchospasm. Salmeterol can be used in children 4 years of age and older, and it is not used to treat acute symptoms or exacerbations. LABA (e.g., salmeterol) should be added to a low- or medium-dosage inhaled corticosteroid for children with persistent asthma not controlled with inhaled corticosteroid treatment alone, in order to decrease asthma symptoms and the need for a short-acting β_2 agonist (Liu et al., 2020; Ortiz-Alvarez et al., 2012/2019). There is some evidence that this combination may actually allow the practitioner to lower the corticosteroid dose and manage asthma symptoms just as effectively. LABAs can only be used as an adjuvant therapy in patients who are currently receiving but are not adequately controlled on a long-term asthma-control medication. LABAs can increase the risk for severely worsening asthma symptoms, potentially leading to hospitalizations and death (Liu et al., 2020).

Theophylline is a methylxanthine medication that was used for decades to relieve symptoms and prevent asthma attacks; however, it is now used primarily in the emergency department when the child is not responding to maximal therapy. Adding theophylline to inhaled glucocorticoids can be more effective than increasing the steroid dose alone. Therapeutic levels should be obtained with this medication because it has a narrow therapeutic window.

Cromolyn sodium is a nonsteroidal anti-inflammatory drug (NSAID) used in maintenance therapy for asthma in children older than 2 years of age. It stabilizes mast cell membranes, inhibits activation and release of mediators from eosinophil and epithelial cells, and inhibits the acute airway narrowing after exposure to exercise, cold dry air, and sulphur dioxide. It does not result in immediate relief of symptoms and has minimal adverse effects (occasional coughing on inhalation of the powder formulation). It is now available as an oral preparation or via nebulizer. *Nedocromil sodium* inhibits the bronchoconstrictor response to inhaled antigens and inhibits the activity of and release of inflammatory cell types, such as histamine, leukotrienes, and prostaglandins. The medication has few adverse effects and is used for maintenance therapy; it is not effective for reversal of acute exacerbations and is not used in children younger than 5 years of age.

Leukotrienes are mediators of inflammation that cause increases in airway hyperresponsiveness. Leukotriene modifiers (such as zafirlukast [Accolate] and montelukast sodium [Singulair]) block inflammatory and bronchospasm effects. These medications are not used to treat acute episodes but are given orally in combination with β_2-agonists and steroids to provide long-term control and prevent symptoms in mild persistent asthma. Montelukast is approved for children aged 12 months and older, whereas zafirlukast is approved for children 5 years and older.

Anticholinergics (atropine and ipratropium [Atrovent]) may also be used for relief of acute bronchospasm. However, these medications have adverse effects that include drying of respiratory secretions, blurred vision, and cardiac and CNS stimulation. The primary anticholinergic medication used is ipratropium, which does not cross the blood–brain barrier and therefore elicits no CNS effects. Ipratropium, when used in combination with albuterol, has been shown to be effective during acute severe asthma in significantly improving lung function and reducing hospitalizations in children coming to the emergency department (Liu et al., 2020).

Omalizumab (Xolair) is a monoclonal antibody that blocks the binding of IgE to mast cells. Blocking this interaction eventually inhibits the inflammation that is associated with asthma. It is used in patients with moderate to persistent asthma who have confirmed perennial aeroallergen sensitivity and have had poor control of symptoms on inhaled steroids. Many patients with asthma are atopic and possess specific IgE antibodies to allergens responsible for airway inflammation. Xolair has been approved for use in children aged 12 years and older. The medication is administered once or twice a month by subcutaneous injection. Efficacy of omalizumab is not immediate but can be an effective therapy for patients with symptomatic moderate to severe allergic asthma that is poorly controlled with inhaled corticosteroids. There were concerns about anaphylaxis with this medication, but this appears to occur infrequently. More than half of all anaphylactic reactions occurred in the first 2 hours after administration. Some children with severe asthma and a history of severe life-threatening episodes may need a prescription for injectable EpiPen (subcutaneous epinephrine).

Exercise. *Exercise-induced bronchospasm (EIB)* is an acute, reversible, usually self-terminating airway obstruction that develops during or after vigorous activity, reaches its peak 5 to 10 minutes after stopping the activity, and usually stops in another 20 to 30 minutes. Patients with EIB experience cough, shortness of breath, chest pain or tightness, wheezing, and difficulties with endurance during exercise; an exercise challenge test in a laboratory is necessary to make the diagnosis.

The condition is rare in activities that require short bursts of energy (e.g., baseball, sprints, gymnastics, skiing) and more common in those that involve endurance exercise (e.g., soccer, basketball, distance running). Swimming is well tolerated by children with EIB because they are breathing air fully saturated with moisture and because of the type of breathing required in swimming.

Children with asthma are often excluded from exercise by parents, teachers, and health care providers, as well as by the children themselves, because they are reluctant to provoke an attack. However, this practice can seriously hamper peer interaction and physical health. Exercise is advantageous for children with asthma, and most children can participate in activities at school and in sports with minimal difficulty, provided their asthma is under control. Participation should be evaluated on an individual basis. Appropriate prophylactic treatment with beta-adrenergic agents or cromolyn sodium before exercise usually permits full participation in strenuous exertion (Philpott et al., 2010/2016).

Hyposensitization. The role of hyposensitization in childhood asthma has become controversial. In the past, immunotherapy was used for seasonal allergies and when single substances were identified as the offending allergen. It is not recommended for allergens that can be eliminated, such as foods, medications, and animal dander.

Immunotherapy can be used for asthma patients in the following situations:

- When there is evidence of a relationship between asthma symptoms and unavoidable exposure to an allergen to which the patient is sensitive
- When symptoms occur all year or at least during a major portion of the year
- When symptom control is difficult with medication therapy because multiple medications are required, the patient is not responsive to available medications, or the patient refuses to take the medications

Injection therapy is usually limited to clinically significant allergens. The initial dose of the offending allergen(s), based on the size of the skin reaction, is injected subcutaneously. The amount is increased at weekly intervals until a maximum tolerance is reached, after which a maintenance dose is given at 4-week intervals. This may be extended to 5- or 6-week intervals during the off-season for seasonal allergens. Successful treatment is continued for a minimum of 3 years and then stopped. If no symptoms appear, acquired immunity is assumed; if symptoms recur, treatment is reinstituted. Hyposensitization injections should be administered only with emergency equipment and medications readily available in the event of an anaphylactic reaction.

Status asthmaticus. Status asthmaticus is a medical emergency that can result in respiratory failure and death if unrecognized and untreated. Children who continue to display respiratory distress despite vigorous therapeutic measures, especially the use of sympathomimetics (e.g., albuterol, epinephrine), are in status asthmaticus. The condition may develop gradually or rapidly, often coincident with complicating conditions, such as pneumonia or a respiratory virus, that can influence the duration and treatment of the exacerbation.

! NURSING ALERT

A child with asthma who sweats profusely, remains sitting upright, and refuses to lie down is in severe respiratory distress. Also, a child who suddenly becomes agitated or an agitated child who suddenly becomes quiet may have serious hypoxia and requires immediate intervention.

Therapy for status asthmaticus is aimed at improving ventilation, decreasing airway resistance and relieving bronchospasm, correcting dehydration and acidosis, allaying child and parent anxiety related to the severity of the event, and treating any concurrent infection. Humidified oxygen is recommended and should be given to maintain an oxygen saturation of greater than 94% (Ortiz-Alverez et al., 2012/2019). Inhaled aerosolized short-acting β_2-agonists are recommended for all patients. Three treatments of β_2-agonists spaced 20 to 30 minutes apart are usually given as initial therapy, and continuous administration of β_2-agonists may be initiated. A systemic corticosteroid (oral, IV, or IM) may also be given to decrease the effects of inflammation. An anticholinergic such as ipratropium bromide may be added to the aerosolized solution of the β_2-agonist. Anticholinergics have been shown to result in additional bronchodilation in patients with severe airflow obstruction. An IV infusion is often initiated to provide a means for hydration and to administer medications. Correction of dehydration, acidosis, hypoxia, and electrolyte disturbance is guided by frequent determination of arterial pH, blood gases, and serum electrolytes.

Additional therapies in acute asthma attacks include the use of IV magnesium sulphate, a potent muscle relaxant that acts to decrease inflammation and improves pulmonary function and peak flow rate among pediatric patients treated in the emergency department with moderate to severe asthma. Heliox may be administered to decrease airway resistance and thereby decrease the work of breathing; it can be delivered via a nonrebreathing face mask from premixed tanks, which may be blended in a stand-alone unit or within a ventilator. It may be used in acute exacerbations as an adjunct to β_2-agonist and IV corticosteroid therapy to improve pulmonary function until the two latter medications have time to take full effect in decreasing bronchospasm. The effects of heliox are usually seen within 20 minutes of administration, whereas other drugs may take longer to exert the desired effect. Ketamine, a dissociative anaesthetic, is believed to cause smooth muscle relaxation and decrease airway resistance caused by severe bronchospasm in acute asthma. It may be administered as an adjunct to other therapies mentioned previously. Antibiotics should not be used to treat acute asthma attacks except when a bacterial infection resulting from another condition such as pneumonia or sinusitis is present (Ortiz-Alvarez et al., 2012/2019).

A child suspected of having status asthmaticus is usually seen in the emergency department and is often admitted to a pediatric critical care unit for close observation and continuous cardiorespiratory monitoring. A key component in the prevention of morbidity is helping the child, parents, teachers, coaches, and other adults in the child's life recognize features of deteriorating respiratory status, use the correct reliever medications effectively, and immediately place the child with deteriorating respiratory status into the care of trained health care providers instead of waiting to see if the asthma gets better on its own. For the child going into early status asthmaticus, immediate medical care is required to prevent irreversible respiratory failure and possible death.

Prognosis. The outlook for children with asthma varies widely. Some children's asthma symptoms may improve at puberty, but up to two thirds of children with asthma continue to have symptoms through puberty and into adulthood. The prognosis for control or disappearance of symptoms varies in children, from those who have rare symptoms to those who are constantly wheezing or are subject to status asthmaticus. Risk factors that may predict the persistence of symptoms into childhood (from infancy) include atopy, male gender, exposure to environmental tobacco smoke, and maternal history of asthma. Many children who outgrow their exacerbations continue to have airway hyperresponsiveness and cough as adults (Liu et al., 2020). Furthermore, airway hyperresponsiveness in adults appears to be associated with decreased lung function.

Risk factors for asthma deaths include early onset, frequent attacks, difficult-to-manage disease, adolescence, history of respiratory failure, psychological issues (refusal to take medications), dependency on or overuse of asthma medications, presence of physical stigmata (barrel chest, intercostal retractions), and abnormal PFTs.

Nursing Care. Nursing care of the child with asthma begins with a review of the child's health history; the home, school, and play environment; parent and child concerns and attitudes about the child's condition; and a comprehensive physical assessment with focus on the respiratory system. (See the Nursing Care Plan: The Child With Asthma, available on Evolve.)

Physical assessment of asthma involves the same observations and techniques described in Chapter 33. In addition to the nursing documentation, an evaluation of physical characteristics of chronic respiratory involvement is required, including chest configuration (e.g., barrel chest), posturing (tripod), and type of breathing. A history of the current and previous episodes and precipitating factors or events provides important information.

Providing acute asthma care. Children who are admitted to the hospital with acute asthma are ill, anxious, and uncomfortable. The progression or resolution of status asthmaticus is variable. The importance of continual observation and assessment cannot be overemphasized.

When β_2-agonists and corticosteroids are given, the child needs to be monitored closely and continuously for relief of respiratory distress and signs of adverse effects or toxicity. Pulse oximetry is monitored along with rate and depth of breathing, auscultation of air movement, adventitious sounds, and any signs of respiratory distress (e.g., nasal flaring, tachypnea, retractions). The child on supplemental oxygen requires intermittent or continuous oxygenation monitoring depending on severity of respiratory compromise and initial oxygenation status. The child in status asthmaticus should be placed on continuous cardiorespiratory (including blood pressure) and pulse oximetry monitoring. Oral fluid intake may be limited during the acute phase; IV fluid replacement may be required to provide adequate tissue hydration.

Older children may be more comfortable standing, sitting upright, or leaning slightly forward. The child is allowed to partake in activity as tolerated (Figure 45.8). When possible, the nurse should communicate in such a way that a child can reply in a few words to avoid fatigue; shortness of breath makes talking difficult. The calm, efficient presence of a nurse can help reassure them that they are safe and will be cared for during this stressful period. It is important to assure children that they will not be left alone and that their parents are allowed to remain with them. Parents need reassurance and want to be informed of their child's condition and therapies. They may believe that they have in some way contributed to the child's condition or could have prevented the episode. Reassurance regarding their efforts expended on the child's behalf and their parenting capabilities can help alleviate their stress. Efforts to reduce parental apprehension also reduce the child's distress, as anxiety is easily communicated to the child from parents and members of the staff.

Long-term asthma care. Care of children with asthma involves helping children and their families learn to live with the condition. The disease can be managed so that it does not require hospitalization or interfere with family life, physical activity, or school attendance.

Nurses may perform a variety of functions in long-term asthma care, including asthma education in the primary care setting and in schools and other community settings, as well as care of the child with asthma in the ambulatory care setting. Nurses also obtain information on how asthma affects the child's everyday activities and self-concept, the child's and family's adherence to the prescribed therapy, and their personal treatment goals. Every effort should be made to build a partnership between the child and family and the health care team, and effective communication is an essential part of this partnership. In particular, the child and family's satisfaction with asthma control and with the quality of care should be assessed. The nurse should also assess their perception of the severity of the disease and their level of social support.

Fig. 45.8 Child with asthma is allowed play activity as tolerated.

One of the major emphases is outpatient management by the family. Parents are taught how to prevent exacerbations, to recognize and respond to bronchospasm, to maintain health and prevent complications, and to promote normal activities. Cultural or ethnic beliefs or practices may influence management and necessitate modifications in approaches to meet the family's needs. Inconsistent home care on the part of either the child or the parents often leads to unnecessary visits to the emergency department for management.

Avoiding allergens. One goal of asthma management is avoidance of an exacerbation. Parents need to know how to prevent or minimize their child's exposure to allergens that precipitate asthma episodes. The nurse can assist the parents in modifying the environment to reduce contact with the offending allergen(s) (see Family-Centred Care box, "Allergy-Proofing" the Home and Community, above). Parents should be cautioned to avoid exposing a sensitive child to excessive cold, wind, or other extremes of weather; smoke (open fire or tobacco); sprays; or other irritants. Foods known to provoke symptoms should be eliminated from the child's diet. Parents should be taught how to read labels on prepared foods and snacks to determine the presence of allergens.

Certain cultural practices and lack of income can make avoidance of allergens difficult. For example, it is common for Indigenous people to live in housing where wood heating and smoke are common, which can be significant irritants and triggers for the child with asthma. Also, tobacco might be used as a therapeutic medicine for some conditions.

Approximately 2 to 6% of children with asthma are sensitive to Aspirin; thus, nurses should caution parents to use other analgesic and antipyretic medications for discomfort or fever and to read package labelling for ingredients. Although Aspirin is rarely given to children, salicylate compounds are in other common medicines, such as Pepto-Bismol. Children with Aspirin-induced asthma may also be sensitive to NSAIDs and tartrazine (yellow dye number 5, a common food colouring).

! NURSING ALERT

Parents should be encouraged to avoid administering Aspirin to any child unless specifically recommended by and under the supervision of a health care provider. Acetaminophen is safe for children and is the analgesic of choice.

Relieving bronchospasm. Parents and older children should be taught to recognize early signs and symptoms of an impending attack so that it can be controlled before symptoms become distressing. Most children can recognize prodromal symptoms well before an attack (about 6 hours) and implement preventive therapy. Objective signs that parents may observe include rhinorrhea, cough, low-grade fever, irritability, itching (especially on the front of the neck and chest), apathy, anxiety, sleep disturbance, abdominal discomfort, and loss of appetite.

Children who use a nebulizer (Figure 45.9), MDI, Diskus, or Turbuhaler to deliver medications need to learn how to use the device correctly. The MDI device delivers medication directly to the airways; thus, the child needs to learn to breathe slowly and deeply for better distribution to narrowed airways (see Patient Teaching box: Use of a Metered-Dose Inhaler).

A spacer or AeroChamber device should be used with MDI inhalers. These devices allow the parent or child to deliver the medication from the MDI and slowly inhale it. Spacers also help prevent yeast infections in the mouth when corticosteroids are inhaled via an MDI (Figure 45.10).

Fig. 45.9 Children with asthma may take a nebulized aerosol treatment with a mask **(A)** or mouthpiece **(B)**. (Courtesy Texas Children's Hospital.)

PATIENT TEACHING

Use of a Metered-Dose Inhaler

Steps for Checking How Much Medicine Is in the Canister

1. If the canister is new, it is full.
2. If the canister has been used repeatedly, it might be empty. (Check product label to see how many inhalations should be in each canister.)
3. The most accurate way to determine how many doses remain in a metered-dose inhaler (MDI) is to count and record each actuation as it is used.
4. Many dry-powder inhalers have a dose-counting device or dose indicator on the canister to let the user know when the canister is empty.
5. Placing dry-powder inhalers or MDIs with hydrofluoroalkanes in water will destroy these inhalers.

Steps for Using the Inhaler With an AeroChamber

This approach is recommended for all age groups and for use with corticosteroids (see Figure 45.10). A parent or caregiver helps with use of this inhaler as required according the child's age and development.

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Attach the AeroChamber.
4. With the inhaler in an upright position, insert the mouthpiece into the back of the AeroChamber.
5. Apply the AeroChamber mask to your face and make sure there is a good seal or if using a mouthpiece, close the mouth tightly around the mouthpiece. A caregiver needs to assist younger children with this.
6. Take slow, regular breaths. Depress the top of the inhaler canister firmly to release the medication (into the AeroChamber) and breathe slowly in and out. Relax the pressure on the top of the canister.
7. Hold the AeroChamber in place over your face until six breaths have been taken. Give one puff at a time.
8. Remove the inhaler and AeroChamber.
9. Wait 1 minute between puffs (if an additional puff is needed) when using a bronchodilator.

Fig. 45.10 Child using a metered-dose inhaler with a spacer.

The child and parents also need to be cautioned about the adverse effects of prescribed medications and the dangers of overuse of β_2-agonists. They should know that it is important to use these medications when needed but not indiscriminately or as a substitute for avoiding the symptom-provoking allergen.

! NURSING ALERT

Long-acting beta-adrenergic inhalers (salmeterol) should be used only as directed (usually every 12 hours) and not more frequently. They are not intended to relieve acute asthmatic symptoms.

Use of a PEFM at home can be helpful in the assessment of asthmatic children with poor symptom perception, moderate to severe asthma, or a history of severe asthma exacerbations. It can be used in children as young as 4 years who are able to master this skill. Young children need to be supervised while they are learning to use their PEFM, and their technique should be checked frequently to ensure that it is correct. Children should use the same PEFM over time, and they should bring it for use at every follow-up visit. Using the same brand of meter is recommended because different brands can give significantly different values (see Patient Teaching box: Use of a Peak Expiratory Flow Meter).

As discussed earlier, a written asthma action plan that includes the three peak flow meter zones and the child's asthma medications can be useful in preventing asthma exacerbations and may be obtained from the child's primary care provider. A home asthma action plan may reduce the risk for asthma death by 70% (Liu et al., 2020). This plan should be used to make decisions about asthma management at home and at school. The nurse may assist the child and family in understanding the written action plan, emphasizing that the child and family determine the success of the plan, not the health care providers.

PATIENT TEACHING

Use of a Peak Expiratory Flow Meter

1. Before each use, make sure the sliding marker or arrow on the peak expiratory flow meter points to zero or is at the bottom of the numbered scale.
2. Stand up straight.
3. Remove gum or any food from your mouth.
4. Close your lips tightly around the mouthpiece. Be sure to keep your tongue away from the mouthpiece.
5. Blow out as hard and as quickly as you can, a "fast hard puff."
6. Note the number by the marker on the numbered scale.
7. Repeat the entire routine three times; wait 30 seconds between each routine.
8. Record the highest of the three readings, not the average.
9. Measure the peak expiratory flow rate (PEFR) close to the same time and same way each day (e.g., morning and evening; before or 15 minutes after taking medication).
10. Keep a chart of your PEFRs.

The child should be protected from a respiratory tract infection, which can trigger an attack or aggravate the asthmatic state. This is especially true for young children whose airways are mechanically smaller and more reactive. Annual influenza vaccinations are recommended for children with persistent asthma (Ortiz-Alvarez et al., 2012/2019). Pneumococcal vaccinations should also be maintained. Equipment used for the child, such as nebulizers, must be kept clean to decrease the chances of contamination with bacteria and fungi.

Breathing exercises and controlled breathing should be taught, and the nurse should provide information on activities that promote diaphragmatic breathing, side expansion, and improved mobility of the chest wall. Play techniques that can be used for younger children to extend their expiratory time and increase expiratory pressure include blowing cotton balls or a ping-pong ball on a table, blowing a pinwheel, blowing bubbles, or preventing a tissue from falling by blowing it against the wall.

Self-care and asthma self-management programs are important in helping the child and family cope with asthma. Most asthma self-management programs for children are based on the following principles:

- Asthma is a common disease that can be controlled with appropriate medication therapy, environmental control, education, and management skills.
- It is much easier to prevent than to treat an asthma episode; adherence to a therapeutic program is necessary to prevent exacerbations.
- Children with asthma can live full and active lives.

Asthma camps provide an opportunity for children with asthma to engage in physical activity while learning about their disease in a controlled environment with their peers and with health care providers. Children who attend asthma camps often demonstrate improved asthma self-management skills.

Self-contained programs, brochures, and websites for patient education are available from Asthma Canada, the Canadian Lung Association, and Canadian Allergy, Asthma, and Immunology Foundation. Asthma Canada has an innovative website that teaches children about asthma. For all of these resources, see the Additional Resources section at the end of this chapter.

Supporting the child or adolescent and family. The nurse working with children with asthma can provide support in a number of ways. Many children voice frustration because their exacerbations interfere with their daily activities and social lives. Children need education about what to do to prevent an asthma episode. These children also need reassurance from the health care team that they can learn to control and cope with their asthma and live a normal life.

Adolescents struggling with a sense of identity and body image often regard asthma as a condition that will "go away," especially if there is a time lapse between symptoms, and may abandon the therapeutic regimen. Referral for counselling and guidance is appropriate when the child or adolescent's life is potentially in harm's way and the therapeutic regimen for asthma is abandoned because of personal or family crises.

The task of living day-to-day with affected children involves the entire family. There are periodic crises and the ever-present threat of a crisis, requiring parental vigilance; sleepless nights; frequent trips to the physician, emergency department, or hospital; and often overwhelming medical expenses. Throughout these stresses, parents should be encouraged to promote as normal a life as possible for their children.

Cystic Fibrosis

Cystic fibrosis (CF) is inherited as an autosomal recessive trait; the affected child inherits the defective gene from both parents, with an overall risk of one in four if both parents carry the gene. The mutated gene responsible for CF is located on the long arm of **chromosome** 7. This gene codes a protein of 1 480 amino acids called the *cystic fibrosis transmembrane regulator (CFTR)*. The CFTR protein is related to a family of membrane-bound glycoproteins. The glycoproteins constitute a cAMP-activated chloride channel and also regulate other chloride and sodium channels at the surfaces of the epithelial cells.

It is estimated that 1 in every 3 600 Canadian children is born with CF. Currently in Canada, approximately 4 370 children and adults attend a CF clinic (Cystic Fibrosis Canada, 2021c).

Pathophysiology. CF is characterized by several clinical features: increased viscosity of mucous gland secretions, a striking elevation of sweat electrolytes, an increase in several organic and enzymatic constituents of saliva, and abnormalities in autonomic nervous system function. Although both sodium and chloride are affected, the defect appears to be primarily a result of abnormal chloride movement; the CFTR appears to function as a chloride channel. Children with CF demonstrate an increase in sodium and chloride in both saliva and sweat. This characteristic is the basis for the sweat chloride diagnostic test. The sweat electrolyte abnormality is present from birth, continues throughout life, and is unrelated to the severity of the disease or the extent to which other organs are involved.

The primary factor, and the one responsible for many of the clinical manifestations of the disease, is mechanical obstruction caused by the increased viscosity of mucous gland secretions (Figure 45.11). Instead

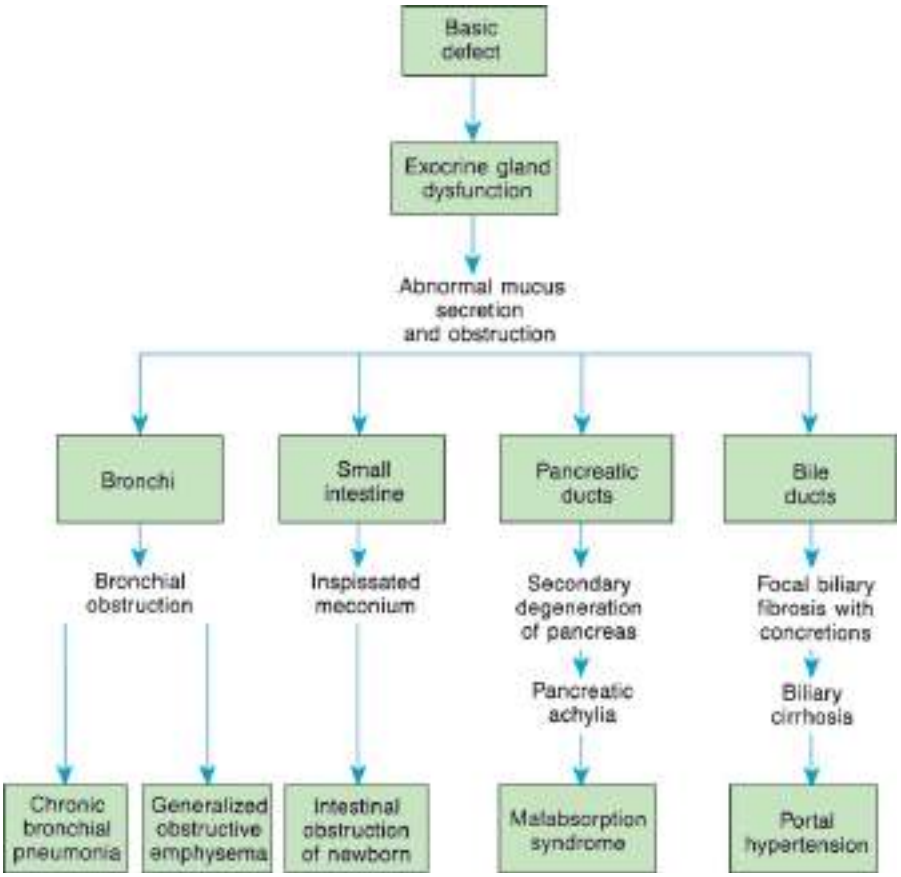

Fig. 45.11 Various effects of exocrine gland dysfunction in cystic fibrosis.

of forming a thin, freely flowing secretion, the mucous glands produce a thick mucoprotein that accumulates and dilates them. Small passages in organs such as the pancreas and bronchioles become obstructed as secretions precipitate or coagulate to form concretions in glands and ducts. The earliest postnatal manifestation of CF is often meconium ileus in the newborn, in which the small intestine is blocked with thick, puttylike, tenacious, mucilaginous meconium.

In the pancreas the thick secretions block the ducts, eventually causing pancreatic fibrosis. This blockage prevents essential pancreatic enzymes from reaching the duodenum, which causes marked impairment in the digestion and absorption of nutrients. The disturbed function is reflected in bulky stools that are frothy from undigested fat (*steatorrhea*) and foul smelling from putrefied protein (*azotorrhea*).

The incidence of diabetes mellitus (DM) (cystic fibrosis–related diabetes [CFRD]) is greater in children with CF than in the general population; it may be caused by changes in pancreatic architecture and diminished blood supply over time. CFRD is a common complication associated with CF. In Canada in 2018, CFRD was reported in 957 (21.9%) individuals with CF, affecting 55 (3.3%) children and 902 (33.5%) adults. The primary characteristic of CFRD is severe insulin deficiency as a result of beta-cell dysfunction; however, CFRD also may demonstrate fluctuating insulin resistance, especially during acute illness. Therefore, CFRD has characteristics of both types 1 and 2 DM, but it is considered to be its own entity. The positive correlation between nutritional status and optimal pulmonary function in patients with CF has been described; the presence of adequate insulin appears to be a key factor in maintaining adequate nutritional status. Experts continue to recommend a high-fat, high-calorie diet for CF patients.

Historically a relatively common event, rectal prolapse occurs much less frequently because of earlier diagnosis and initiation of pancreatic enzyme replacement therapy (Egan et al., 2020). Affected children of all ages are subject to intestinal obstruction from heavy or impacted feces. Gumlike masses can obstruct the bowel and produce a partial or complete obstruction, a condition that is referred to as *distal intestinal obstruction syndrome*.

Pulmonary complications are present in almost all children with CF, but the onset and extent of involvement vary. Symptoms are produced by stagnation of mucus in the airways, with eventual bacterial colonization leading to destruction of lung tissue. The abnormally viscous and tenacious secretions are difficult to expectorate and gradually obstruct the bronchi and bronchioles, causing scattered areas of bronchiectasis, atelectasis, and hyperinflation. The stagnant mucus offers a favourable environment for bacterial growth.

The reproductive systems of both males and females with CF are affected. Females with CF have normal fallopian tubes and ovaries, but fertility can be inhibited by highly viscous cervical secretions, which act as a plug, blocking sperm entry. Patients with CF who become pregnant have an increased incidence of premature labour and birth and of having a low-birthweight newborn. Favourable nutritional status and pulmonary function are positively correlated with favourable pregnancy outcomes. Most adult men (95%) with CF are sterile, which may be caused by blockage of the vas deferens with abnormal secretions or by failure of normal development of the wolffian duct structures (vas deferens, epididymis, and seminal vesicles), resulting in decreased or absent sperm production.

Growth and development are often affected in children with moderate to severe forms of CF. Physical growth may be restricted as a result

of decreased absorption of nutrients, including vitamins and fat; increased oxygen demands for pulmonary function; and delayed bone growth. The usual pattern is one of growth failure (failure to thrive), with increased weight loss despite an increased appetite, and gradual deterioration of the respiratory system. Clinical manifestations of CF are listed in Box 45.15.

Diagnostic Evaluation. Traditionally, the diagnosis of CF was based on a positive sweat chloride test, absence of pancreatic enzymes, radiography, chronic obstructive pulmonary disease, and family history. Newer diagnostic methods make it possible to diagnose CF early in infancy so that therapies can be implemented to increase the child's overall survival and quality of life. In addition to the sweat chloride test and factors listed previously, diagnosis may be confirmed by any one of the following: newborn screening, DNA identification of mutant genes, and abnormal nasal potential difference measurement.

Universal newborn screening for CF is done in all provinces and territories of Canada (Cystic Fibrosis Canada, 2018). The newborn screening test consists of an immunoreactive trypsinogen (IRT) analysis performed on a dried spot of blood, which may be followed by direct analysis of DNA for the presence of the ΔF508 mutation or other mutations on the same dried-blood spot. A positive screen indicates persistent hypertrypsinogenemia and does not diagnose CF but identifies infants at risk for CF. Further testing is needed to confirm or rule out CF. Benefits of early screening and detection include earlier nutritional intervention for identified infants to optimize lung function and improve height and weight. A disadvantage of newborn screening is parental anxiety associated with a false-positive result. An in utero diagnosis of CF is also possible, based on detection of two CF mutations in the fetus.

The consistent finding of abnormally high sodium and chloride concentrations in the sweat is a unique characteristic of CF. Parents may report that their infant tastes "salty" when they kiss the infant. The quantitative sweat chloride test (pilocarpine iontophoresis) involves stimulating the production of sweat with a special device (involves stimulation with 3-mA electric current), collecting the sweat on filter paper, and measuring the sweat electrolytes. The quantitative analysis requires a sufficient volume of sweat (more than 75 mg). Two separate samples are collected to ensure the reliability of the test for any individual. Normally, sweat chloride content is less than 40 mmol/L, with a mean of 18 mmol/L. A chloride concentration greater than 60 mmol/L is diagnostic of CF; in infants younger than 3 months a sweat chloride concentration greater than 40 mmol/L is highly suggestive of CF. In some situations, DNA testing may be substituted for the sweat test. The presence of a mutation known to cause CF on each *CFTR* gene predicts with a high degree of certainty that the individual has CF. However, there are 2 000 multiple *CFTR* mutations that may also be present and detected with DNA assay.

Chest X-ray reveals characteristic patchy atelectasis and obstructive emphysema. PFTs are sensitive indices of lung function, providing evidence of abnormal small airway function in CF. Other diagnostic tools that may aid in diagnosis include stool fat or enzyme analysis. Stool analysis requires a 72-hour sample with accurate recording of food intake during that time. Radiographs, including contrast dye enema, are used for diagnosis of meconium ileus.

Therapeutic Management. Improved survival among patients with CF during the past two decades can be attributed largely to antibiotic therapy and improved nutritional management. Goals of CF therapeutic management are to (1) prevent or minimize pulmonary complications, (2) ensure adequate nutrition for growth, (3) encourage appropriate physical activity, and (4) promote a reasonable quality of life for the child and the family. An interprofessional approach to treatment is needed to accomplish these goals.

Management of pulmonary conditions. Management of pulmonary conditions is directed toward prevention and treatment of pulmonary infection by improving ventilation, removing mucopurulent secretions, and administering antimicrobial agents. Many children develop respiratory symptoms by 3 years of age. The large amounts and viscosity of respiratory secretions in children with CF contribute to the likelihood of respiratory tract infections. Recurrent pulmonary infections in the child with CF result in greater damage to the airways; small airways are destroyed, causing bronchiectasis.

The most common pathogens responsible for pulmonary infections are *Pseudomonas aeruginosa, Burkholderia cepacia, S. aureus, H. influenzae, Escherichia coli,* and *Klebsiella pneumoniae. P. aeruginosa* and *B. cepacia* are particularly pathogenic for children with CF, and infections with these organisms are difficult to eradicate. In addition, children with CF who are chronically colonized with these organisms have poorer survival rates than those of children who are not colonized. Colonization and infection with methicillin-resistant *S. aureus* (MRSA) has emerged as a critical factor in lung infection and pulmonary

BOX 45.15 Clinical Manifestations of Cystic Fibrosis

Meconium Ileus*
Abdominal distension
Vomiting
Failure to pass stools
Rapid development of dehydration

Gastrointestinal Manifestations
Large, bulky, loose, frothy, extremely foul-smelling stools
Voracious appetite (early in disease)
Loss of appetite (later in disease)
Weight loss
Marked tissue wasting
Failure to grow
Distended abdomen
Thin extremities
Sallow skin
Evidence of deficiency of fat-soluble vitamins A, D, E, and K
Anemia

Pulmonary Manifestations
Initial signs:
- Wheezing respirations
- Dry, nonproductive cough

Eventually:
- Increased dyspnea
- Paroxysmal cough
- Evidence of obstructive emphysema and patchy areas of atelectasis

Progressive involvement:
- Overinflated, barrel-shaped chest
- Cyanosis
- Clubbing of fingers and toes
- Repeated episodes of bronchitis and bronchopneumonia

*In about 15–20% of cases.

function in patients with CF, especially in patients 11 to 24 years of age (Zobell et al., 2015). Depending on the severity of the infection, patients with MRSA can be treated with oral antibiotics as an outpatient or may require IV antibiotics as an inpatient. Fungal colonization with *Candida* or *Aspergillus* organisms in the respiratory tract is also common in patients with CF.

The use of amphotericin is being trialled in the laboratory as a medication to treat all infections. Amphotericin is approved to treat fungal infections, but researchers have discovered that it may be able to restore infection-fighting properties in lung tissue and has the potential to become the first treatment to address all types of CF, no matter what genetic mutation is causing the protein deficiency. This medication needs human trials to see if it is ultimately effective (Muraglia et al., 2019).

Children with specific CF mutations may benefit by taking ivacaftors (Kalydeco or Orkambi). These CF transmembrane conductance regulator modulators allow salt and fluid to move through the airways and prevent the buildup of thick mucus in the airways, with concomitant improvement of pulmonary function. Cayston, and Quinsair are used to improve breathing symptoms in people with CF who have *P. aeruginosa* in their lungs. TOBI Podhaler is an inhaled powder that treats *P. aeruginosa*. Not all of these medications are accessible across the country as there are disparities among provinces in how they are funded.

A new medication, Trikafta, which is also a CFTR modulator therapy, is a combination of elexacaftor/tezacaftor/ivacaftor and has been approved for use by Health Canada in children 12 years of age and older. Trikafta can be used to treat up to 90% of Canadians with CF (Cystic Fibrosis Canada, 2021b). This medication has improved lung function by an average of 14% and repairs the defective protein (Heijerman et al., 2019). At this time, although it is approved by Health Canada, it is not available to all patients because of lack of funding from provincial health plans and private insurance companies.

Airway clearance therapies (ACT) are an essential part of CF management and include percussion and postural drainage, positive expiratory pressure (PEP), active cycle-of-breathing technique, autogenic drainage, oscillatory PEP, high-frequency chest compressions (HFCCs), and exercise. Studies have demonstrated that no particular ACT has any advantage over the other in terms of outcomes of sputum production; however, it is recommended that individualized assessment occur to determine the best ACT for each patient. ACTs such as percussion and postural drainage are usually performed, on average, twice daily (on rising and in the evening) and more frequently if needed, especially during pulmonary infection. The Flutter mucus clearance device is a small, handheld plastic pipe with a stainless steel ball on the inside that facilitates removal of mucus. It has the advantage of increasing sputum expectoration and being used without an assistant. Handheld percussors may be used to loosen secretions. With HFCC, the child temporarily wears a mechanical vest device that provides high-frequency chest wall oscillation.

The active cycle of breathing technique is a series of breathing methods to help clear secretions. Forced expiration, or "huffing," with the glottis partially closed helps move secretions from the small airways so that subsequent coughing can move secretions forcefully from the large airways. Another mucus-clearing technique involves use of a PEP mask. The patient breathes into a mask attached to a one-way valve, which creates resistance—as the patient exhales, the airway is kept open by the pressure, and mucus is forced into the upper airway for expulsion.

Bronchodilator medication delivered in an aerosol opens bronchi for easier expectoration and is administered before percussion and postural drainage when the patient exhibits evidence of reactive airway disease or wheezing. Another aerosolized medication is recombinant human deoxyribonuclease (DNase, known generically as dornase alfa [Pulmozyme]), which decreases the viscosity of mucus. It is well tolerated and has no major adverse effects; minor reactions are voice alterations and laryngitis. This medication, given daily via nebulization, has resulted in improvements in spirometry, PFTs, dyspnea scores, and perceptions of well-being and has reduced the viscosity of sputum.

Nebulized hypertonic saline (7%) has been shown to be effective in improving airway hydration and increases mucus clearance in patients with CF. However, this treatment causes bronchospasm and may not be recommended for patients with severe disease (Furnari et al., 2012).

Physical exercise is an important adjunct to daily ACT. Exercise stimulates mucus excretion and provides a sense of well-being and increased self-esteem. Any aerobic exercise that the patient enjoys should be encouraged. The ultimate aim of exercise is to increase lung vital capacity, remove secretions, increase pulmonary blood flow, and maintain healthy lung tissue for effective ventilation.

Pulmonary infections need to be treated as soon as they are recognized. In patients with CF, characteristic signs of pulmonary infection—fever, tachypnea, and chest pain—may be absent. Therefore, a careful history and physical examination are essential. The presence of **anorexia**, weight loss, and decreased activity should alert the practitioner to pulmonary infection and the need for an antibiotic regimen. Aerosolized antibiotics, such as tobramycin, aztreonam, and colistin, are beneficial for patients with frequent pulmonary exacerbations and are administered in 2- to 4-week cycles.

IV antibiotics may be administered at home as an alternative to hospitalization. The use of peripherally inserted central catheters (PICCs) for the administration of antibiotics in children with CF is a viable option with limited complications and fewer needle punctures to obtain blood specimens and to maintain often lengthy treatment with parenteral antibiotics. Alternatively, an implanted vascular access device offers the advantage of access for blood draws and antibiotic infusion. When pulmonary function does not improve with outpatient management, hospitalization may be recommended for continued antibiotic therapy and vigorous ACT. Periodic hospitalizations for preventive IV antibiotic therapy and percussion and postural drainage occur less frequently than in the past due to limited evidence to support this practice and concern about making organisms more multidrug resistant. Oxygen administration is used for children with acute episodes but must be used with caution because many children with CF have chronic carbon dioxide retention and the unsupervised use of oxygen can be harmful (see Oxygen Therapy, Chapter 44). With repeated infection and inflammation, bronchial cysts and emphysema may develop. These cysts may rupture, resulting in a pneumothorax.

! NURSING ALERT

Signs of a pneumothorax are usually nonspecific and include tachypnea, tachycardia, dyspnea, pallor, and cyanosis. A subtle drop in oxygen saturation (measured by pulse oximetry) may be an early sign of pneumothorax.

Blood streaking of the sputum is usually associated with increased pulmonary infection and often requires no specific treatment. Hemoptysis greater than 250 mL/24 hours for the older child (less for a younger child) indicates a potentially life-threatening event and needs to be treated immediately. Sometimes bleeding can be controlled with bed rest, IV antibiotics, replacement of acute blood loss, IV conjugated estrogens (Premarin) or vasopressin (Pitressin), and correction of any coagulation defects with vitamin K or fresh-frozen plasma. If hemoptysis persists, the site of bleeding should be localized via bronchoscopy and cauterized or embolized.

Nasal polyps can develop in two thirds of patients with CF and occur from chronic inflammation. Treatment of nasal polyps includes intranasal corticosteroids, decongestants, and mucolytics. If these measures are ineffective, surgical interventions may be necessary. Saline irrigations are often prescribed to remove thick nasal secretions and to treat chronic sinusitis associated with CF.

Because pulmonary damage in patients with CF is believed to be caused by the inflammatory process that occurs with frequent infections, the use of corticosteroids has been studied; however, treatment with corticosteroids for prolonged periods found only a modest effect and numerous adverse effects including linear growth restriction, glucose tolerance abnormalities, and cataract formation. Anti-inflammatory medications such as ibuprofen are becoming more important in the treatment of CF, but careful monitoring for adverse effects (gastrointestinal bleeding) is essential.

Management of gastrointestinal conditions. Among Canadians with CF, 84% require treatment for gastrointestinal issues (Cystic Fibrosis Canada, 2018). The principal treatment for pancreatic insufficiency is replacement of pancreatic enzymes, which are administered with meals and snacks to ensure that digestive enzymes are mixed with food in the duodenum. Enteric-coated products prevent the neutralization of enzymes by gastric acids, thus allowing activation to occur in the alkaline environment of the small bowel. The amount of enzymes depends on the severity of the insufficiency, the child's response to enzyme replacement, and the health care provider's philosophy. Usually one to five capsules (or 2 500 lipase units per kilogram) are administered with a meal, and a smaller amount is taken with snacks. Capsules can be swallowed whole or taken apart, with the contents sprinkled on a small amount of food taken at the beginning of the meal. The amount of enzyme is adjusted to achieve normal growth and a decrease in the number of stools to one or two per day. Pancreatic enzymes should be taken within 30 minutes of eating. The enteric-coated beads should not be chewed or crushed, since destroying the enteric coating can lead to inactivation of the enzymes and excoriation of oral mucosa. The powder form should be used with caution because inhalation of the powder may precipitate acute bronchospasm, and if mixed with food, it predigests the food, making it unpalatable. The mouth must be rinsed after enzymes are administered to avoid breakdown of the oral mucosa or a breastfeeding parent's nipples.

Children with CF require a well-balanced, high-protein, high-caloric diet (because of the impaired intestinal absorption). In fact, they often require up to 150% of the recommended daily allowances to meet their needs for growth. Breastfeeding with enzyme supplementation should be continued as long as possible and, when necessary, supplemented with a higher-calorie-per-mL formula. For formula-fed infants, commercial cow's milk–based formulas are usually adequate, although frequently a partial hydrolysate formula with medium-chain triglycerides (e.g., Progestimal, Alimentum) may be recommended. In older children with CF, three daily meals and three snacks are recommended to meet energy and growth requirements. Enzymes can be mixed into cereal or fruit such as applesauce. Because the uptake of fat-soluble vitamins is decreased, water-miscible forms of these vitamins (A, D, E, and K) are given, along with multivitamins and the pancreatic enzymes. When high-fat foods are eaten, the child should be encouraged to add extra enzymes.

Growth failure despite adequate nutritional support may indicate deterioration of pulmonary status. Patients with CF may experience frequent anorexia as a result of the copious amounts of mucus produced and expectorated, persistent cough, effect of medications, fatigue, and sleep disruption. They may be placed on oral nutritional supplements, nighttime supplemental gastrostomy or NG tube feedings or, rarely, parenteral alimentation, in an effort to build up nutritional reserves if there has been a history of inability to maintain weight.

Meconium ileus and meconium ileus equivalent, or distal intestinal obstruction syndrome can occur at any age. Constipation is often the result of a combination of malabsorption (either from inadequate pancreatic enzyme dosage or a failure to take the enzymes), decreased intestinal motility, and abnormally viscous intestinal secretions. These conditions usually do not require surgical intervention and may be treated with MiraLAX or Colyte (osmotic solutions given orally or by NG tube), other laxatives, stool softeners, or rectal administration of meglumine diatrizoate (Gastrografin).

Rectal prolapse occurs only in a small number of individuals; fewer are affected as result of early diagnosis and administration of pancreatic enzymes (Egan et al., 2020). The first episode of rectal prolapse is frightening to both the parents and child. Its reduction usually requires immediate guidance and intervention, which is managed by simply guiding the rectum back into place with a gloved, lubricated finger. Further management usually involves attempting to decrease the bulk of daily stools through enzyme replacement.

Children with CF often experience transient or chronic gastroesophageal reflux, which should be treated with the appropriate histamine-receptor antagonist and gastrointestinal motility medication, dietary modifications, and an upright position after feedings or meals.

Liver disease is a serious complication of CF and is likely caused by abnormally thick fluids in the liver. It is the second most common cause of death in people with CF. Between 6 and 8% of people with CF have potentially fatal liver disease requiring liver transplantation. About 25% of people with CF over the age of 4 years have serious issues with liver function (Cystic Fibrosis Canada, 2021a).

Management of endocrine conditions. The management of CFRD is critical in the therapeutic treatment of the child with CF. CFRD presents a combination of insulin resistance and insulin deficiency, with unstable glucose homeostasis in the presence of acute lung infection and treatment. Children with CFRD require close monitoring of blood glucose, administration of oral glucose-lowering agents or insulin injections, management of diet and exercise, and quarterly glycated hemoglobin (HgA1c) measurements. Children with CF may be at increased risk for glucose management issues as a result of decreased nutrient absorption, anorexia, and severity of pulmonary illness. The prevalence of CFRD increases with age, and there is increased morbidity and mortality among children with CFRD compared to those without CFRD. Microvascular complications such as retinopathy and nephropathy may occur in children and adolescents with CFRD. However, ketoacidosis is rare in individuals with CFRD (Egan et al., 2020). Children with CFRD should perform self-blood glucose monitoring (SBGM) three times a day and should be on an insulin regimen. Target glucose levels should be the same as for any other patient with diabetes. There is no evidence that oral glycemic agents are effective. During acute CF exacerbations, the nondiabetic child should be monitored closely for hyperglycemia. Although HgA1c may be low in patients with CF, the HgA1c trend may be useful to identify overall blood sugar control (Siwamogsatham et al., 2014).

Bone health is of concern in children and adults with CF. The pancreatic insufficiency of CF and chronic steroid use present potential risks for less than optimum bone growth in such children. Assessment of bone health by history and bone mass density evaluation should be considered in assessing the child's (8 years old and older) health status to detect and prevent osteoporosis or osteopenia.

Prognosis. In 2018, the median age of survival was estimated to be 52.1 years of age. The estimated median age of survival is the age beyond which it is expected that 50% of babies with CF born today will live, under the assumption that recent age-specific mortality rates will hold for the rest of their lives (Cystic Fibrosis Canada, 2018). The

probability of surviving beyond age 20 years is 91.4% for those born in 1985 or later, compared to 62.1% for persons born before 1975 (Cystic Fibrosis Canada, 2018). Lung, heart, pancreas, and liver transplantation have increased survival rates among some individuals with CF. Heart-lung and double-lung transplants have been successfully performed in children with advanced pulmonary vascular disease and hypoxia. Between 1988 and 2018, a total of 873 lung transplants took place, and 488 patients are reported as still being alive. The probability of survival post–lung transplant is 88.2% at 1 year, 75.9% at 3 years, and 67% at 5 years. Overall, 50% of those patients transplanted today would be expected to live beyond 10.5 years following lung transplantation (Cystic Fibrosis Canada, 2018). The obstacles surrounding this technique are availability of donated organs; complications from surgery; pulmonary infections; and recurrence of obstructive bronchiolitis, which decreases transplanted lung function.

Despite considerable progress and a recent surge in new treatment modalities, CF remains a progressive and incurable disease. The pulmonary involvement ultimately determines the patient's outcome because pancreatic enzyme deficiency is less of a concern if adequate nutrition is ensured. With the advances in treatment technology, parents and adolescents are challenged to set future goals that may include college, careers, social relationships, and marriage. Concurrently, they are faced with increasing morbidity and higher rates of CF complications as they grow older.

Nursing Care. Assessment of the child with CF involves comprehensive assessment of all affected systems with special focus on the pulmonary and gastrointestinal systems. Pulmonary assessment is the same as that described for asthma, with special attention to lung sounds, observation of cough, and evidence of decreased activity or fatigue. Gastrointestinal assessment primarily involves observing the frequency and nature of the stools and abdominal distension. Newborns should be assessed for feeding and stooling patterns, which may indicate a potential issue such as meconium ileus. Evidence of growth failure (e.g., weight loss, muscle wasting, pallor, anorexia, decreased activity [from baseline norm]) in the child with CF also needs to be noted. Family members should be interviewed to determine the child's eating and eliminating habits and to confirm the child's history of frequent respiratory tract infections or bowel obstruction in infancy.

The uncertainty, fear, and initial shock associated with the diagnosis of CF can be overwhelming to parents. They must face the impact of the chronic, life-threatening nature of the disease and the prospect of intensive treatment, for which they must assume a major part of the responsibility and are usually ill prepared. They often fear that they will be unable to provide the care that the child needs. One of the most difficult aspects of the diagnosis is the implications inherent in its etiology (i.e., the recognition that each parent contributed the gene responsible for the defect).

Hospital care. Most patients with CF require hospitalization only for the treatment of pulmonary infection, uncontrolled diabetes, or a coexisting medical condition that cannot be treated on an outpatient basis. When patients with CF are hospitalized, routine precautions with meticulous hand hygiene should be implemented to decrease the health care–associated spread of organisms to the patient with CF and between hospitalized patients with CF (especially when MRSA is prevalent). Contact precautions may be required for specific infections.

When the child with CF is hospitalized for diagnosis or treatment of pulmonary complications, aerosol therapy, percussion, and postural drainage are instituted or continued. While respiratory therapy and physiotherapists often initiate, supervise, and provide these treatments, it is the nurse's responsibility to monitor the patient's tolerance of the procedure and evaluate its effectiveness in relation to treatment goals. The nurse may at times administer aerosol therapy, perform chest percussion and postural drainage, assist with ACTs such as the mechanical vest, and teach breathing exercises. Chest percussion and postural drainage should be done before meals and bedtime. Planning percussion and postural drainage so that it does not coincide with meals can be difficult in the hospital but is essential to the effectiveness of this treatment.

Nursing assessments, including observation of respiratory pattern, work of breathing, and lung auscultation, are vital assessments. Noninvasive pulse oximetry provides valuable data about the patient's oxygenation status. Supplemental oxygen therapy is administered to the child with mild or moderate respiratory distress, and the child requires frequent assessment of tolerance of the procedure.

One of the nursing challenges in care of the child with CF is encouraging adherence to the often daunting therapeutic medication regimen, which often involves a significant number of medications—pancreatic enzymes; vitamins A, D, E, and K; oral antifungals for *Candida* infection; antihistamines; anti-inflammatory agents; and oral antibiotics. This regimen may be overwhelming to the child. With multiple inhaled bronchodilators, ACTs and postural and aerosol treatments, blood glucose monitoring and insulin administration, taking of various other medications, and increased mucus production during the acute phase, it is not uncommon for the child with CF to rebel and be reluctant to adhere to the prescribed regimen. Education, positive reinforcement, and frank negotiation may be required to enlist cooperation for effective medical treatment.

The child's sleep may be disrupted frequently by hospital routines; nursing care should be flexible enough to allow the child some quiet time without affecting vital care. In some cases a daily schedule of events, including medication administration, ACT, aerosolized therapy, and dressing changes, may need to be mutually developed with the child, nurses, and other health care providers so that the child feels that the child has some control of the care.

The diet for the child with CF represents another challenge; careful planning with a pediatric dietitian and the child may help decrease the loss of appetite and weight loss that are often part of the condition. Children in the early stages of CF often have a good appetite. With infection and increased lung involvement, their appetite diminishes, and eventually it becomes a challenge to tempt failing appetites. When dietary intake fails to meet the child's needs for growth, enteral feedings or supplements may need to be considered. These feedings may be administered via gastrostomy tube during the night to minimize the disruption of daily activities, including school. A low-profile gastrostomy affords the child few activity restrictions and minimal disruption of body image in comparison to an NG tube or conventional gastrostomy tube. The child and parents should be encouraged to perceive this therapy not as a last-ditch effort but as an adjunct therapy to maintain optimum growth and prevent excessive weight loss.

The child or adolescent needs support during the many treatments and tests that are a part of hospitalization. IV fluids, IV antibiotics and antifungals, PICC line placement or port accessing, and blood tests are almost always a part of the acute care treatment, and the child may soon associate hospitalization with these stress-provoking procedures.

The child or adolescent who is immobilized as a result of CF requires the same care and attention as the child with immobility from any other chronic or acute illness, including skin care, bowel management, passive range of motion, and positioning.

Depression, anxiety, and disturbed self-image may occur in children and adolescents with CF. Young adults with severe symptoms may be especially prone to depression as a result of the realization of the poor prognosis and the reality of unmet life expectations and goals.

Providing support to both the child and their family is essential. Skilled nursing care and sympathetic attention to the emotional needs

of the child and family can help them cope with the stresses associated with repeated respiratory tract infections and hospitalizations. The use of support groups or counselling may also be beneficial to the child.

Home care. Most children and adolescents with CF can be cared for at home. The goals of care include **normalization** and daily activities, including school and peer involvement. The care plan should be flexible so that family activities are disrupted as little as possible. Parents may initially require assistance in finding and contacting medical equipment companies that provide home care equipment. They also need opportunities to learn how to use the equipment and to solve problems they may encounter while delivering therapy at home. A home health care nurse may be required for initial assistance. The many aspects of home care for the child with CF are similar to those of home care for children with other complex conditions and are discussed in Chapter 41.

Patients and family members need education about the preferred diet of nutritious meals with tolerated fat, increased protein and carbohydrates, and administration of pancreatic enzymes and nutritional supplements. It is important to stress to parents that the enzymes, in the amount regulated to the child's needs, should be given at the beginning of all meals and snacks. For enteral feeds administered overnight, enzymes are generally given at the start and finish of the feeds.

One of the most important aspects of educating parents for home care is teaching techniques for the removal of mucus (ACT, vest, forced expiration) and assisting with breathing exercises. The success of a therapy program depends on conscientious performance of these treatments regularly as prescribed. The number of times these therapies are performed each day is determined on an individual basis, and often parents readily learn to adjust the number and intensity of the treatments to the child's needs. For pulmonary infection, home IV antibiotics may be prescribed. Home IV care may be preferred for some families, as it reduces tension and usually brings a sense of belonging to the family members. This option depends on a number of factors, including availability of an agency with adequate staff to perform multiple daily home antibiotic infusions. With use of the venous access devices such as PICC lines and implanted ports, the parents and child can be taught the technique of direct administration into the IV line.

Families also need information about medications and possible adverse effects. Children receiving multiple antibiotics may require serum drug levels to ensure therapeutic dosing. If a child is receiving ibuprofen, observations for adverse effects such as gastrointestinal irritation are essential.

If the child has CFRD, education on blood glucose monitoring, insulin therapy, diet control, and possible related complications is needed. Follow-up with a pediatric endocrinologist is recommended.

Children and adolescents with CF should receive routine primary care with special attention to diet, growth and development, and immunizations. Primary care providers should be alert to any weight loss or flattening in the growth curve associated with loss of appetite, which could indicate a pulmonary exacerbation in children with CF. In addition to all the recommended routine immunizations, patients with CF should be immunized against influenza starting at age 6 months; this should be followed by an annual booster (Government of Canada, 2019a). Infants with CF also meet the inclusion criteria to receive the RSV prophylaxis. Anticipatory guidance concerning issues of discipline, how to incorporate aspects of the treatment regimen into the school environment, and delayed pubertal development are also important considerations for the primary care provider.

Home palliative care for the child or adolescent with CF who is in the terminal stages of illness may be carried out with the assistance of palliative care or hospice, as appropriate (see Chapter 41).

The nurse can assist the family in contacting resources that provide help to families with affected children. Various special child health services, many local clinics, private agencies, service clubs, and other community groups often offer equipment and medications either free of charge or at reduced rates. Cystic Fibrosis Canada has chapters throughout Canada to provide education and services to families and health care providers (see Additional Resources at the end of this chapter).

Family support. One of the most challenging aspects of providing care for the family of a child or adolescent with CF is meeting the emotional needs of the child and family. The diagnosis, treatment, and prognosis for CF are often associated with many challenges and frustrations. The diagnosis can evoke feelings of guilt and self-recrimination in parents.

The long-range issues for an infant, child, or adolescent with CF are those encountered in any chronic illness (see Chapter 41). Both the child and their family must make many adjustments, the success of which depends on their ability to cope and on the quality and quantity of support they receive from outside sources. Combined efforts of a variety of health care providers are needed to provide the most comprehensive services to families. It is often the nurse who assesses the home situation, organizes and coordinates these services, and collects the data needed to evaluate the effectiveness of the services.

The persistent need for treatment several times a day can place tremendous strain on the family. When the child is young, a family member must perform postural drainage and other ACTs. Children often struggle to accept these treatments, and the parents are placed in the position of insisting on adherence. The stress and anxiety related to this routine may produce feelings of resentment in both the child and family members. When possible, occasional trusted respite care should be made available to allow parents to leave the situation for short periods without undue anxiety about their child's welfare.

The affected child or adolescent may become resentful about the disease, its relentless routine of therapy, and the necessary curtailment it places on activities and relationships. The child's activities are interrupted or built around treatments, medications, and diet. This regimen imposes hardships and influences their quality of life. The child should be encouraged to attend school and join age-appropriate peer groups to foster a life that is as normal and productive as possible. Sports are often an important part of the child and adolescent's life; interaction with peers is a valuable life experience, especially to adolescents. The child or adolescent with CF should be encouraged to participate in sports activities to the extent that their physical and pulmonary health allows. Exercise should be encouraged to increase pulmonary vital capacity, promote muscle development, and enhance cardiovascular function.

As the disease progresses, however, family stress should be expected, and the patient may become angry and may resist medical therapy. It is important for the nurse to recognize the family's changing needs and the grief they may experience as the CF worsens. Families should be made aware of sources for counselling. Patients need to be guided into activities that enable them to express anger, sorrow, and fear, without guilt.

Transition to adulthood. As life expectancy continues to rise for children and adolescents with CF, issues related to marriage, sexuality, childbearing, and career choice become more pressing. Males must be informed at some point that they may be unable to produce offspring. It is important that the distinction be made between sterility and impotence. Normal sexual relationships can be expected. Female patients may be able to bear children but should be informed of the possible deleterious effects on their respiratory system created by the pregnancy. They also need to know that their children will be carriers of the CF gene. Adolescent females may need counselling in the use of oral contraceptives and other contraceptive options.

Adolescents with CF should be encouraged to take responsibility for management of the illness to enhance life expectancy. Many

adolescents and young persons with the illness enroll in college or vocational and technical training school. Young people should be encouraged to set life goals and live normal lives to the extent their illness allows.

It is important to prepare the child and family members for end-of-life decisions and care, when appropriate. Anticipatory grieving and other aspects related to the care of a child with a terminal illness are also part of nursing care.

Obstructive Sleep-Disordered Breathing

Pediatric obstructive sleep-disordered breathing reportedly affects 12% of children, and approximately 6 out of 10 children with obesity have sleep apnea (MacLean, 2019). *Obstructive sleep-disordered breathing* is an abnormal respiratory pattern or abnormal deoxygenation associated with hypoventilation that results in repetitive partial or complete airway obstruction of the upper airway during sleep. The most severe form of this condition is **obstructive sleep apnea syndrome (OSAS)**. Common symptoms include nightly snoring, laboured breathing during sleep, interrupted or disturbed sleep patterns, sleep enuresis, and daytime neurobehavioural issues (Marcus et al., 2012). OSAS is to be distinguished from primary snoring, which is snoring without obstructive apnea, frequent sleep arousals, or abnormalities in gas exchange. Children with OSAS usually do not exhibit daytime sleepiness as do adults, with the possible exception of children with obesity. If left untreated, obstructive sleep-disordered breathing may result in complications such as growth failure, cor pulmonale, hypertension, poor learning, behavioural issues, attention-deficit/hyperactivity disorder, and death (MacLean, 2019).

The diagnosis of obstructive sleep-disordered breathing is made by an overnight in-laboratory sleep study (*polysomnography*), which provides evidence of sleep disturbance, respiratory pauses, and changes in oxygenation. The six-channel polysomnography can be performed in children of all ages through videotaping or audiotaping, and abbreviated (vs. full night sleep study) polysomnography, nocturnal oximetry, or daytime nap polysomnography may be useful; however, these latter methods do not predict the severity of OSAS. Polysomnography can be used to distinguish between OSAS and primary snoring (Owens, 2020).

Obstructive sleep-disordered breathing in children has been associated with enlarged tonsils, obesity, chronic nasal congestion, asthma, prematurity, cerebral palsy, muscular dystrophy, Down syndrome, craniofacial anomalies, and nasal septal deviation (Owens, 2020). In most cases of pediatric OSAS, adenotonsillectomy is the first-line treatment in any child with significant adenotonsillar hypertrophy, even in the presence of additional risk factors such as obesity (Owens, 2020). Evidence indicates that tonsillectomy or adenoidectomy alone may not be sufficient to resolve OSAS because residual lymphoid tissue may contribute to continual obstruction (Owens, 2020). CPAP and bilevel (cycles between high and low pressure) positive airway pressure (BiPAP) may be helpful in older children with sleep-disordered breathing whose condition persists after surgical intervention. CPAP or BiPAP is a long-term therapy that requires frequent assessments to evaluate the required amount of pressure and the overall effectiveness of the intervention. For children with obesity who have OSAS, a weight management plan is implemented. Care of the child with sleep-disordered breathing involves early detection by observation of the infant's or child's sleep patterns, active participation in the diagnostic polysomnography, observation of oxygenation and vital signs, application of CPAP when indicated, and monitoring of the patient's response to diagnostic therapy. Topical intranasal corticosteroids may be used for children with mild OSAS (Zhang et al., 2017).

Surgical interventions such as tracheotomy may be required for children with craniofacial syndromes such as Goldenhar, Pierre Robin, Apert, and Crouzon, in which there is partial or complete upper airway obstruction.

Nursing Care. Nursing care of the child with sleep-disordered breathing involves early detection by observation of the infant's or child's sleep patterns and active participation in the diagnostic polysomnography. Important nursing roles are insertion of the pH probe into the esophagus, ensuring accurate placement by radiography, and monitoring the sleep study and the patient's response to diagnostic therapy. Counselling families of children with sleep-disordered breathing may involve dietary counselling for exercise programs and weight management, use of the CPAP equipment, and direct postoperative care after surgical intervention of tonsillectomy or adenoidectomy. The nurse can be instrumental in helping the child and family cope with the chronic illness diagnosis if intervention such as CPAP is required.

CONGENITAL RESPIRATORY SYSTEM ANOMALIES

Choanal Atresia

Choanal atresia, the most common congenital anomaly of the nose, is a bony or membranous septum located between the nose and the pharynx (Figure 45.12). It occurs in 2.6 of every 10 000 births (Government of Canada, 2019b). The atresia may be unilateral or bilateral. Because most newborns are preferential nose breathers, bilateral choanal atresia may be associated with apnea and cyanosis when the newborn is at rest and may require intubation and ventilation. When newborns cry, they breathe in through the mouth and become pink. Unilateral choanal atresia may not be associated with apnea. The inability to pass a suction catheter through the nose into the pharynx or cyanosis without obvious respiratory distress usually leads to detection of choanal atresia. Nearly half of newborns with choanal atresia have other anomalies. Surgical correction is usually via endoscope through the nasal passages but sometimes requires an approach through the palate. Intranasal stent plugs that administer steroids can be effective. Debridement and surgical repairs may have to be redone at a later date. Unilateral choanal atresia surgery should be delayed until after age 6 months and/or the

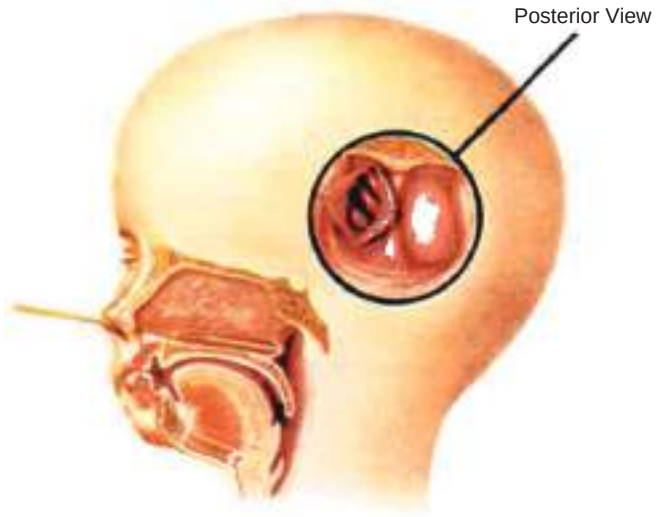

Fig. 45.12 Choanal atresia. Posterior nares are obstructed by membrane or bone, either bilaterally or unilaterally. (Used with permission of Ross Products Division, Abbott Laboratories, Inc., Columbus, OH. From Clinical Education Aid No. 6, Copyright © 1963, Ross Products Division, Abbott Laboratories, Inc.)

weight is greater than 5 kg, when possible (Moreddu et al., 2019). If an infant has choanal atresia, the child should be evaluated for both airway and feeding issues. Management of the airway often requires a combination of supportive, medical, and surgical care. Feeding and swallowing issues are very common in children with these conditions and often need to be addressed by speech pathologists and gastrointestinal specialists. Children born with syndromes often need other subspecialty evaluations (cardiology, ophthalmology) and benefit greatly from the coordinated care provided in the interprofessional setting.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) results from a defect in the formation of the diaphragm, allowing the abdominal organs to be displaced into the thoracic cavity. It occurs in approximately 3 in 3 300 births (Puligandla et al., 2018). Herniation of the abdominal viscera into the thoracic cavity may cause severe respiratory distress and represent a newborn emergency (Figure 45.13). The defect and herniation may be minimal and easily repaired, or the defect may be so extensive that the viscera present in the thoracic cavity during embryonic life have prevented the normal development of pulmonary tissue. CDH is one of the most severe birth defects, with extremely high newborn mortality. The defect is usually on the left because that is the side of the diaphragm that fuses last.

Most cases of CDH are discovered prenatally on ultrasound. Fetal surgery using an inflated intrathoracic balloon, which leads to the accumulation of the lung fluid and causes increased lung tissue to stretch and accelerated growth, has had promising results (Kosiński & Wielgoś, 2017).

At birth, most affected newborns have severe respiratory distress, and respiratory assessment reveals worsening distress as the bowel fills with air. Typically, breath sounds are diminished and bowel sounds are heard in the chest. Heart sounds may be shifted to the right side of the chest because the heart has been displaced by the abdominal contents. Physical examination reveals a flat or scaphoid abdomen and a prominent ipsilateral chest. Diagnosis can be made on the basis of the X-ray finding of loops of intestine in the thoracic cavity and the absence of intestine in the abdominal cavity.

Preoperatively, nursing interventions include assessment and stabilization of the newborn's condition until surgical repair can be performed. Conventional mechanical ventilation, high-frequency oscillatory ventilation, and ECMO may be used as respiratory support. Permissive hypercapnia may be allowed as long as the pH is maintained above or equal to 7.30 (Puligandla et al., 2018). Inhaled nitric oxide to relieve pulmonary hypertension of CDH has also been used in some cases, with mixed results. Gastric contents are aspirated and suction applied to decompress the gastrointestinal tract and prevent further cardiothoracic compromise. Oxygen therapy, mechanical ventilation, and the correction of acidosis are necessary in newborns with early clinical respiratory distress from CDH. ECMO may be used in newborns with severe circulatory and respiratory complications. Traditional management has been early surgical repair of the defect. However, increased survival rates have been reported with surgery after a period of preoperative stabilization and resolution of pulmonary hypertension.

The prognosis depends largely on the degree of fetal pulmonary development, but the prognosis in severe cases is often poor. The overall survival rate for live-born newborns has improved to 80% (Puligandla et al., 2018). The incidence of gastroesophageal reflux disease in survivors is approximately 50%, and a significant number will have neurocognitive impairments.

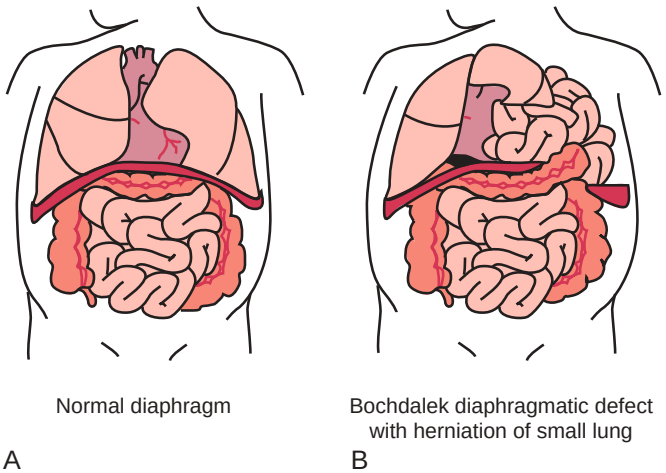

Fig. 45.13 **A:** Normal diaphragm separating the abdominal and thoracic cavities. **B:** Diaphragmatic hernia with a small lung and abdominal contents in the thoracic cavity. (From Ehrlich, P. F., & Coran, A. G. [2011]. Diaphragmatic hernia. In R. M. Kliegman, B. F. Stanton, J. St. Geme, et al. [Eds.], *Nelson textbook of pediatrics* [19th ed.]. Saunders.)

RESPIRATORY EMERGENCY

Respiratory Failure

Effective pulmonary gas exchange requires clear airways, normal lungs and chest wall, and adequate pulmonary circulation. Anything that affects these functions or their relationships can compromise respiration. In general, the term *respiratory insufficiency* is applied to two situations: (1) when there is increased work of breathing but gas exchange function is near normal, and (2) when normal blood gas tensions cannot be maintained and hypoxemia and acidosis develop secondary to carbon dioxide retention.

Respiratory failure is defined as the inability of the respiratory apparatus to maintain adequate oxygenation of the blood, with or without carbon dioxide retention. This process involves pulmonary dysfunction that generally results in impaired alveolar gas exchange, which can lead to hypoxemia or hypercapnia. Respiratory failure is the most common cause of cardiopulmonary arrest in children. *Respiratory arrest* is the cessation of respiration. *Apnea* is the cessation of breathing for more than 20 seconds or for a shorter period when associated with cyanosis, pallor, or bradycardia. Apnea can be (1) central, in which respiratory efforts are absent; (2) obstructive, in which respiratory efforts are present; or (3) mixed, in which both central and obstructive components are present (see Brief Resolved Unexplained Events, Chapter 36). Respiratory dysfunction may have an abrupt or an insidious onset. Respiratory failure can occur as an emergency situation or may be preceded by gradual and progressive deterioration of respiratory function. Most clinical manifestations are nonspecific and are affected by variations among individual patients and differences in the severity and duration of inadequate gas exchange.

Diagnostic Evaluation. The diagnosis of respiratory failure is determined by the combined application of three sources of information:

1. Presence or history of a condition that might predispose the patient to respiratory failure
2. Observation of respiratory failure
3. Measurement of ABG values and pH

Nursing observation and judgement are vital to the recognition and early management of respiratory failure. Nurses must be able to assess a situation and initiate appropriate action within moments. Signs of respiratory failure are listed in Box 45.16.

BOX 45.16 Clinical Manifestations of Respiratory Failure

Cardinal Signs
Restlessness
Tachypnea
Tachycardia
Diaphoresis (except in newborns)

Early but Less Obvious Signs
Mood changes such as euphoria or depression
Headache
Altered depth and pattern of respirations
Hypertension
Exertional dyspnea
Anorexia
Increased cardiac output and renal output
Central nervous system symptoms (decreased efficiency, impaired judgement, anxiety, confusion, restlessness, irritability, depressed level of consciousness)
Nasal flaring
Chest wall retractions
Expiratory grunt
Wheezing or prolonged expiration

Signs of More Severe Hypoxia
Hypotension or hypertension
Altered vision
Somnolence
Stupor
Coma
Dyspnea
Depressed respirations
Bradycardia
Cyanosis, peripheral or central

Therapeutic Management. The interventions used in the management of respiratory failure are often dramatic, requiring special skills and emergency procedures. If respiratory arrest occurs, the primary objectives are to recognize the situation and immediately initiate resuscitative measures, such as opening the airway, positioning, administration of supplemental oxygen, and cardiopulmonary resuscitation (CPR). When the situation is not an arrest, suspicion of respiratory failure is confirmed by assessment; the severity may be defined by ABG analysis. Interventions such as administering supplemental oxygen, positioning, stimulation, suctioning, and CPAP, BiPAP, or early intubation may avert an arrest. When the severity is established, an attempt is made to determine the underlying cause by thorough evaluation.

The principles of management are to (1) maintain ventilation and maximize oxygen delivery, (2) correct hypoxemia and hypercapnia, (3) treat the underlying cause, (4) minimize extrapulmonary organ failure, (5) apply specific and nonspecific therapy to control oxygen demands, and (6) anticipate complications. Monitoring closely the patient's condition is critical.

Nursing Care. For families whose child has respiratory arrest, support is aimed at keeping the family informed of the child's status and helping them cope with a near-death experience or an actual death (see Chapter 41). Knowing that their child requires CPR is a frightening and often overwhelming experience for parents. Uncertainty regarding the outcome—both mortality and morbidity—is a primary concern. Traditionally, family members were not allowed to be present during resuscitation efforts in the emergency department. However, studies indicate that family presence during emergencies alleviates the family's anger about being separated from the patient during a crisis, reduces their anxiety, eliminates doubts about what was done to help the patient, and facilitates the grieving process if the patient dies (Meert et al., 2013).

Regardless of whether an institution permits parental presence during CPR, nurses must consider the needs, fears, and concerns of family members during an arrest situation. Whether family presence is permitted or not permitted, nurses should arrange for someone to remain with the family during the emergency treatment. After the child's recovery or death, the family will continue to need support and thorough medical information regarding lifesaving measures, the prognosis if the child survives, and the cause of death if the child dies.

Cardiopulmonary Resuscitation

Cardiac arrest in children is less often of cardiac origin than from prolonged hypoxemia secondary to inadequate oxygenation, ventilation, and circulation (shock). Some causes of cardiac arrest include injuries, suffocation (e.g., FB aspiration), smoke inhalation, or infection. In small infants the small size of the airway may easily be compromised by improper positioning with the chin resting on the chest; this can easily be remedied by positioning the infant with the chin elevated (but not hyperextended) so the airway is open. This is common in infants who are not positioned properly in an infant seat or car restraint seat. Respiratory arrest is associated with a better survival rate than cardiac arrest. After cardiac arrest occurs, the outcome of resuscitative efforts is poor.

Complete apnea signals the need for rapid, vigorous action to prevent cardiac arrest. In such situations nurses must initiate action immediately. In the hospital, emergency equipment must be available and easily accessible in all patient care areas. The status of emergency equipment must be checked at least once daily. Regardless of the cause of the arrest, basic procedures need to be carried out and modified according to the child's size.

If a child requires resuscitation, nurses must follow the most up-to-date Heart and Stroke Foundation of Canada (2018) guidelines.

KEY POINTS

- Acute infection of the respiratory tract is the most common cause of illness in infancy and childhood.
- The incidence and severity of respiratory tract infections are influenced by the infectious agents involved, the child's age, and the child's natural defences.
- Common respiratory tract infections of childhood include nasopharyngitis, pharyngitis (including tonsillitis), influenza, infectious mononucleosis, and OM.
- Croup syndromes involve acute inflammation and variable degrees of obstruction of the epiglottis, larynx, or trachea.
- The primary goals in the care of children with croup are observation for signs of respiratory distress and relief of laryngeal inflammation.
- Common infections of the lower airways are bacterial tracheitis, bronchitis, and RSV-bronchiolitis.
- Pneumonias are classified according to site or by etiological agent (viral, bacterial, mycoplasmal) or are associated with aspiration of foreign material.

- In TB, susceptibility to the bacillus can be influenced by heredity, age, stress, poor nutrition, and intercurrent infection.
- Secondhand smoke exposure is a major environmental pollutant contributing to respiratory illness in children.
- Asthma is the leading cause of chronic illness in children.
- General therapeutic management of asthma includes assessment of asthma severity, allergen control, medication therapy, symptom management, and sometimes hyposensitization.
- Support for the family and the child with asthma includes education about the disease and its therapy and facilitation of self-management.
- CF is the most common inherited disease in children.
- The diagnosis of CF is based on newborn screening finding of elevated IRT, DNA analysis showing a *CFTR* mutation, and a positive sweat chloride test (increased sweat electrolyte content).
- General therapeutic management of CF is highly individualized, requiring an interprofessional approach and a strong support network for children and their families.
- Choanal atresia and diaphragmatic hernia are congenital respiratory conditions.

Gastrointestinal Conditions

Constance O'Connor and
Originating US chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify children at increased risk of developing nutritional disorders.
2. Outline a nutritional counselling plan for vitamin or mineral deficiency or excess.
3. Identify factors that may cause fluid loss or gain in a child.
4. Formulate a plan of care for the child with acute diarrhea.
5. Outline a teaching plan designed to prevent transmission of intestinal parasites.
6. Describe the nursing care of the child with appendicitis.
7. Compare and contrast the inflammatory bowel diseases.
8. Identify the routes of transmission for hepatitis A, B, and C.
9. Describe the nursing care of the child with hepatitis.
10. Formulate a plan for teaching parents preoperative and postoperative care of the child with a cleft lip or cleft palate.
11. Describe the nursing care for a child with a tracheoesophageal fistula or esophageal atresia.
12. Formulate a plan of care for the child with an obstructive gastrointestinal disorder.
13. Identify nutritional therapies for the child with a malabsorption syndrome.
14. Identify the principles in the emergency treatment of accidental poisoning.
15. Describe the nursing care of the child with lead poisoning.

GASTROINTESTINAL SYSTEM STRUCTURE AND FUNCTION

The gastrointestinal (GI) system has a multitude of important functions. The system includes all the structures from the mouth to the anus. The major functions are to break down and digest foods so that the nutrients may be absorbed through the digestive tract and waste products may be eliminated.

During fetal development, the GI system begins to form during the fourth week of the embryonic stage, starting with the mouth and anal tube. The GI tract becomes more mature in the last few weeks of development. Congenital anomalies of the GI tract can be present at birth or shortly after birth.

Pediatric Differences Related to the Gastrointestinal System

The mouth is highly vascular and is a common portal for infection. Infants and young children are at a higher risk of contracting infectious agents via the oral route because they may put objects in their mouths when exploring their environment.

The esophagus connects the mouth and stomach and allows for passage of food. The lower esophageal sphincter (LES) prevents regurgitation of the stomach's contents into the esophagus and mouth. LES muscle tone is not fully developed until 1 month of age, so young infants tend to regurgitate after feedings. Usually the regurgitation vanishes after 1 year of age.

A child's stomach capacity increases with age. The newborn has a capacity of 10 to 20 mL, and 2-month-olds have a 200-mL capacity, although many cannot tolerate that amount of volume per feeding. Adolescents' capacity increases to 1 500 mL. By 6 months of age, the level of hydrochloric acid in gastric contents (to aid in digestion) is equal to that of adults.

A full-term newborn has approximately half the GI length of an adult. Intestinal growth spurts occur between 1 and 3 years for young children, and between 15 and 16 years of age for adolescents.

With regard to the biliary system, the liver is relatively large in the newborn. The pancreatic enzymes develop at different times postnatally and reach adult levels by 2 years of age.

NUTRITIONAL DISTURBANCES

Nurses can promote healthy eating habits early in children's lives by providing families and their children with information regarding good nutrition and healthy lifestyle. Such education covers diet and exercise that can foster good health, as well as ways to prevent morbidities associated with poor nutrient intake and a sedentary lifestyle. See Chapter 33 for conducting a nutritional assessment and Chapter 35 for more information regarding nutritional needs and issues specific to each stage.

Vitamin Imbalances

While most vitamin deficiencies are rare in North America, vitamin D–deficiency rickets continues to be a concern in Canada, especially among Indigenous people. The Canadian Paediatric Society (CPS) (Godel & CPS, First Nations, Inuit and Métis Health Committee, 2007/2017) has identified the following populations to be at risk:

- Children exclusively breastfed by mothers with an inadequate intake of vitamin D or mothers who had vitamin D deficiency during pregnancy
- Children with dark skin pigmentation
- Children with diets that are low in sources of vitamin D and calcium
- Children who live in northern communities (They have less exposure to sunlight because of fewer sunlight hours and covering the skin during sunlight hours to prevent black fly, mosquito, or other bites.)
- Children who live in polluted urban sites
- Children who cover the skin for religious purposes

The recommendations for daily vitamin D intake are listed in Table 35.1.

Children may also be at risk for vitamin deficiencies secondary to disorders or their treatment. For example, vitamin deficiencies of the fat-soluble vitamins A and D may occur in malabsorptive disorders such as cystic fibrosis and short bowel syndrome. Preterm infants may develop rickets in the second month of life as a result of inadequate intake of vitamin D, calcium, and phosphorus. Children receiving high doses of salicylates may have impaired vitamin C storage. Environmental tobacco smoke exposure has been implicated in decreased concentrations of vitamin A and E in newborns (Titova et al., 2012). Children with chronic illnesses resulting in anorexia, decreased food intake, or possible nutrient malabsorption as a result of multiple medications should be evaluated carefully for adequate vitamin and mineral intake in some form (parenteral or enteral).

An excessive dose of a vitamin is generally defined as 10 or more times the Recommended Dietary Allowance (RDA), although the fat-soluble vitamins, especially A and D, tend to cause toxic reactions at lower doses. With the addition of vitamins to commercially prepared foods, the potential for hypervitaminosis has increased, especially when combined with the excessive use of vitamin supplements. Hypervitaminosis of vitamins A and D presents the greatest concern because these fat-soluble vitamins are stored in the body. High intakes of vitamin A present with dry, scaly skin that progresses to desquamation and fissures, and include anorexia, vomiting, and bulging fontanelle (Hayman & Dalziel, 2012). While vitamin D intoxication is rare, children supplemented at high levels for prolonged periods of time may have poor appetite, weight loss, abdominal pain, constipation dehydration, and in severe cases, life-threatening dehydration. It is therefore recommended that children receiving long-term vitamin D supplementation above the upper limit of typical dosing have routine monitoring by obtaining serum 25-hydroxyvitamin D levels (Vogiatzi et al., 2014). The water-soluble vitamins, primarily niacin, B_6, and C, can also cause toxicity. Poor outcomes in infants (e.g., fatal hypermagnesemia) have been associated with megavitamin therapy with high doses of magnesium oxide.

Deficiencies and excesses of vitamins A, B complex, C, D, E, and K are summarized in Table 46.1.

TABLE 46.1 Vitamins and Their Nutritional Significance

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care
Vitamin A (Retinol)*		
Functions	***Deficiency***	***Deficiency***
Necessary component in formation of pigment rhodopsin (visual purple)	Night blindness	Encourage foods rich in vitamin A, such as whole cow's milk (after 12 mo).
Formation and maintenance of epithelial tissue	Keratinization (hardening and scaling) of epithelium	As milk consumption decreases, encourage foods rich in vitamin A.
Normal bone growth and tooth development	Xerophthalmia (hardening and scaling of cornea and conjunctiva)	Ensure adequate intake in preterm infants.
Needed for growth and spermatogenesis	Phrynoderma (toad skin)	Advise parents of safe use of supplements in child with measles.
Involved in thyroxine formation	Drying of respiratory, gastrointestinal, and genitourinary tracts	It may play a role in prevention of severity of bronchopulmonary dysplasia in preterm infants (affects growth of respiratory tract epithelial cells).
Antioxidant	Defective tooth enamel	***Excess***
Sources	Delayed growth	Emphasize correct use of vitamin supplements and potential hazards of excess.
Natural form—Liver, kidney, fish oils, milk and nonskim milk products, egg yolk	Impaired bone formation	Evaluate child's dietary habits to calculate approximate intake; if excessive, remove supplemental source (e.g., daily feeding of liver).
Provitamin A (carotene)—Carrots, sweet potatoes, squash, apricots, spinach, collards, broccoli, cabbage, artichokes	Decreased thyroxine formation	Advise parents of the benign nature of carotenemia; treatment is avoidance of excess pigmented fruits or
	Decreased resistance to infections	
	Excess	
	Early signs—Irritability, anorexia, pruritus, fissures at corners of nose and lips, dry skin	
	Later signs—Hepatomegaly, jaundice, restricted growth, poor weight gain, thickening of the cortex of long bones with pain and fragility, hard tender lumps in extremities and occiput of the skull	

Continued

TABLE 46.1 Vitamins and Their Nutritional Significance—cont'd

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care
	Can cause birth defects if excessive maternal intake **NOTE:** Overdose results from ingestion of large quantities of the vitamin only, not the provitamin; large amounts of carotene (carotenemia) cause yellow or orange discoloration of the skin (not the sclera, urine, or feces as in jaundice) but none of the above symptoms.	vegetables, especially carrots; skin colour returns to normal in 2 to 6 wk.
Vitamin B_1 (Thiamine)† ***Functions*** Coenzyme (with phosphorus) in carbohydrate metabolism Needed for healthy nervous system Digestion and normal appetite ***Sources*** Pork, beef, liver, legumes, nuts, whole or enriched grains and cereals, green vegetables, fruits, milk, brown rice	***Deficiency*** **Gastrointestinal**—Anorexia, constipation, indigestion **Neurological**—Apathy, fatigue, emotional instability, polyneuritis, tenderness of calf muscles, partial anaesthesia, muscle weakness, paresthesia, hyperesthesia, decreased or absent tendon reflexes, convulsions, coma (in infants) **Cardiovascular**—Palpitations, cardiac failure, peripheral vasodilation, edema ***Excess*** Headache Irritability Insomnia Weakness	***Deficiency: Vitamin B Complex*** Encourage foods rich in B vitamins. Stress proper cooking and storage techniques to preserve potency, such as minimum cooking of vegetables in small amount of liquid and storage of milk in opaque container. Encourage fortified breakfast cereals and soy milk (which have B_{12}) for persons on strict vegetarian diet; dairy products and eggs contain B_{12} if these are allowed; otherwise supplementation may be required. Evaluate need for vitamin supplements when dieting, when using unfortified goat's milk exclusively for infant feeding (deficient in folic acid), or when the breastfeeding parent is a strict vegetarian (vitamin B_{12}). ***Excess*** Emphasize correct use of vitamin supplements and potential hazards of excess. Individuals with malabsorption syndrome or being treated with hemodialysis or peritoneal dialysis may have increased need for thiamine.
Vitamin B_2 (Riboflavin)† ***Functions*** Coenzyme (with phosphorus) in carbohydrate, protein, and fat metabolism Maintains healthy skin, especially around mouth, nose, and eyes ***Sources*** Milk and its products, eggs, organs (liver, kidney, heart), enriched cereals, some green leafy vegetables,‡ legumes	***Deficiency*** Ariboflavinosis **Lips**—Cheilosis (fissures at corners of lips), perlèche (inflammation at corners of lips) **Tongue**—Glossitis **Nose**—Irritation and cracks at nasal angle **Eyes**—Burning, itching, tearing, photophobia, blurred vision, corneal vascularization, cataracts **Skin**—Seborrheic dermatitis, delayed wound healing and tissue repair ***Excess*** Paresthesia, pruritus	Same as for vitamin B complex
Niacin (Nicotinic Acid, Nicotinamide)† ***Functions*** Coenzyme (with riboflavin) in protein and fat metabolism Needed for healthy nervous system and skin and for normal digestion May lower cholesterol ***Sources*** Meat, poultry, fish, peanuts, beans, peas, whole or enriched grains (except corn and rice) Milk and its products are sources of tryptophan (60 mg tryptophan = 1 mg niacin)	***Deficiency*** Pellagra (rash, diarrhea, mental status changes, stomatitis) **Oral**—Stomatitis, glossitis **Cutaneous**—Scaly dermatitis on exposed areas **Gastrointestinal**—Anorexia, weight loss, diarrhea, fatigue **Neurological**—Apathy, anxiety, confusion, depression, dementia ***Excess*** Release of histamine, a vasodilator (flushing, decreased	Same as for vitamin B complex ***Excess*** If used as hypolipidemic agent, stress safe storage to prevent child's accidental ingestion.

TABLE 46.1 Vitamins and Their Nutritional Significance—cont'd

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care
	blood pressure, increased cerebral blood flow; aggravates asthma) Dermatological conditions (pruritus, rash, hyperkeratosis, acanthosis nigricans) Increased gastric acidity (aggravates peptic ulcer disease) Hepatotoxicity Increased serum uric acid levels Elevated plasma glucose levels Certain cardiac arrhythmias	
Vitamin B_6 (Pyridoxine)†		
Functions Coenzyme in protein and fat metabolism Needed for formation of antibodies and hemoglobin Needed for utilization of copper and iron Aids in conversion of tryptophan to niacin ***Sources*** Meats, especially liver and kidney, cereal grains (wheat, corn), yeast, soybeans, peanuts, tuna, chicken, salmon	***Deficiency*** Scaly dermatitis Weight loss Anemia Restricted growth Irritability Seizures Peripheral neuritis ***Excess*** Peripheral nervous system toxicity (unsteady gait, numb feet and hands, clumsiness of hands, sometimes perioral numbness) May cause peptic ulcer disease or seizures	Same as for vitamin B complex ***Deficiency*** Stress proper cooking and storing techniques to preserve potency. Cook food covered in small amount of water. Do not soak food in water. Store in light-resistant container.
Folic Acid (Folacin; Reduced Form Called Folinic Acid or Citrovorum Factor)†		
Functions Coenzyme for single-carbon transfer (purines, thymine, hemoglobin) Necessary for formation of red blood cells Prevents neural tube defects (i.e., myelomeningocele) and facial clefts (cleft lip and palate) ***Sources*** Green leafy vegetables, beets, cabbage, asparagus, liver, kidneys, nuts, eggs, whole-grain cereals, legumes, bananas	***Deficiency*** Macrocytic anemia Bone marrow depression Glossitis Intestinal malabsorption Growth failure ***Excess*** Rare because megadoses are not available over the counter May cause insomnia and irritability	Same as for vitamin B complex ***Deficiency*** Stress proper cooking and storing techniques to preserve potency: Cook food covered in small amount of water. Do not soak food in water. Store in light-resistant container. Persons of childbearing age should supplement to prevent neural tube defects and orofacial clefts.
Vitamin B_{12} (Cobalamin)†		
Functions Coenzyme in protein synthesis; indirect effect on formation of red blood cells (particularly on formation of nucleic acids and folic acid metabolism) Needed for normal functioning of nervous tissue ***Sources*** Meat, liver, kidney, fish, shellfish, poultry, milk, eggs, cheese, nutritional yeast, sea vegetables	***Deficiency*** Pernicious anemia (one form of deficiency from absence of intrinsic factor in gastric secretions) General signs of severe anemia Lemon-yellow tinge to skin Spinal cord degeneration Delayed brain growth ***Excess*** Rare	Same as vitamin B complex ***Deficiency*** Consider fortified foods or supplements in persons over 50 yr of age to meet RDA because malabsorption of food-bound vitamin B_{12} is common.
Vitamin C (Ascorbic Acid)†		
Functions Essential for collagen formation Increases absorption of iron for hemoglobin formation Enhances conversion of folic acid to folinic acid Affects cholesterol synthesis and conversion of proline to hydroxyproline	***Deficiency*** Scurvy **Skin**—Dry, rough, petechiae; perifollicular hyperkeratotic papules (raised areas around hair follicles) **Musculoskeletal**—Bleeding muscles and joints, pseudoparalysis from pain, swelling of joints,	***Deficiency*** Encourage foods rich in vitamin C. Evaluate child's diet for sources of vitamin, especially when cow's milk is principal source of nutrition. Tobacco smokers require an additional 35 mg/day; nonsmokers exposed to secondhand smoke should make sure they meet RDA.

Continued

TABLE 46.1 Vitamins and Their Nutritional Significance—cont'd

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care
Probably a coenzyme in metabolism of tyrosine and phenylalanine May play role in hydroxylation of adrenal steroids May have stimulating effect on phagocytic activity of leukocytes and formation of antibodies Antioxidant agent (spares other vitamins from oxidation) ***Sources*** Citrus fruits, strawberries, tomatoes, potatoes, cabbage, broccoli, cauliflower, spinach, papaya, mango, cantaloupe, watermelon, enriched fruit juice	costochondral beading (scorbutic rosary) **Gums**—Spongy, friable, swollen, bleed easily, bluish red or black, teeth loosen and fall out **General disposition**—Irritable, anorexic, apprehensive, in pain, refuses to move, assumes semi-froglike position when supine (scorbutic pose) Signs of anemia Decreased wound healing Increased susceptibility to infection ***Excess*** **Diarrhea** Increased excretion of uric acid and acidification of urine (may cause urate precipitation and formation of oxalate stones) **Hemolysis** Impaired leukocytosis activity Damage to beta cells of pancreas and decreased insulin production Reproductive failure "Rebound scurvy" from withdrawal of large amounts	Stress proper cooking and storage techniques to preserve potency. Wash vegetables quickly; do not soak in water. Cook vegetables in covered pot with minimum water and for short time; avoid copper or cast iron cookware. Do not add baking soda to cooking water. Use fresh fruits and vegetables as soon as possible; store in refrigerator. Store juice in airtight, opaque container. Wrap cut fruit or eat soon after exposing to air. ***Excess*** Emphasize correct use of vitamin supplements and potential hazards of excess. Identify groups at risk for excessive vitamin C supplements (e.g., those with thalassemia or those receiving anticoagulant or aminoglycoside antibiotic therapy).
Vitamin D_2 (Ergocalciferol) and D_3 (Cholecalciferol)*		
Functions Absorption of calcium and phosphorus and decreased renal excretion of phosphorus ***Sources*** Direct sunlight Cod liver oil, herring, mackerel, salmon, tuna, sardines Enriched food sources—Milk, milk products, enriched cereals, margarine, breads, many breakfast drinks	***Deficiency*** Rickets **Head**—Craniotabes (softening of cranial bones, prominence of frontal bones [bossing]), deformed shape (skull flat and depressed toward middle), delayed closure of fontanels **Chest**—Rachitic rosary (enlargement of costochondral junction of ribs), Harrison groove (horizontal depression in lower portion of rib cage), pigeon chest (sharp protrusion of sternum) **Spine**—Kyphosis, scoliosis, lordosis **Abdomen**—Pot belly, constipation **Extremities**—Bowing of arms and legs, knock knee, sabre shins, instability of hip joints, pelvic deformity, enlargement of epiphyses at ends of long bones **Teeth**—Delayed calcification, especially of permanent teeth **Rachitic tetany**—Seizures ***Excess*** **Acute**—Vomiting, dehydration, fever, abdominal cramps, bone pain, seizures, coma **Chronic**—Lassitude, mental slowness, anorexia, failure to thrive, thirst, urinary urgency, polyuria, vomiting, diarrhea, abdominal cramps, bone pain, pathological fractures Calcification of soft tissue—Kidneys, lungs, adrenal glands, vessels (hypertension), heart, gastric lining, tympanic membrane (deafness) Osteoporosis of long bones Elevated serum levels of calcium and phosphorus	***Deficiency*** Encourage foods rich in vitamin D, especially fortified whole cow's milk (>12 mo of age). Encourage use of vitamin D supplement in all exclusively breastfed infants starting within first 2 wk of life. Observe for possibility of overdose from supplements. If prescribed, supervise proper use of orthoses (splints and braces). ***Excess*** Same as for vitamin A; may include low-calcium diet during initial therapy
Vitamin E (Tocopherol)*		
Functions Production of red blood cells and protection from hemolysis Muscle and liver integrity	***Deficiency*** Hemolytic anemia from hemolysis caused by shortened life of red blood cells, especially in preterm infants; focal necrosis of tissues	***Deficiency*** Initiate early feeding in preterm infants; may need supplementation. Potential role as antioxidant in immune function,

TABLE 46.1 Vitamins and Their Nutritional Significance—cont'd

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care
Coenzyme factor in tissue respiration Minimizes oxidation of polyunsaturated fatty acids and vitamins A and C in intestinal tract and tissues ***Sources*** Vegetable oils, wheat germ oil, milk, egg yolk, fish, whole grains, nuts, legumes, spinach, broccoli	***Excess*** Little is known; less toxic than other fat-soluble vitamins	preventing or limiting the severity of retinopathy and prevention of hemolytic anemia, bronchopulmonary dysplasia, and intracranial hemorrhage
Vitamin K*		
Functions Catalyst for production of prothrombin and blood-clotting factors II, VII, IX, and X by the liver ***Sources*** Pork, liver, green leafy vegetables, cabbage, tomatoes, egg yolk, cheese	***Deficiency*** Hemorrhage ***Excess*** Hemolytic anemia in individuals who are deficient in glucose 6-phosphate dehydrogenase	***Deficiency*** Administer prophylactically to all newborns. Other indications include intestinal disease, lack of bile, prolonged antibiotic therapy; may be used in management of blood-clotting time when anticoagulants such as warfarin (Coumadin) and dicumarol (bishydroxycoumarin), which are vitamin K antagonists, are used.

*Fat soluble.
†Water soluble.
‡Green leafy vegetables include spinach, broccoli, kale, turnip greens, mustard greens, collards, dandelion greens, and beet greens.
Table is not intended to be all inclusive.
RDA, Recommended dietary allowance.

Mineral Imbalances

A number of minerals are essential nutrients. The *macrominerals* refer to those with daily requirements greater than 100 mg and include calcium, phosphorus, magnesium, sodium, potassium, chloride, and sulphur. *Microminerals*, or trace elements, have daily requirements of less than 100 mg and include several essential minerals and those whose exact role in nutrition is still unclear. The greatest concern with minerals is deficiency, especially iron-deficiency anemia (Box 46.1). However, other minerals that may be inadequate in children's diets, even with supplementation, include calcium, phosphorus, magnesium, and zinc. Low levels of zinc can cause nutritional growth failure (failure to thrive). Some of the macrominerals may be overlooked inadvertently when a child with intestinal failure or recent surgery is making the transition from total parenteral to enteral intake.

An imbalance in the intake of calcium and phosphorus may occur in infants who are given whole cow's milk instead of infant formula; neonatal tetany may be observed in such cases. Whole cow's milk is also a poor source of iron, and inadequate intake of iron from other food sources may cause iron-deficiency anemia.

The regulation of mineral balance in the body is complex. Dietary extremes of mineral intake can cause a number of mineral–mineral interactions that could result in unexpected deficiencies or excesses. For example, excessive amounts of one mineral such as zinc can result in a deficiency of another mineral such as copper, even if sufficient amounts of copper are ingested. Thus megadose intake of one mineral may cause deficiency of another essential mineral by blocking its absorption in the blood or intestinal wall or by competing with binding sites on protein carriers needed for metabolism.

Deficiencies can also occur when various substances in the diet interact with minerals. For example, iron, zinc, and calcium can form insoluble complexes with phytates or oxalates (substances found in plant proteins), which impair the bioavailability of the mineral. This type of interaction is important in **vegetarian** diets (see Chapter 35) because plant foods such as soy are high in phytates. Contrary to

BOX 46.1 Factors That Affect Iron Absorption

Increase	Decrease
Acidity (low pH)—Administer iron between meals (gastric hydrochloric acid)	Alkalinity (high pH)—Avoid any antacid preparation
Ascorbic acid (vitamin C)—Administer iron with juice, fruit, or multivitamin preparation	Phosphates—Milk is an unfavourable vehicle for iron administration
Vitamin A	Phytates—Found in cereals
Calcium	Oxalates—Found in many fruits and vegetables (plums, currants, green beans, spinach, sweet potatoes, tomatoes)
Tissue need	Tannins—Found in tea, coffee
Meat, fish, poultry	Tissue saturation
Cooking in cast iron pots	Malabsorptive disorders
	Disturbances that cause diarrhea or steatorrhea
	Infection

popular opinion, spinach is not an ideal source of iron or calcium because of its high oxalate content.

Children with certain illnesses are at greater risk for growth failure, especially in relation to bone mineral deficiency as a result of the treatment of the disease, decreased nutrient intake, or decreased absorption of necessary minerals. Those at risk for such deficiencies include children who are receiving or have received radiation and chemotherapy for cancer; children with human immunodeficiency virus (HIV), sickle cell disease, cystic fibrosis, GI malabsorption, or nephrosis; and extremely low-birth-weight (ELBW) and very low–birth weight (VLBW) preterm infants.

Deficiencies and excesses of the essential macrominerals and microminerals are summarized in Table 46.2.

Nursing Care. Identification of the adequacy of nutrient intake is the initial nursing goal and requires assessment based on a dietary history

TABLE 46.2 Minerals and Their Nutritional Significance

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care Management
Calcium*		
Functions	***Deficiency***	***Deficiency***
Bone and tooth development and maintenance (in combination with phosphorus)	Rickets	Encourage foods rich in calcium, especially dairy products.
Muscle contractions, especially the heart	Tetany	Give vitamin D supplements in breastfed infants from birth until adequate amounts received from introduction of solid foods.
Blood clotting	Impaired growth, especially of bones and teeth	Caution that oxalates in leafy vegetables (spinach), oxalates in chocolates, and a high phosphorus intake (especially from carbonated beverages) can decrease calcium absorption.
Absorption of vitamin B_{12}	Osteoporosis	Discourage use of whole cow's milk or other animal milks in newborns and infants under 12 mo because the phosphorus/calcium ratio favours excretion of calcium.
Enzyme activation	***Excess***	Advise against diets that restrict dairy products unless adequate supplementation is followed.
Nerve conduction	Drowsiness, extreme lethargy	***Excess***
Integrity of intracellular cement substances and various membranes	Impaired absorption of other minerals (iron, zinc, manganese)	Emphasize correct use of calcium supplements, especially the possible interaction between megadoses of calcium and resulting deficiency states of other minerals.
Sources	Calcium deposits in tissues (renal failure)	
Dairy products, egg yolk, sardines, canned salmon with bones, green leafy vegetables† (except spinach), soybeans, dried beans, peas		
Chloride*		
Functions	***Deficiency***	Deficiency and excess are unusual; most diets supply adequate chloride (usually in combination with sodium).
Acid–base and fluid balance	Acid–base disturbances (hypochloremic alkalosis, dehydration); occurs mostly in combination with sodium loss	Disease states such as excessive vomiting can necessitate chloride replacement.
Enzyme activation in saliva	***Excess***	
Component of hydrochloric acid in stomach	Acid–base disturbance	
Sources		
Salt, meat, eggs, dairy products, many prepared and preserved foods		
Copper‡		
Functions	***Deficiency***	***Deficiency***
Production of hemoglobin	Anemia, leukopenia, neutropenia	Emphasize that the correct use of any vitamin supplement with mineral because deficiency from inadequate food sources is less likely than from excess intake of other minerals, especially zinc and possibly iron.
Essential component of several enzyme systems	***Excess***	***Excess***
Sources	Severe vomiting and diarrhea	Cooking acid foods in unlined copper pots can lead to chronic and toxic accumulation of copper.
Organ meats, oysters, nuts, seeds, legumes, corn oil margarine	Hemolytic anemia	
Fluoride‡		
Functions	***Deficiency***	Fluoride has the narrowest range of safe and adequate intake; therefore, stress the importance of storing supplements in a safe area.
Formation of caries-resistant teeth	Increased susceptibility to tooth decay	***Deficiency***
Strong bone development	***Excess***	In areas with optimally fluoridated water, encourage sufficient intake to supply recommended amount of fluoride.
Sources	Fluorosis (mottling or pitting of enamel)	
Fluoridated water and foods or beverages prepared with fluoridated water, fish, tea	Severe bone deformities	

TABLE 46.2 Minerals and Their Nutritional Significance—cont'd

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care Management
		In areas of unfluoridated water or when ready-to-use formula, powder formula, bottled water, or breast milk is used, stress the importance of fluoride supplements (age appropriate). ***Excess*** In areas with excess fluoride in the water, consider the use of bottled water (without fluoride) in drinking and cooking to reduce the fluoride intake to safe levels.
Iodine‡ ***Functions*** Production of thyroid hormone Normal reproduction ***Sources*** Seafood, kelp, iodized salt, sea salt, enriched bread, milk (from dairy processing); medications, including amiodarone, povidone-iodine, and prenatal vitamins	***Deficiency*** Goitre (enlarged thyroid from decreased thyroxine formation) ***Excess*** Thyrotoxicosis; goitre; hypothyroidism	***Deficiency*** Encourage use of iodized salt for individuals living far from the sea. ***Excess*** If iodine preparations are in the home, stress the importance of safe storage.
Iron ***Functions*** Formation of hemoglobin and myoglobin Essential part of several enzymes and proteins ***Sources*** Liver, especially pork, followed by calf, beef, and chicken; kidney, red meat, poultry, shellfish, whole grains, iron-enriched infant formula and cereal, enriched cereals and bread, legumes, nuts, seeds, green leafy vegetables† (except spinach), dried fruits, potatoes, molasses, tofu, prune juice	***Deficiency*** Anemia (see Chapter 48) ***Excess*** Hemosiderosis (excess iron storage in various tissues of the body, especially the spleen, liver, lymph glands, heart, and pancreas) Hemochromatosis (excess iron storage with cellular damage)	***Deficiency*** Discourage excessive iron-fortified milk consumption, especially more than 1 L/day (cow's milk is a poor source of iron). If iron supplements are prescribed, teach parents factors that affect absorption. ***Excess*** Stress the importance of storing iron supplements in a safe area.
Magnesium* ***Functions*** Bone and tooth formation Production of proteins Nerve conduction to muscles Activation of enzymes needed for carbohydrate and protein metabolism ***Sources*** Whole grains, nuts, soybeans, meat, green leafy vegetables (uncooked), tea, cocoa, raisins	***Deficiency*** Tremors, spasm Irregular heartbeat Muscular weakness Lower extremity cramps Convulsions, delirium ***Excess*** Nervous system disturbances caused by imbalance in calcium/magnesium ratio	Deficiency and excess are unusual, except in disease states such as prolonged vomiting or diarrhea or kidney dysfunction, where replacement may be needed.
Phosphorus* ***Functions*** Bone and tooth development (in combination with calcium) Involved in numerous chemical reactions, including protein, carbohydrate, and fat metabolism Acid–base balance ***Sources*** Dairy products, eggs, meat, poultry, legumes, carbonated beverages	***Deficiency*** Weakness, anorexia, malaise, bone pain ***Excess*** Produces secondary calcium deficiency from imbalanced calcium/phosphorus ratio	***Deficiency*** Dietary deficiency is uncommon, although prolonged use of antacids can produce deficiency, in which case supplementation is recommended. To preserve calcium/phosphorus ratio in newborns and infants, discourage use of cow's milk.
Potassium* ***Functions*** Acid–base and fluid balance (major extracellular fluid areas)	***Deficiency*** Cardiac arrhythmias Muscular weakness	Dietary deficiency and excess are unlikely, although disease states such as prolonged nausea and vomiting or the use of certain diuretics can result in hypokalemia;

Continued

TABLE 46.2 Minerals and Their Nutritional Significance—cont'd

Physiological Functions and Sources	Results of Deficiency or Excess	Nursing Care Management
Nerve conduction Muscular contraction, especially the heart Release of energy ***Sources*** Bananas, citrus fruit, dried fruits, meat, fish, bran, legumes, peanut butter, potatoes, coffee, tea, cocoa	Lethargy Kidney and respiratory failure Heart failure ***Excess*** Cardiac arrhythmias Respiratory failure Mental confusion Numbness of extremities	in such instances encourage replacement with supplements of rich food sources such as bananas.
Selenium‡		
Functions Antioxidant, especially protective of vitamin E Protects against toxicity of heavy metals Associated with fat metabolism ***Sources*** Seafood, organs, egg yolk, whole grains, chicken, meat, tomatoes, cabbage, garlic, mushrooms, milk	***Deficiency*** Keshan disease (cardiomyopathy in children; found in China) ***Excess*** Eye, nose, and throat irritation Increased dental caries Liver and kidney degeneration	Deficiency and excess are uncommon in North America, although selenium deficiency can occur in patients receiving prolonged total parenteral alimentation; in these instances supplementation is required.
Sodium*		
Functions Acid–base and fluid balance (major extracellular fluid cation) Cell permeability; absorption of glucose Muscle contraction ***Sources*** Table salt, seafood, meat, poultry, numerous prepared foods	***Deficiency*** Dehydration Hypotension Convulsions Muscle cramps ***Excess*** Edema Hypertension Intracranial hemorrhage	***Deficiency*** Deficient intake is rare, although losses secondary to nausea, vomiting, excessive sweating, and use of diuretics can occur and require replacement. ***Excess*** Encourage parents to limit excessive use of salt in preparing foods and to limit commercial foods with high sodium content, such as smoked meats.
Zinc‡		
Functions Component of about 100 enzymes Synthesis of nucleic acids and protein in immune system and coagulation Release of vitamin A from liver Improved wound healing with vitamin C Normal taste sensitivity ***Sources*** Seafood (especially oysters), meat, poultry, eggs, wheat, legumes	***Deficiency*** Loss of appetite Diminished taste sensation Delayed healing Skin lesions—Erythematous, crusted lesions around body orifices (mouth, nares, anus) Alopecia Diarrhea Growth failure Delayed sexual maturity ***Excess*** Vomiting and diarrhea Malaise, dizziness Anemia, gastric bleeding Impaired absorption of calcium and copper	Emphasize correct use of zinc supplements and the possible interaction with other minerals. ***Deficiency*** Encourage food sources rich in zinc, especially protein. Caution that fibre, phytates, oxalates, tannins (in tea or coffee), iron, and calcium adversely affect zinc absorption. Recognize groups at risk for zinc deficiency, such as vegetarians and those whose diets may have restricted or low meat content and high fibre and phytate content; and patients with malabsorption syndromes.

Table is not intended to be all inclusive.
*Macrominerals—required intake >100 mg/day.
†Green leafy vegetables include spinach, broccoli, kale, turnip greens, mustard greens, collards, dandelion greens, and beet greens.
‡Microminerals or trace elements—required intake <100 mg/day.

and physical examination for signs of deficiency or excess (see Chapter 33, Performing a Nutritional Assessment). After assessment data are collected, this information is evaluated against standard intakes to identify areas of concern. Dietary Reference Intake (DRI) values are one source of standard nutrient intakes.

Standardized growth reference charts should be used for infants, children, and adolescents to compare and assess growth parameters such as height and head circumference with the percentile distribution of other children at the same ages. The World Health Organization (WHO) growth charts are a standardized growth reference recommended for use with infants and toddlers up to 24 months of age and children 2 to 19 years of age. These growth charts include head circumference, height/length, and weight references plus body mass index (BMI) calculations. The growth charts have been adopted and

developed into the *WHO Growth Charts for Canada* through collaboration between the Dietitians of Canada, CPS, College of Family Physicians of Canada, and Community Health Nurses of Canada (CPS, 2014).

Infants should be exclusively breastfed for the first 6 months; breastfeeding can continue for up to 2 years. They should be introduced to some solid foods after 6 months and receive foods high in iron for at least 18 months. Vitamin B_{12} supplementation is recommended if the breastfeeding person's intake of the vitamin is inadequate or if they are not taking vitamin supplements. A variety of foods should be introduced during the early years to ensure a well-balanced intake. Infants who are identified as having particular nutritional deficits should be treated; an interprofessional approach should be used to determine the deficit and the etiology, and a plan needs to be established with the caregiver to promote adequate growth and development.

Severe Acute Malnutrition

Malnutrition continues to be a major health challenge in the world today, particularly among children under 5 years of age. However, lack of food is not always the primary cause for malnutrition. In many developing and underdeveloped nations, diarrhea (gastroenteritis) is a major factor. Additional factors leading to malnutrition are bottle-feeding (in poor sanitary conditions), inadequate knowledge of proper child care practices, parental illiteracy, economic and political factors, climate conditions, cultural and religious food preferences, and food insecurity (see Chapter 30). Poverty is an important determinant of health and an underlying contributing cause of malnutrition due to inadequate resources.

Children with severe acute malnutrition (SAM) have had a diet insufficient in energy and nutrients relative to their needs. The magnitude of the deficits will differ depending on the duration of inadequacy, quantity and diversity of food consumed, presence of antinutrients (e.g., phytate), individual variation in requirements, and number and severity of coexisting infections and their duration. SAM may also be seen in persons with chronic health conditions, such as cystic fibrosis, renal dialysis, chronic diarrhea syndromes, burns, inborn errors of metabolism, and GI malabsorption.

SAM may be subdivided into edematous (kwashiorkor), severe wasting (marasmus) types, or marasmic kwashiorkor, which has features of both marasmus and kwashiorkor (Ashworth, 2020).

Kwashiorkor is a deficiency of high-quality protein along with an adequate supply of carbohydrate calories. A diet consisting mainly of starch grains or tubers provides adequate calories in the form of carbohydrates but an inadequate amount of high-quality proteins. However, some evidence supports a multifactorial etiology, including cultural, psychological, and infective factors that may interact to place the child at risk for kwashiorkor. Kwashiorkor may result from the interplay of nutrient deprivation and infectious or environmental stresses, which produces an imbalanced response to such insults (Trehan & Manary, 2015). Kwashiorkor often occurs subsequent to an infectious outbreak of measles and dysentery. The child with kwashiorkor has thin, wasted extremities and a prominent abdomen from edema (ascites). The edema often masks severe muscular atrophy, making the child appear less debilitated than they actually are. These children are at high risk of a fatal deterioration due to diarrhea, infection, or circulatory failure.

Marasmus is caused by a general malnutrition of protein and calories. It commonly occurs in underdeveloped countries during times of drought, especially in cultures where adults eat first; the remaining food is often insufficient in quality and quantity for the children. Marasmus is characterized by gradual wasting and atrophy of body tissues, especially of subcutaneous fat. The child appears to be very old, with loose and wrinkled skin, unlike the child with kwashiorkor, who appears more rounded from the edema. Fat metabolism is less impaired than in kwashiorkor; thus deficiency of fat-soluble vitamins is usually minimal or absent. The child with marasmus is fretful, apathetic, withdrawn, and so lethargic that prostration frequently occurs. Intercurrent infection with debilitating diseases such as tuberculosis, parasitosis, HIV, and dysentery is common.

Treatment of SAM includes a high-quality level of proteins, carbohydrates, vitamins, and minerals. When SAM occurs as a result of persistent diarrhea, three management goals are identified:

1. Rehydration with an oral rehydration solution that also replaces electrolytes
2. Administration of antibiotics to prevent intercurrent infections
3. Provision of adequate (energy intake) nutrition by either breastfeeding or a proper weaning diet

Food Sensitivity

Food sensitivity is a general term that includes any type of adverse reaction to food or food additives. Food sensitivities can be divided into two broad categories:

1. **Food allergy or hypersensitivity**, which refers to reactions involving immunological mechanisms, usually immune globulin E (IgE); the reactions may be immediate or delayed and mild or severe, such as an anaphylactic reaction. *Food allergens* are defined as specific components of food or ingredients in food, such as a protein, that are recognized by allergen-specific immune cells eliciting an immune reaction that results in the characteristic symptoms (Boyce et al., 2011).
2. **Food intolerance**, which refers to when a food or food component elicits a reproducible adverse reaction but does not have an established or likely immunological mechanism (Boyce et al., 2011). For example, a person may have an immune-mediated allergy to cow's milk protein, but the person who is unable to digest the lactose in cow's milk is considered to be intolerant, not allergic to it.

The US National Institute of Allergy and Infectious Diseases guidelines classify food allergy according to the following: food-induced anaphylaxis, GI food allergies, and specific syndromes; cutaneous reactions to foods; respiratory manifestation; and Heiner syndrome (Boyce et al., 2011). The exact prevalence of food allergies in children is reported to be much lower than that which parents report. Approximately 6% of children may experience food allergic reactions in the first 2 to 3 years of life; 2% will have an allergy to eggs, 2.5% to cow's milk, and 2 to 3% to peanuts (Nowak-Wegrzyn et al., 2020).

The clinical manifestations of food hypersensitivity may be divided as follows:

Systemic—Anaphylactic, growth failure
Gastrointestinal—Abdominal pain, vomiting, cramping, diarrhea
Respiratory—Cough, wheezing, rhinitis, infiltrates
Cutaneous—Urticaria, rash, atopic dermatitis

Food hypersensitivities usually occur either as an IgE-mediated or non–IgE-mediated immune response; some toxic reactions may occur as a result of a **toxin** found within the food. Food allergy is caused by exposure to allergens, usually proteins (but not the smaller amino acids) that are capable of inducing IgE antibody formation (sensitization) when ingested. *Sensitization* refers to the initial exposure of an individual to an allergen, resulting in an immune response; subsequent exposure induces a much stronger response that is clinically apparent. Consequently, food hypersensitivity typically occurs after the food has been ingested one or more times. The National Institute of Allergies and Infectious Disease states that sensitization alone is not sufficient to classify as a food allergy, but it is an immune-mediated response and manifestation of specific signs and symptoms that are necessary to categorize an individual as having a food allergy (Boyce et al., 2011). The most common food allergens are listed in Box 46.2.

BOX 46.2 Hyperallergenic Foods and Food Sources

Milk*—Ice cream, butter, margarine (if it contains dairy products), yogurt, cheese, pudding, baked goods, wieners, bologna, canned creamed soups, instant breakfast drinks, powdered milk drinks, milk chocolate

Eggs*—Mayonnaise, creamy salad dressing, baked goods, egg noodles, some cake icing, meringue, custard, pancakes, French toast, root beer

Wheat*—Almost all baked goods, wieners, bologna, pressed or chopped cold cuts, gravy, pasta, some canned soups

Legumes—Peanuts,* peanut butter or oil, beans, peas, lentils

Nuts*—Some chocolates, candy, baked goods, cherry beverages (may be flavoured with a nut extract), walnut oil

Fish or shellfish*—Cod liver oil, pizza with anchovies, Caesar salad dressing, any food fried in same oil as fish

Soy*—Soy sauce, teriyaki or Worcestershire sauce, tofu, baked goods using soy flour or oil, soy nuts, soy infant formulas or milk, soybean paste, tuna packed in vegetable oil, many margarines

Chocolate—Cola beverages, cocoa, chocolate-flavoured drinks

Buckwheat—Some cereals, pancakes

Pork, chicken—Bacon, wieners, sausage, pork fat, chicken broth

Strawberries, melon, pineapple—Gelatin, syrups

Corn—Popcorn, cereal, muffins, cornstarch, corn meal, corn bread, corn tortilla

Citrus fruits—Orange, lemon, lime, grapefruit; any of these in drinks, gelatin, juice, or medicines

Tomatoes—Juice, some vegetable soups, spaghetti, pizza sauce, ketchup

Spices—Chili, pepper, vinegar, cinnamon

*Most common allergens.

Oral allergy syndrome occurs when a food allergen (commonly fruits and vegetables) is ingested and there is subsequent edema and pruritus involving the lips, tongue, palate, and throat. Recovery from symptoms is usually rapid. *Immediate GI hypersensitivity* is an IgE-mediated reaction to a food allergen; reactions include nausea, abdominal pain, cramping, diarrhea, vomiting, anaphylaxis, or all of these. Additional food allergies seen in young children include allergic eosinophilic esophagitis, allergic eosinophilic gastroenteritis, food protein–induced proctocolitis, and food protein–induced enterocolitis.

Food allergy or hypersensitivity may also be classified according to the interval between ingestion and the manifestation of symptoms: immediate (within minutes to hours) or delayed (2 to 48 hours) (American Academy of Pediatrics [AAP], 2014).

Food allergies can occur at any time but are common during infancy because the immature intestinal tract is more permeable to proteins than the mature intestinal tract, thus increasing the likelihood of an immune response. Allergies in general demonstrate a genetic component: children who have one parent with an allergy have a 50% or greater risk of developing an allergy. Children who have two parents with an allergy have up to a 100% risk of developing an allergy. Allergies with a hereditary tendency are referred to as *atopy*. Some infants with atopy can be identified at birth from elevated levels of IgE in cord blood. Breastfeeding has been shown to decrease the risk for developing atopy.

Deaths have been reported in children who suffered an anaphylactic reaction to food, as onset of the reaction occurs shortly after ingestion (5 to 30 minutes). In most of the children the reactions did not begin with skin signs, such as hives, red rash, and flushing, but rather mimicked an acute asthma attack (wheezing, decreased air movement in airways, dyspnea). Children with food anaphylaxis should be watched closely, because a biphasic response has been recorded in a number of cases in which there is an immediate response, apparent recovery, and then acute recurrence of symptoms or symptoms, which may not appear for several hours after exposure (Alqurashi et al., 2015). Children with extremely sensitive food allergies should wear a medical alert identification bracelet and have an injectable epinephrine cartridge (EpiPen) readily available (see Anaphylaxis, Chapter 47). Any child with a history of food allergy or previous severe reaction to food should have a written emergency treatment plan and an EpiPen (see Emergency box: Emergency Management of Anaphylaxis). Note that diphenhydramine and cetirizine are effective for cutaneous and nasal manifestations but not for airway manifestations (Cheng & CPS, Acute Care Committee, 2011/2018).

EMERGENCY

Emergency Management of Anaphylaxis

Medication—Epinephrine 0.01 mg/kg up to maximum of 0.5 mg

Dose—EpiPen Jr. (0.15 mg) intramuscularly (IM) for child weighing 10 to 25 kg; EpiPen (0.3 mg) IM for child weighing 25 kg or more

For children weighing less than 10 kg, care providers and families will need to judge the benefits and risks of administering epinephrine via syringes after being drawn up by a competent family member. The risks have proven to be an error in the dosage and delay in administration.

Monitor—for adverse reactions, such as tachycardia, hypertension, irritability, headaches, nausea, and tremors

Data from Cheng, A., & Canadian Paediatric Society, Acute Care Committee. (2011). *Emergency treatment of anaphylaxis in infants and children.* Reaffirmed 2018. http://www.cps.ca/documents/position/emergency-treatment-anaphylaxis.

NURSING ALERT

The Canadian Paediatric Society (CPS) suggests that indications for the administration of intramuscular epinephrine in a child with a life-threatening anaphylactic reaction or one who is experiencing severe symptoms include any one of the following: itching sensation or tightness in throat, hoarseness, "barky" cough, difficulty swallowing, dyspnea, wheezing, cyanosis, respiratory or cardiac arrest, mild dysrhythmia or mild hypotension, severe bradycardia, hypotension, or loss of consciousness (Cheng & CPS, Acute Care Committee, 2011/2018).

Although the reason is unknown, many children "outgrow" their food allergies, especially to milk and eggs. Approximately 50% of all infants who are intolerant to cow's milk usually develop tolerance by 3 to 5 years of age (Nowak-Wegrzyn et al., 2020). More than half (60%) of infants have an IgE-mediated reaction to cow's milk, and 25% retain sensitivity until the second decade of life. Children who are allergic to more than one food may develop tolerance to each food at a different time. The most common allergens, such as peanuts, are outgrown less readily than other food allergens. Because of the tendency to lose the hypersensitivity, allergenic foods should be reintroduced into the diet after a period of abstinence (usually $\geq$1 year) to evaluate whether the food can safely be added to the diet. However, foods that are associated with severe anaphylactic reactions continue to present a lifelong risk and must be avoided.

The CPS does not recommend avoiding milk, eggs, peanuts, or other foods while a person is pregnant or breastfeeding. There is also no evidence to support the theory that avoiding certain foods during this time will prevent allergies in children (Abrams et al., 2019/2020). Infants who are at high risk (defined as infants with a first-degree relative with an allergic condition) of developing a food allergy can be exposed to potential food allergens as early as 4 to 6 months of age. Delaying dietary exposure to potential allergens like peanuts, fish, or eggs will not reduce a child's risk of developing a food allergy. Once a new food is introduced, it is important to continue to offer it regularly to maintain a child's tolerance (Abrams et al., 2019/2020). Parents should be advised to discuss infant feeding practices with the primary care provider and obtain adequate information to make an informed decision if there is a family history of atopy. The strategies listed in the Guidelines box: Early Introduction of Common Allergenic Foods to High-Risk Infants are those recommended by most authorities for infants with a family history of atopy or first-degree relative with atopy.

GUIDELINES

Early Introduction of Common Allergenic Foods to High-Risk Infants

- For high-risk infants, and based on developmental readiness, consider introducing common allergenic solids at around 6 months of age, but not before an infant is 4 months of age.
- Breastfeeding should be protected, promoted, and supported for up to 2 years and beyond.
- Allergenic foods should be introduced one at a time, to gauge reaction, without unnecessary delay between each new food.
- If an infant appears to be tolerating a common allergenic food, advise parents to offer it a few times a week to maintain tolerance. If an adverse reaction is observed, advise parents to consult with a primary care provider about next steps.
- The texture or size of any complementary food should be age-appropriate to prevent choking.

Source: Abrams, E. A., Hildebrand, K., Blair, B., Chan, E. S., & Canadian Paediatric Society, Allergy Section. (2019). *Timing of introduction of allergenic solids for infants at high risk.* Updated 2020. https://www.cps.ca/en/documents/position/allergenic-solids.

Nursing Care. Nursing care of children with potential food allergy consists of assisting in collecting vital health assessment data for the establishment of a diagnosis and assisting with diagnostic tests. It is important for nurses to be informed about food allergy and to provide parents, caregivers, and older children with accurate information regarding food allergy.

Parents, teachers, and day care workers should be educated about signs and symptoms of food hypersensitivity reactions. Children with a history of food allergy may spend a considerable amount of time in day care; therefore people working in day care centres and other children's settings need to be educated properly regarding recognition and management of severe anaphylactic reactions (see Clinical Reasoning Case Study: Food Allergy Anaphylaxis). People with food sensitivity should avoid eating unfamiliar foods and avoid restaurants that do not disclose food ingredients. New labelling guidelines require that food additives such as spices and flavouring be clearly labelled on commercially sold, store-bought foods. Hidden ingredients in prepared foods have been implicated as a potential source of food hypersensitivity.

CLINICAL REASONING CASE STUDY

Food Allergy Anaphylaxis

A group of nursing students is holding a health promotion fair at a local elementary school for first-, second-, and third-graders. The nursing students have several booths set up in the school cafeteria. Three second-grade boys are horseplaying in front of one of the booths when one of the boys, Jason, an 8-year-old child, suddenly starts coughing and clutching his throat. The students also observe that he is developing red splotches on his face, neck, and throat and that he is scratching. Jason says, "I can't breathe!" A teacher is nearby and comes over to see what's causing the commotion. One of the boys with Jason says, "We didn't mean any harm; we were just goofing around when we put peanuts in his trail mix." One of the student nurses says, "He's in obvious distress. What should we do?"

1. Evidence—Is there sufficient evidence to draw any conclusions at this time about Jason's condition?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Clinical manifestations of food allergy
   b. The emergency treatment of a food allergy "reaction," or anaphylaxis
   c. Which one of the following interventions would have highest immediate priority and give the rationale?
      (1) Call Jason's parents and ask them to come pick him up from school.
      (2) Call Jason's family practitioner to obtain orders for medication.
      (3) Promptly administer an intramuscular dose of epinephrine.
      (4) Call 911 and wait for the emergency response personnel to arrive.
3. What implication for nursing care exists in this situation after an intervention in the previous question has been chosen and implemented?
4. Describe the potential results of taking a "Let's observe Jason for a few minutes before we do anything" stance in this scenario.

Cow's Milk Allergy. Cow's milk allergy (CMA) is a multifaceted disorder representing adverse systemic and local GI reactions to cow's milk protein. Approximately 2.5% of infants develop cow's milk hypersensitivity, with 60% of these being IgE mediated (Nowak-Węgrzyn et al., 2020). It is estimated that 50% of these children may outgrow the hypersensitivity by 3 to 5 years of age (Nowak-Wegrzyn et al., 2020). Some studies suggest that milk allergy may persist and some children may not be able to tolerate milk until they are 16 years of age (AAP, 2014). (The following discussion is centred on cow's milk protein found in commercial infant formulas; whole milk is not recommended for infants younger than the age of 12 months.) The allergy may be manifested within the first 4 months of life through a variety of signs and symptoms that may appear within 45 minutes of milk ingestion or after a period of several days (Box 46.3).

The diagnosis may initially be made from the history, although the history alone is not diagnostic; the timing and diversity of clinical manifestations vary greatly. For example, CMA may be manifested as colic (see Chapter 36), diarrhea, vomiting, GI bleeding, gastroesophageal reflux (GER), chronic constipation, or sleeplessness in an otherwise healthy infant.

Diagnostic evaluation. A number of diagnostic tests may be performed, including stool analysis for blood, eosinophils, and leukocytes (both frank and occult bleeding can occur from the colitis); serum IgE levels; skin-prick or scratch testing; and radioallergosorbent test (RAST) (measures IgE antibodies to specific allergens in serum by radioimmunoassay). Both skin testing and RAST may help identify the offending food, but the results are not always conclusive. No single diagnostic test is considered definitive for the diagnosis (AAP, 2014).

BOX 46.3 Common Clinical Manifestations of Cow's Milk Sensitivity

Gastrointestinal
Diarrhea
Vomiting
Colic
Abdominal pain

Respiratory
Rhinitis
Bronchitis
Asthma
Wheezing
Sneezing
Coughing
Chronic nasal discharge

Other Signs and Symptoms
Eczema
Excessive crying
Pallor (from anemia secondary to chronic blood loss in gastrointestinal tract)

The most definitive diagnostic strategy is elimination of milk in the diet, followed by challenge testing after improvement of symptoms. A clinical diagnosis is made when symptoms improve after removal of milk from the diet and two or more challenge tests produce symptoms (Nowak-Wegrzyn et al., 2020). If a parent is breastfeeding they need to eliminate cow's milk from their diet during the testing. Challenge testing involves reintroducing small quantities of milk in the diet to detect resurgence of symptoms; at times it involves the use of a placebo so that the parent is unaware of (or "blind" to) the timing of allergen ingestion. A double-blind, placebo-controlled food challenge is the gold standard for diagnosing food allergies such as CMA, yet it may not be used very often for diagnosing CMA because of the expense, time involved, and risk for further exposure and anaphylactic reaction (Dupont, 2014). Careful observation of the child is required during a challenge test because of the possibility of anaphylactic reaction.

Therapeutic management. Treatment of CMA comprises elimination of cow's milk–based formula and all other dairy products. For infants fed cow's milk formula, this primarily involves changing the formula to a casein hydrolysate milk formula or extensively hydrolyzed formula (Nutramigen or Alimentum), in which the protein has been broken down into its amino acids through enzymatic hydrolysis. Approximately 50% of infants who are sensitive to cow's milk protein will also demonstrate a sensitivity to soy. The CPS advises that soy, rice, and other plant-based beverages, whether or not they are fortified, are inappropriate feeding alternatives for children under 2 years of age (Critch & CPS, 2104/2020).

Other choices for children who are intolerant to cow's milk–based formula are the amino acid–based formulas Neocate or EleCare, but their cost is a major consideration and they are not available in all provinces. Goat milk formula may be an alternative as it has been shown that growth and nutritional outcomes in infants that did not differ from those provided by a standard whey-based cow milk formula (Zhou et al., 2014). Infants are maintained on the milk-free diet until after 1 year of age, after which time small quantities of milk can be reintroduced.

Nursing care. Nurses have an important role in identifying potential CMA and providing appropriate counselling to parents on the signs and symptoms of CMA and the use of substitute formulas. Parents often interpret GI symptoms such as spitting up and loose stools or fussiness as indications that the infant is allergic to cow's milk and switch the infant to a variety of formulas in an attempt to resolve the issue.

Parents need much reassurance regarding the needs of nonverbal infants with such an array of symptoms. Endless nights of lost sleep and a crying infant may promote feelings of parenting inadequacy and role conflict, thus aggravating the situation. Nurses can reassure parents that many of these symptoms are common and the reasons are often never found, yet the child does achieve appropriate growth and development. Acute symptoms need to be reported to the health care provider for further evaluation. Parents need reassurance that the infant will receive complete nutrition from the new formula and will have no ill effects from the absence of cow's milk.

When solid foods are started, parents need guidance in avoiding feeding their child milk products. Carefully reading all food labels helps prevent the child's exposure to prepared foods containing milk products. Although labelled as nondairy, milk, cream, and butter substitutes may contain cow's milk protein.

DISTRIBUTION OF BODY FLUIDS

The distribution of body fluids, or total body water (TBW), involves the presence of intracellular fluid (ICF) and extracellular fluid (ECF). Water is the major constituent of body tissues, and the TBW in an individual ranges from 75% (in term newborns) to 45% (in late adolescence) of total body weight.

The *ICF* refers to the fluid contained within the cells, whereas the *ECF* is the fluid outside the cells. The ECF is further broken down into several components: intravascular (contained within the blood vessels), interstitial (surrounding the cell; the location of most ECF), and transcellular (contained within specialized body cavities, such as cerebrospinal, synovial, and pleural fluid). In the newborn, about 50% of the body fluid is contained within the ECF, whereas 30% of a toddler's body fluid is contained within the ECF.

Under normal conditions, the amount of water ingested closely approximates the amount of urine excreted in a 24-hour period. *Maintenance water requirement* is the volume of water needed to replace obligatory fluid loss, such as that from insensible water loss (IWL) through the skin and respiratory tract, evaporative water loss, and losses through urine and stool formation. The amount and type of these losses may be altered by disease states such as fever (with increased sweating), diarrhea, gastric suction, and pooling of body fluids in a body space (often referred to as *third spacing*).

Nurses should be alert for altered fluid requirements in various conditions:

Increased requirements:
- Fever (add 12% per rise of 1°C)
- Vomiting, diarrhea
- High-output kidney failure
- Diabetes insipidus
- Diabetic ketoacidosis
- Burns
- Shock
- Tachypnea
- Radiant warmer (preterm newborn)
- Phototherapy (newborns)
- Postoperative bowel surgery (e.g., gastroschisis)

BOX 46.4 Daily Maintenance Fluid Requirements

Formula Method

(100 mL for each of the first 10 kg) + (50 mL for each kg 11–20) + (20 mL for each additional kg)/24 hour

4 / 2 / 1 Method

(4 mL/kg for the first 10 kg) + (2 mL/kg for kg 11–20) + (1 mL/kg for every kg above 20) = hourly rate

Source: SickKids. (2020). *Calculating maintenance fluid rates.* http://www.sickkids.ca/Nursing/Education-and-learning/Nursing-Student-Orientation/module-two-clinical-care/paediatric-iv-therapy/Calculating-Maintenance-Fluid-Rates/index.html.

Decreased requirements:

- Heart failure
- Syndrome of inappropriate antidiuretic hormone (SIADH)
- Mechanical ventilation
- After surgery
- Oliguric renal failure
- Increased intracranial pressure

Basal maintenance calculations for required body water are based on the body's requirements for water in a normometabolic state at rest; estimated fluid requirements are then increased or decreased from these parameters based on increased or decreased water losses, such as with elevated body temperature (increased) or heart failure (decreased). Daily maintenance fluid requirements for infants, toddlers, and older children are listed in Box 46.4.

Maintenance fluids contain both water and electrolytes and can be estimated from the child's age, body weight, degree of activity, and body temperature. Basal metabolic rate (BMR) is derived from standard tables and adjusted for the child's activity, temperature, and disease state. For example, for afebrile patients at rest, the maintenance water requirement is approximately 100 mL for each 100 kcal expended. Children with fluid losses or other alterations require adjustment of these basic needs to accommodate abnormal losses of both water and electrolytes as a result of a disease state. For example, insensible losses increase when basal expenditure increases by fever or hypermetabolic states. Hypometabolic states, such as hypothyroidism and hypothermia, decrease the BMR.

The percentage of TBW varies among individuals and in adults and older children; it is related primarily to the amount of body fat. Consequently, females, who have more body fat than males, and people with obesity tend to have less water content in relation to weight.

GASTROINESTINAL DYSFUNCTION

The extensive surface area of the GI tract and its digestive function represent the major means of exchange between the human organism and the environment. Disorders that impair the functional integrity of the GI system have the potential to cause serious alterations in fluid and electrolyte balance. Disorders that involve GI losses of large amounts of fluid, absorption disorders, inflammatory disorders, and decreased or excessive water intake have the potential to cause fluid and electrolyte imbalance in infants and children. Numerous clinical observations provide clues to specific GI conditions (Box 46.5). In any disorder that involves GI losses of large amounts of fluid, dehydration poses a serious threat to life and demands immediate attention.

Dehydration

Dehydration is a common body fluid disturbance in infants and children and occurs whenever the total output of fluid exceeds the total intake, regardless of the cause. Dehydration may result from a number of diseases that cause insensible losses through the skin and respiratory tract, through increased renal excretion, and through the GI tract. Although dehydration can result from lack of oral intake (especially

BOX 46.5 Clinical Manifestations of Gastrointestinal Dysfunction in Children

Growth failure—Weight consistently below the third percentile, body mass index below the fifth percentile, or a decrease from established growth pattern

Spitting up or regurgitation—Passive transfer of gastric contents into the esophagus or mouth

Vomiting—Forceful ejection of gastric contents; involves a complex process under central nervous system control that causes salivation, pallor, sweating, and tachycardia; usually accompanied by nausea

Projectile vomiting—Vomiting accompanied by vigorous peristaltic waves and typically associated with pyloric stenosis or pylorospasm

Nausea—Unpleasant sensation vaguely referred to the throat or abdomen with an inclination to vomit

Constipation—Delay or difficulty with the passage of stools that is present for 2 weeks or longer; associated with symptoms that may include blood-streaked stools and abdominal discomfort

Encopresis—Involuntary overflow of incontinent stool causing soiling or incontinence secondary to fecal retention or impaction

Diarrhea—Increase in the number of stools with increased water content as a result of alterations of water and electrolyte transport by the gastrointestinal (GI) tract; may be acute or chronic

Hypoactive, hyperactive, or absent bowel sounds—Evidence of intestinal motility issues that may be caused by inflammation or obstruction

Abdominal distension—Protuberant contour of the abdomen that may be caused by delayed gastric emptying, accumulation of gas or stool, inflammation, or obstructions

Abdominal pain—Pain associated with the abdomen that may be localized or diffuse, acute or chronic; often caused by inflammation, obstruction, or hemorrhage

Gastrointestinal bleeding—May be from an upper or lower GI source and may be acute or chronic

Hematemesis—Vomiting of bright red or denatured blood that results from bleeding in the upper GI tract or from swallowed blood from the nose or oropharynx

Hematochezia—Passage of bright red blood per rectum, usually indicating lower GI tract bleeding

Melena—Passage of dark-coloured, "tarry" stools resulting from denatured blood, suggesting upper GI tract bleeding or bleeding from the right colon

Jaundice—Yellow discoloration of the skin and sclerae associated with liver dysfunction in infants and in children over 4 weeks of age

Dysphagia—Difficulty swallowing caused by abnormalities in the neuromuscular function of the pharynx or upper esophageal sphincter or by disorders of the esophagus

Dysfunctional swallowing—Impaired swallowing caused by central nervous system defects or structural defects of the oral cavity, pharynx, or esophagus; can cause feeding difficulties or aspiration

Fever—Common manifestation of illness in children with GI disorders; usually associated with dehydration, infection, or inflammation

in elevated environmental temperatures), more often it is a result of abnormal losses, such as those that occur in vomiting or diarrhea, when oral intake only partially compensates for the abnormal losses. Other significant causes of dehydration are diabetic ketoacidosis and extensive burns.

Types of Dehydration. Sodium is the chief solute in ECF and the primary determinant of ECF volume. It is considered a unique electrolyte in that water balance determines sodium concentration; when water is lost and sodium concentration becomes elevated, compensatory mechanisms in the kidney stop antidiuretic hormone (ADH) secretion, so water is retained. The thirst mechanism (not fully functioning in infants) is also stimulated, so water is replaced, thus increasing the total body water content and returning sodium to a normal level (Greenbaum, 2020). Potassium is primarily inside the cell (intracellular), but small amounts are found in the ECF. When ECF volume is reduced in acute dehydration, the total body sodium content is almost always reduced as well, regardless of serum sodium measurements. Replacement of fluid volume should therefore be accompanied by sodium replacement as well. Sodium depletion in diarrhea occurs in two ways: out of the body in stool, and into the ICF compartment to replace potassium to maintain electrical equilibrium.

Dehydration is classified into three categories on the basis of osmolality and depends primarily on the serum sodium concentration: (1) isotonic, (2) hypotonic, and (3) hypertonic.

Isotonic (*isosmotic* or **isonatremic**) **dehydration**, the primary form of dehydration in children, occurs in conditions in which electrolyte and water deficits are present in approximately balanced proportions. Water and sodium are lost in approximately equal amounts. The observable fluid losses are not necessarily isotonic, since losses from other avenues make adjustments so that the sum of all losses, or the net loss, is isotonic. There is no osmotic force between the ICF and the ECF; thus the major loss is sustained from the ECF compartment. This significantly reduces the plasma volume and the circulating blood volume, which affects the skin, muscles, and kidneys. Shock is the greatest threat to life; the child with isotonic dehydration displays symptoms characteristic of hypovolemic shock. Plasma sodium remains within normal limits, between 130 and 150 mmol/L.

Hypotonic (*hyposmotic* or **hyponatremic**) **dehydration** occurs when the electrolyte deficit exceeds the water deficit, leaving the serum hypotonic. Because ICF is more concentrated than ECF in hypotonic dehydration, water moves from the ECF to the ICF to establish osmotic equilibrium. This movement further increases the ECF volume loss, and shock is a frequent finding. Because there is a greater proportional loss of ECF in hypotonic dehydration, the physical signs tend to be more severe with smaller fluid losses than with isotonic or hypertonic dehydration. Serum sodium concentration is less than 130 mmol/L.

Hypertonic (*hyperosmotic* or **hypernatremic**) **dehydration** results from water loss in excess of electrolyte loss and is usually caused by a proportionately larger loss of water or a larger intake of electrolytes. This type of dehydration is the most dangerous and requires more specific fluid therapy. Hypertonic diarrhea may occur in infants who are given fluids by mouth that contain large amounts of solute or in children who receive high-protein nasogastric (NG) tube feedings that place an excessive solute load on the kidneys. In hypertonic dehydration, fluid shifts from the lesser concentration of the ICF to the ECF. Plasma sodium concentration is greater than 150 mmol/L.

Because the ECF volume is proportionately larger, hypertonic dehydration consists of a greater degree of water loss for the same intensity of physical signs. However, central nervous system (CNS) disturbances, such as seizures, are more likely to occur. Cerebral changes are serious and may result in permanent damage. These include disturbances of consciousness, poor ability to focus attention, lethargy, increased muscle tone with hyperreflexia, and hyperirritability to stimuli (tactile, auditory, bright lights).

Degree of dehydration. Diagnosis of the type and degree of dehydration is necessary to develop an effective plan of therapy. The degree of dehydration has been described as a percentage of body weight dehydrated: mild—less than 3% in older children or less than 5% in infants; moderate—5 to 10% in infants and 3 to 6% in older children; and severe—more than 10% in infants and more than 6% in older children (Greenbaum, 2020). Water constitutes only 60 to 70% of the infant's weight. However, adipose tissue contains little water and is highly variable in individual infants and children. A more accurate means of describing dehydration is to reflect acute loss (over a period of 48 hours or less) in millilitres per kilogram of body weight. For example, a loss of 50 mL/kg is considered to be a mild fluid loss, whereas a loss of 100 mL/kg produces severe dehydration.

A detailed history is the first step when assessing for dehydration. Parent reports of fluid intake, urine output, diarrhea, and emesis can aid in the identification of dehydration. In addition, parents are asked about tears; a child who is able to produce tears is less likely to have moderate or severe dehydration (Churgay & Aftab, 2012a). Clinical signs provide clues to the extent of dehydration (Table 46.3). Weight is the most important determinant of the percent of total body fluid loss in infants and younger children. Other predictors of fluid loss include a changing level of consciousness (irritability to lethargy), altered response to stimuli, decreased skin elasticity and turgor, prolonged capillary refill (greater than 2 seconds), increased heart rate, and sunken eyes and fontanels. The earliest detectable sign is usually tachycardia followed by dry skin and mucous membranes, sunken fontanels, signs of circulatory failure (coolness and mottling of extremities), loss of skin elasticity, and prolonged capillary filling time (Table 46.4).

Compensatory mechanisms try to maintain fluid equilibrium by adjusting to the losses. Interstitial fluid moves into the vascular compartment to maintain the blood volume in response to hemoconcentration and hypovolemia, and vasoconstriction of peripheral arterioles helps to maintain pumping pressure. When fluid losses exceed the ability of the body to sustain blood volume and blood pressure, circulation is seriously compromised and the blood pressure falls. This results in tissue hypoxia with accumulation of lactic acid, pyruvate, and other acid metabolites, which contribute to development of metabolic acidosis.

Renal compensation is impaired by decreased blood flow through the kidneys and little urine is formed. Increased serum osmolality simulates ADH to conserve fluid and initiates the renin–angiotensin mechanisms in the kidneys, leading to further vasoconstriction. Aldosterone is released to promote sodium retention and conserve water in the kidneys. If dehydration increases in severity, urine formation is greatly diminished and metabolites and hydrogen ions that are normally excreted by this route are retained.

Shock, a common manifestation of severe depletion of ECF volume, is preceded by tachycardia and signs of poor perfusion and tissue oxygenation (by pulse oximeter readings). Peripheral circulation is poor as a result of reduced blood volume; therefore, the skin is cool and mottled, with decreased capillary filling after blanching. Impaired kidney circulation often results in oliguria and azotemia. Although low blood pressure may accompany other symptoms of shock, in infants and young children it is usually a late sign of shock and could be signalling the onset of cardiovascular collapse (see Shock, Chapter 47).

Diagnostic Evaluation. In the examination of an infant or younger child, one of the most important determinants of the extent of dehydration is body weight because this can help to determine the percentage of

TABLE 46.3 Evaluating the Extent of Dehydration

	LEVEL OF DEHYDRATION		
Clinical Signs	**Mild**	**Moderate**	**Severe**
Weight loss—infants	3–5%	6–9%	≥10%
Weight loss—children	3–4%	6–8%	10%
Pulse	Normal	Slightly increased	Very increased
Respiratory rate	Normal	Slight tachypnea (rapid)	Hyperpnea (deep and rapid)
Blood pressure	Normal	Normal to orthostatic (more than 10 mm Hg change)	Orthostatic to shock
Behaviour	Normal	Irritable, more thirsty	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes*	Normal	Dry	Parched
Tears	Present	Decreased	Absent, sunken eyes
Anterior fontanel	Normal	Normal to sunken	Sunken
External jugular vein	Visible when supine	Not visible except with supraclavicular pressure	Not visible even with supraclavicular pressure
Skin*	Capillary refill less than 2 sec	Slowed capillary refill (2–4 sec [decreased turgor])	Very delayed capillary refill (more than 4 sec) and tenting; skin cool, acrocyanotic or mottled
Urine specific gravity	>1.020	>1.020; oliguria	Oliguria or anuria

*These signs are less prominent in patients with hypernatremia.

Data from Jospe, N., & Forbes, G. (1996). Fluids and electrolytes—clinical aspects. *Pediatrics in Review, 17*(11), 395–403; and Steiner, M. J., DeWalt, D. A., & Byerley, J. S. (2004). Is this child dehydrated? *Journal of the American Medical Association, 291*(22), 2746–2754.

TABLE 46.4 Clinical Manifestations of Dehydration

Manifestation	**Isotonic (Loss of Water and Sodium)**	**Hypotonic (Loss of Sodium in Excess of Water)**	**Hypertonic (Loss of Water in Excess of Sodium)**
Skin			
Colour	Grey	Grey	Grey
Temperature	Cold	Cold	Cold or hot
Turgor	Poor	Very poor	Fair
Feel	Dry	Clammy	Thickened, doughy
Mucous membranes	Dry	Slightly moist	Parched
Tearing and salivation	Absent	Absent	Absent
Eyeball	Sunken	Sunken	Sunken
Fontanel	Sunken	Sunken	Sunken
Body temperature	Subnormal or elevated	Subnormal or elevated	Subnormal or elevated
Pulse	Rapid	Very rapid	Moderately rapid
Respirations	Rapid	Rapid	Rapid
Behaviour	Irritable to lethargic	Lethargic or comatose; seizures	Marked lethargy with extreme hyperirritability on stimulation

total body fluid lost; however, because the pre-illness weight is often unknown, clinical manifestations must be evaluated. Clinical signs of abnormal capillary refill, abnormal skin turgor, and abnormal respiratory pattern are the most useful signs in predicting dehydration in children (Churgay & Aftab, 2012a). Objective signs of dehydration are present at a fluid deficit of less than 5%.

Laboratory data are useful only when results are significantly abnormal. Urine specific gravity and blood urea nitrogen (BUN) measurements are unreliable assessments for determining dehydration in children (Churgay & Aftab, 2012a). However, a serum bicarbonate level greater than 17 mEq/L reduces the chances of dehydration, whereas a bicarbonate level less than 13 mEq/L increases the chance of dehydration requiring intravenous (IV) intervention (Churgay & Aftab, 2012a). Shock, tachycardia, and very low blood pressure are common features of severe depletion of ECF volume (see Shock, Chapter 42).

Therapeutic Management. To initiate a therapeutic plan, several factors must be determined:

- The degree of dehydration based on physical assessment
- The type of dehydration based on the pathophysiology of the specific illness responsible for the dehydrated state
- Specific physical signs other than general signs

- Initial plasma sodium concentrations
- Serum bicarbonate concentration
- Any associated electrolyte (especially serum potassium) and acid–base imbalances (as indicated)

Initial and regular ongoing evaluations are required to assess the patient's progress toward equilibrium and the effectiveness of therapy.

Medical management is directed at correcting the fluid imbalance and treating the underlying cause. When the child is alert, awake, and not in danger, correction of dehydration may be attempted with oral fluid administration. Mild cases of dehydration can be managed at home by this method. Oral rehydration management consists of replacement of fluid loss over 4 to 6 hours, replacement of continuing losses, and provision for maintenance fluid requirements. In general, a mildly dehydrated child may be given 50 mL/kg of oral rehydration solution (ORS), and a child with moderate dehydration may be given 100 mL/kg of ORS. A child with fluid losses from diarrhea or vomiting may be given 10 mL/kg for each stool or emesis (Churgay & Aftab, 2012b). Amounts and rates are determined from body weight and the severity of dehydration and are increased if rehydration is incomplete or if excess losses continue until the child is well hydrated and the basic issue is under control.

The flavour of an ORS such as Pedialyte (unflavoured) may need to be enhanced by adding 5 mL of unsweetened flavoured drink mix, such as Kool-Aid, to each 60 to 90 mL of ORS. Older children may take a small popsicle orally instead of fluids that require drinking. Many commercially available popsicles are relatively inexpensive and contain small amounts of sucrose and approximately 40 to 50 mL of fluid. Frozen oral hydration may be accepted by some children when conventional ORS is rejected.

The child may not be thirsty even though dehydrated and may refuse oral fluids initially for fear of continued emesis (if occurring) or because of decreased strength, oral stomatitis, or thrush. In such children, rehydration may proceed by administering 2 to 5 mL of ORS by a syringe or small medication cup every 2 to 3 minutes until the child is able to tolerate larger amounts; if the child has emesis, administering small amounts (5 to 10 mL) of ORS after 10 minutes and administering it every 5 minutes may help overcome fluid deficit, and the emesis often lessens over time (Churgay & Aftab, 2012b). Oral rehydration therapy (ORT) is effective for treating mild or moderate dehydration in children, is less expensive, and involves fewer complications than parenteral therapy (AAP, 2014). ORSs are available in Canada as commercially prepared solutions and are successful in treating the majority of infants and children with dehydration.

Parenteral fluid therapy. Parenteral fluid therapy is initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to (1) meet ongoing daily physiological losses, (2) replace previous deficits, and (3) replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, uncontrollable vomiting, inability to drink for any reason (e.g., extreme fatigue, coma), and severe gastric distension.

Because dehydration (volume depletion) constitutes a great threat to life, the first priority is the restoration of circulation by rapid expansion of the ECF volume to treat or prevent shock. IV administration of fluid begins immediately, although the exact nature of the dehydration and the serum electrolyte values may not initially be known. The solution selected is based on what is known regarding the probable type and cause of the dehydration. This usually involves an isotonic solution such as 0.9% sodium chloride or lactated Ringer's solution, both of which are close to the body's serum osmolality of 285 to 300 mmol/kg and do not contain dextrose (which is contraindicated in the early treatment stages of diabetic ketoacidosis).

Parenteral rehydration therapy has three phases. The initial therapy is used to expand volume quickly to ensure tissue perfusion (Greenbaum, 2020). During initial therapy, an isotonic electrolyte solution is used at a rate of 20 mL/kg given as an IV bolus over 20 minutes and repeated as necessary after assessment of the child's response to therapy. Subsequent therapy is used to replace deficits, meet maintenance water and electrolyte requirements, and catch up with ongoing losses. Water and sodium requirements for the deficit, maintenance, and ongoing losses are calculated at 8-hour intervals, taking into consideration the amount of fluids given with the initial boluses and the amount administered during the first 24-hour period. With improved circulation during this phase, water and electrolyte deficits can be evaluated, and acid–base status can be corrected either directly through the administration of fluids or indirectly through improved renal function. Potassium is withheld until kidney function is restored and assessed and circulation has improved. See Box 46.4 for calculation of daily fluid requirements.

The final phase of therapy allows the patient to return to normal and begin oral feedings, with a gradual correction of total body deficits. The potassium loss in ICF is replaced slowly by way of the ECF. The body fat and protein stores are replaced through diet. If the child is unable to eat or if feeding aggravates a chronic condition, IV maintenance fluids are provided.

Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, it is contraindicated in hypertonic dehydration because of the risk for water intoxication, especially in the brain cells, specifically the central pontine cells. Central pontine myelinolysis may occur with an overcorrection of fluid deficit and an overly rapid correction of serum sodium concentration (Greenbaum, 2020). There is an apparent lag time for sodium to reach a steady state when diffusing in and out of brain cells, but water diffuses almost instantaneously. Consequently, rapid administration of fluid causes equally rapid diffusion of water into the dehydrated brain cells, causing marked cerebral edema. Because ECF volume is maintained relatively well in hypertonic as opposed to the other types of dehydration, shock is not a usual manifestation.

Nursing Care. Nursing observation and intervention are essential for detection and therapeutic management of dehydration. A variety of circumstances cause fluid losses in infants and small children, and changes can take place quickly. An important nursing responsibility is observing for signs of dehydration. Nursing assessment should begin with assessing general appearance and proceed to more specific observations. Ill children usually have drawn expressions, have dry mucous membranes and lips, and "look sick." Loss of appetite is one of the first behaviours observed in most childhood illnesses, and the infant's or child's activity level is diminished from baseline or usual activities. The cry of an ill infant is less vigorous, often whining, and higher pitched than usual. The child is irritable, seeks the parent's comfort and attention, and displays purposeless movements and inappropriate responses to people and familiar objects. In some cases the child may not protest advances by the health care worker and procedures such as taking vital signs or starting an IV infusion. These are signs that the child truly feels ill and that the condition is serious and immediate intervention is necessary. As the child's illness and level of dehydration become more severe, irritability progresses to lethargy and even unconsciousness.

Capillary filling time is assessed by pinching the abdominal skin, chest, arm, or leg and estimating the time it takes for the blood to return. Capillary filling time in mild dehydration is less than 2 seconds, increasing to more than 4 seconds in severe dehydration. The technique is effective for assessing dehydration in children of all ages. However, it can be altered in the presence of heart failure, which affects circulation time, and hypertonic dehydration, in which fluid loss is primarily

intracellular. Additional clinical signs observed in children with dehydration include cool mottled extremities, sunken eyes, tachypnea, and changes in sensorium.

When caring for the ill child, the vital signs are assessed as often as every 15 to 30 minutes and fluid intake and output and body weight recorded frequently during the initial phase of therapy. Routine weights should be obtained at the same time each day. It is important to use the same scale each time the child is weighed and predetermine the weight of any equipment or devices that must remain attached during the weighing process, and any clothing the child might be wearing.

Accurate measurements of fluid intake and output are vital to the assessment of dehydration. This includes oral and parenteral intake and losses from urine, stools, vomiting, fistulas, NG losses, sweat, and wound drainage:

Urine—Frequency, colour, consistency, and volume (when weighing diapers, approximately 1 g wet diaper weight equals 1 mL urine)
Stools—Frequency, volume, and consistency
Vomitus—Volume, frequency, and type
Sweating—Can be only estimated from frequency of clothing and linen changes

In addition to fluid intake and output, the following observations assist in assessment of dehydration:

Vital signs—Temperature (normal, elevated, or lowered depending on degree of dehydration), pulse (tachycardia), respirations (hyperpnea), and blood pressure (hypotension)
Skin—Colour, temperature, turgor, presence or absence of edema, and capillary refill
Mucous membranes—Moisture, colour, and presence and consistency of secretions
Body weight—Decreased in relation to degree of dehydration
Fontanel (infants)—Sunken, soft, or normal
Sensory alterations—Presence of thirst

Parents should be advised to observe the number of times and how much the child voids. Parents should be instructed to notify the nurse or clinician if the child appears to be voiding an insufficient amount or persistently losing fluid through vomiting or diarrhea.

DISORDERS OF MOTILITY

Changes in bowel movement patterns or stool consistency are common signs of motility disorders in infants and children. Assessing stool consistency objectively is helpful in discerning the difference between "normal" stools, which can range in texture and consistency, and "abnormal" stools, which may require monitoring and investigation. The Bristol Stool Chart is a useful tool that helps to objectively describe stool consistency (Figure 46.1).

Diarrhea

Diarrhea is a symptom that results from disorders involving digestive, absorptive, and secretory functions. It is caused by abnormal intestinal water and electrolyte transport. Diarrheal disease is a leading cause of child mortality and morbidity in the world and occurs mostly in developing countries. Worldwide, there are an estimated 525 000 deaths per year from diarrhea in children under 5 years of age (WHO, 2017). The estimated incidence of acute gastroenteritis in children younger than 5 years of age is approximately one to two episodes annually in industrialized countries (Doré-Bergeron et al., 2018). In some Indigenous communities, the risk of enteric illness is higher than the national average. This higher rate could be due to consumption of certain game meats, as well as the use of traditional fermentation practices along with lack of access to clear water (Jung & Skinner, 2017).

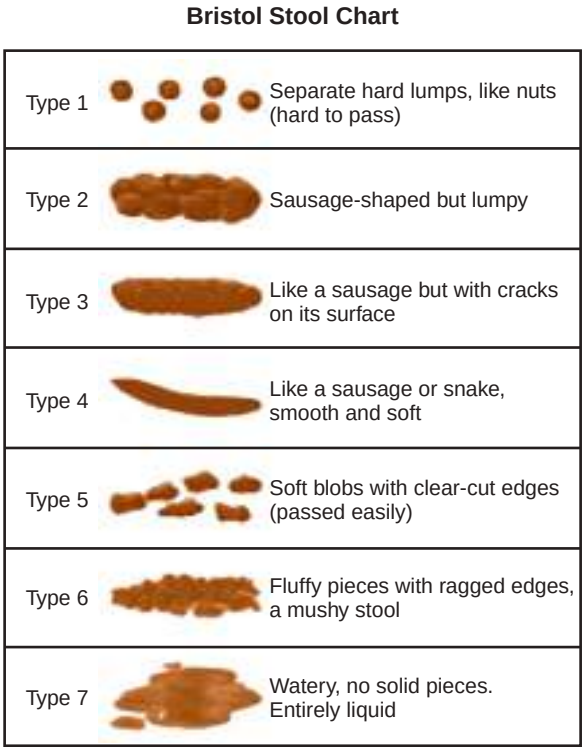

Fig. 46.1 The Bristol Stool Chart shows normal and abnormal stools. (Courtesy Elder, J. [2020]. Enuresis and voiding dysfunction. In R. M. Kliegman, J. St. Geme, N. J. Blum, et al., [Eds.], *Nelson textbook of pediatrics* [21st ed.]. Elsevier.

Diarrheal disturbances involve the stomach and intestines (gastroenteritis), the small intestine (enteritis), the colon (colitis), or the colon and intestines (enterocolitis). Diarrhea is classified as acute or chronic.

Acute diarrhea, a leading cause of illness in children younger than 5 years of age, is defined as a sudden increase in frequency and a change in consistency of stools, often caused by an infectious agent in the GI tract. It may be associated with upper respiratory or urinary tract infections, antibiotic therapy, or laxative use. Acute diarrhea is usually self-limiting (less than 14 days' duration) and subsides without specific treatment if dehydration does not occur. *Acute infectious diarrhea (infectious gastroenteritis)* is caused by a variety of viral, bacterial, and parasitic **pathogens** (Table 46.5).

Chronic diarrhea is defined as an increase in stool frequency and increased water content for a duration of more than 14 days. It is often caused by chronic conditions such as malabsorption syndromes, inflammatory bowel disease (IBD), immunodeficiency, food allergy, lactose intolerance, or chronic nonspecific diarrhea, or it can be the result of inadequate management of acute diarrhea.

Intractable diarrhea of infancy is a syndrome that occurs in the first few months of life, persists for longer than 2 weeks with no recognized pathogens, and is refractory to treatment. The most common cause is inadequately managed acute infectious diarrhea.

Chronic nonspecific diarrhea (CNSD), also known as irritable colon or childhood and toddlers' diarrhea, is a common cause of chronic diarrhea in children 6 to 54 months of age. These children have loose stools, often with undigested food particles, and diarrhea greater than 2 weeks' duration. Children with CNSD grow normally and have no evidence of malnutrition, no blood in their stool, and no enteric infection. Dietary indiscretions and food sensitivities have been linked to chronic diarrhea. The excessive intake of juices and artificial sweeteners such as

TABLE 46.5 Infectious Causes of Acute Diarrhea

Organism	Pathology	Characteristics	Comments
Viral Agents			
Rotavirus			
Incubation: 48 hr Diagnosis: enzyme immunoassay (EIA) and latex agglutination assay	Fecal–oral transmission Seven groups (A–G): Most group A virus replicates in mature villus epithelial cells of small intestine; leads to (1) imbalance in ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates	Mild to moderate fever Vomiting followed by the onset of watery stools Fever and vomiting generally abate in approximately 2 days, but diarrhea persists 5–7 days Adult contacts in household may develop symptomatic infection	Most common cause of diarrhea in children <5 yr of age Infants 6–12 mo most vulnerable Peak occurrences in winter months; important cause of health care–associated infections Affects all ages; usually milder in children >3 yr of age; immune-compromised children at greater risk for complications Virus can live on toys and hard surfaces (sinks, countertops) Vaccine available for infants
Noroviruses (Formerly Norwalk-like) Caliciviruses			
Incubation: 12–48 hr Diagnosis: EIA, reverse-transcriptase polymerase chain reaction (RT-PCR)	Fecal–oral; contaminated food or water Pathology similar to rotavirus Affects villus epithelial cells of small intestine Leads to (1) imbalance in ratio of intestinal fluid absorption to secretion and (2) malabsorption of complex carbohydrates	Abdominal cramps; nausea, vomiting, malaise, low-grade fever, watery diarrhea without blood; duration brief, 2–3 days; tends to resemble food poisoning symptoms with nausea predominating	Affects all ages Multiple strains often named for the location of outbreak (e.g., Norwalk, Sapporo, Snow Mountain, Montgomery)
Bacterial Agents			
Escherichia coli			
Incubation: 3–4 days Variable depending on strain Diagnosis: sorbitol MacConkey agar (SMAC agar) for blood but fecal leukocytes are absent or rare	Five *E. coli* strains produce diarrhea as a result of enterotoxin production, adherence, or invasion; these strains include enterotoxigenic-producing (ETEC), enteroaggregative (EAEC), Shiga toxin–producing (STEC), enteropathogenic (EPEC), and enteroinvasive (EIEC) *E. coli*	Watery diarrhea 1–2 days; then severe abdominal cramping and bloody diarrhea STEC can progress to hemolytic uremic syndrome (HUS) and postdiarrheal thrombotic thrombocytopenia (TTP); 50% require dialysis and 3–5% die	Food-borne pathogen Traveller's diarrhea Highest incidence in summer Cause of nursery epidemics Symptomatic treatment Antibiotics may worsen course, but meta-analysis shows no harm or benefit from antibiotic therapy Antimotility agents and opioids should be avoided
Salmonella Groups (Nontyphoidal; Gram-Negative Rods, Nonencapsulated, Nonsporulating)			
Incubation 6–72 hr Diagnosis: Gram-stained stool culture	Invasion of mucosa in the small and large intestine; edema of the lamina propria; focal acute inflammation with disruption of the mucosa and microabscesses	Nausea, vomiting, colicky abdominal pain, bloody diarrhea, fever; symptoms variable: mild to severe May have headache, cerebral manifestations (e.g., drowsiness, confusion, meningismus, seizures) Infants may be afebrile and nontoxic May result in life-threatening septicemia and meningitis Nausea and vomiting typically of short duration; diarrhea may persist as long as 2–3 wk Typically shed virus for average of 5 wk; cases reported up to 1 yr	Incidence highest in warm months: July to November Food-borne outbreaks common Usually transmitted person to person but may be transmitted via undercooked meats or poultry Poultry and poultry products cause about half the cases In children: coming into contact with animals (e.g., snakes and turtles) that are contaminated Antibiotics not recommended in uncomplicated cases Antimotility agents also not recommended—prolong transit time and carrier state Incidence decreasing over past 10 yr

TABLE 46.5 Infectious Causes of Acute Diarrhea—cont'd

Organism	Pathology	Characteristics	Comments
Salmonella typhi			
Produces enteric fever—systemic syndrome Incubation usually 7–14 days but could be 3–30 days, depending on size of inoculum Diagnosis: positive blood cultures; also sometimes positive stool and urine Late stage: positive bone marrow culture	Bloodstream invasion; after ingestion, organism attaches to microvilli of ileal brush borders, and bacteria invade the intestinal epithelium via Peyer's patches; organism is then transported to intestinal lymph nodes and enters bloodstream via thoracic ducts, and circulating organisms reach reticuloendothelial cells, causing bacteremia	Manifestations depend on age Abdominal pain; diarrhea; nausea, vomiting, high fever, lethargy Must be treated with antibiotics	Incidence is much lower in developed countries Ingestion of food, water, or both contaminated with human feces is most common mode of transmission Congenital and intrapartum transmission can occur Three vaccines are available
Shigella Species			
Gram-negative organisms Nonmotile Anaerobic bacilli Incubation: 1–7 days Diagnosis: stool culture Loaded with polymorphonuclear leukocytes	Enterotoxins: invade the epithelium with superficial mucosal ulcerations	Patients appear sick Symptoms begin with fever, fatigue, anorexia Crampy abdominal pain precedes watery or bloody diarrhea Symptoms usually subside in 5–10 days	Most cases in children younger than 9 yr with about one third of cases in children ages 1–4 wk Antibiotics shorten illness and lower mortality risk All patients are at risk for dehydration Acute symptoms may persist for 1 wk or more Antidiarrheal medications not recommended; may predispose to toxic megacolon
Yersinia enterocolitica			
Incubation period: dose dependent, 1–3 wk Diagnosis: stool culture serology; enzyme-linked immunosorbent assay (ELISA) Patients have leukocytosis; elevated sedimentation rate	Pathology is poorly understood; may be production of enterotoxin	Mucoid diarrhea, sometimes bloody; abdominal pain suggestive of appendicitis; fever, vomiting	Seen more frequently in winter months Transmitted by pets and food Antibiotics usually do not alter the clinical course in uncomplicated cases; they should be used in complicated infections and compromised hosts
Campylobacter jejuni* and *Campylobacter coli			
Microaerophilic, motile, Gram-negative bacilli Incubation period: 1–7 days Ability to cause illness appears dose related Diagnosis by stool culture, sometimes in the blood Commonly found in gastrointestinal (GI) tract of wild or domestic animals	Not fully understood; possibly (1) adherence to intestinal mucosa by toxin; (2) invasion of the mucosa in the terminal ileum and colon; (3) translocation, in which organisms penetrate the mucosa and replicate in lamina propria	Fever, abdominal pain, diarrhea, can be bloody; vomiting Watery, profuse, foul-smelling diarrhea Clinically similar to *Salmonella* or *Shigella* Fecal–oral transmission	Most infections in humans relate to consumption of contaminated foods or water; undercooked meats, particularly chicken; unpasteurized milk Also acquired from contaminated household pets (e.g., dogs, cats, hamsters) Bimodal peaks in infants <1 yr and again at ages 15–29 mo Antibiotics do not prolong the carriage of bacteria and may eliminate organism more quickly Erythromycin and azithromycin are medications of choice (5–7 days) Antimotility agents not recommended and tend to prolong symptoms

Continued

TABLE 46.5 Infectious Causes of Acute Diarrhea—cont'd

Organism	Pathology	Characteristics	Comments
Vibrio cholera			
Gram-negative, motile, curved bacillus living in bodies of salt water Incubation period: 1–3 days Diagnosis by stool culture	Enters via oral route in contaminated food or water; if survives acid stomach environment, travels to the small intestine, adheres to mucosa, and produces toxin	Onset abrupt; vomiting, watery diarrhea without cramping or tenesmus Dehydration can occur quickly	More prevalent in developing countries Rehydration most important treatment Antibiotics can shorten diarrhea No vaccine
Clostridium difficile			
Gram-positive anaerobic bacillus Diagnosis by detecting *C. difficile* toxin in stool culture	Produces two important toxins (A and B) Toxin binds to enterocyte surface receptor, resulting in alteration of permeability, protein synthesis, and direct cytotoxicity	Most cases: mild, watery diarrhea lasting a few days; abdominal cramping Some cases: prolonged diarrhea and illness May cause pseudomembranous colitis Some individuals are extremely ill with high fever, leukocytosis, hypoalbuminemia	Associated with alteration of normal intestinal flora by antibiotics More common in hospitalized persons Adults tend to have more severe symptoms than children Treatment with antibiotics in symptomatic patients—metronidazole Resistant strains have developed Relapse common
Clostridium perfringens			
Incubation period: 8–24 hr; anaerobic, Gram-positive, spore-producing bacilli	Toxins produced in the intestine after ingestion of organism	Acute onset: watery diarrhea, crampy abdominal pain Fever, nausea, and vomiting rare Duration of illness usually 24 hr	Transmitted by contaminated food products, most often meats and poultry Usually self-limiting and medical intervention not needed Oral rehydration usually sufficient Antibiotics serve no purpose and should not be used
Clostridium botulinum			
Incubation period: 12–26 hr (range, 6 hr to 8 days) Gram-positive, anaerobic, spore-producing bacilli Blood and stool culture should be obtained and transmitted to special laboratory (usually provincial department) to detect toxin	Botulism caused by binding of toxin to the neuromuscular junction	Clinical presentation related to age and the strain of the botulism Abdominal pain, cramping, and diarrhea Usually infants present with constipation Other strains: respiratory compromise, central nervous system symptoms	Transmitted in contaminated food products Can be acquired via wound infection Treatment involves supportive care and neutralization of the toxin
Staphylococcus			
Incubation period: generally short, 1–8 hr Gram-positive, nonmotile, aerobic, or facultative anaerobic bacteria Diagnosis by identifying organism in food, blood, pus, aspirate	Direct tissue invasion and production of toxin	Clinical presentation depends on site of entry In food poisoning: profuse diarrhea, nausea, and vomiting Low-grade fever and hypothermia may occur	GI illness transmitted in inadequately cooked or refrigerated foods Self-limiting in GI illness Symptomatic treatment Antibiotics not recommended

sorbitol, a substance found in many commercially prepared beverages and foods, may be a factor.

Etiology. Most pathogens that cause diarrhea are spread by the fecal–oral route through contaminated food or water or are spread from person to person where there is close contact (e.g., day care centres). Lack of clean water, crowding, poor hygiene, nutritional deficiency, and poor sanitation are major risk factors, especially for bacterial or parasitic pathogens. Infants are often more susceptible to frequent and severe bouts of diarrhea because their immune system has not been exposed to many pathogens and has not acquired protective antibodies. Worldwide, the most common causes of acute gastroenteritis are infectious agents, viruses, bacteria, and parasites.

Rotavirus is the most important cause of serious gastroenteritis among children and a significant health care–associated pathogen. Rotavirus disease is most severe in children 3 to 24 months of age. Children younger than 3 months of age have some protection from the disease because of maternally acquired antibodies. Approximately 25% of severe cases of rotavirus occur in older children (Bass, 2020).

Salmonella, Shigella, and *Campylobacter* organisms are the most frequently isolated bacterial pathogens. These organisms are Gram-negative bacteria and can be contracted through raw or undercooked food, contaminated food or water, or through the fecal–oral route. *Salmonella* has the highest occurrence in infants; *Giardia* and *Shigella* have the highest incidence among toddlers. *Shigella* infection is uncommon in Canada, accounting for less than 5% of diarrheal illnesses in infants and toddlers. *Campylobacter* infection has a bimodal presentation (highest in children younger than 12 months of age with a second rise in incidence at age 15 to 19 years). *Giardia* and *Cryptosporidium* organisms are parasites. *Cryptosporidium* infection is often associated with outbreaks in young children in day care centres; an increase in infections has been seen in association with outdoor swimming (pools, lakes, splash fountains) in the summer and early fall (AAP, Committee on Infectious Diseases, 2018). *Plesiomonas* and *Yersinia* are also parasites that are frequently responsible for causing traveller's diarrhea.

Antibiotic administration is frequently associated with diarrhea because antibiotics alter the normal intestinal flora, resulting in an overgrowth of other bacteria such as *Clostridium difficile*. Antibiotic-associated diarrhea can also be caused by *Salmonella* organisms, *Clostridium porringers* type A, and *Staphylococcus aureus* pathogens. The Public Health Agency of Canada (PHAC) requires that occurrences of *C. difficile* be reported so that rates can be tracked (Government of Canada, 2019).

Pathophysiology. Invasion of the GI tract by pathogens results in increased intestinal secretion as a result of enterotoxins, cytotoxic mediators, or decreased intestinal absorption secondary to intestinal damage or inflammation. Enteric pathogens attach to the mucosal cells and form a cuplike pedestal on which the bacteria rest. The pathogenesis of the diarrhea depends on whether the organism remains attached to the cell surface, resulting in a secretory toxin (noninvasive, toxin-producing, noninflammatory type diarrhea), or penetrates the mucosa (systemic diarrhea). Noninflammatory diarrhea is the most common diarrheal illness, resulting from the action of enterotoxin that is released after attachment to the mucosa. The most serious and immediate physiological disturbances associated with severe diarrheal disease are (1) dehydration, (2) acid–base imbalance with acidosis, and (3) shock that occurs when dehydration progresses to the point that circulatory status is seriously impaired.

Diagnostic Evaluation. Evaluation of the child with acute gastroenteritis begins with a careful history to discover the possible cause of diarrhea, assess the severity of symptoms and the risk of complications, and elicit information about current symptoms indicating other treatable illnesses that could be causing the diarrhea. The history should include questions about recent travel, exposure to untreated drinking or washing water sources, contact with animals or birds, day care centre attendance, recent treatment with antibiotics, or recent diet changes. History questions should also explore the presence or absence of other symptoms such as fever and vomiting, frequency and character of stools (e.g., watery, bloody), urinary output, dietary habits, and recent food intake.

Extensive laboratory evaluation is not indicated in children who have uncomplicated diarrhea and no evidence of dehydration because most diarrheal illnesses are self-limiting. Laboratory tests are indicated for children who are severely dehydrated and receiving IV therapy. Watery, explosive stools suggest glucose intolerance; foul-smelling, greasy, bulky stools suggest fat malabsorption. Diarrhea that develops after the introduction of cow's milk, fruits, or cereal may be related to enzyme deficiency or protein intolerance. Neutrophils or red blood cells in the stool indicate bacterial gastroenteritis or IBD. The presence of eosinophils suggests protein intolerance or parasitic infection. Stool cultures should be performed only when blood, mucus, or polymorphonuclear leukocytes are present in the stool; when symptoms are severe; when there is a history of travel to a country with the presence of a known pathogen; and when a specific pathogen is suspected. Gross blood or occult blood may indicate pathogens such as *Shigella, Campylobacter*, or hemorrhagic *Escherichia coli* strains. An enzyme-linked immunosorbent assay (ELISA) may be used to confirm the presence of rotavirus or *Giardia* organisms. If there is a history of recent antibiotic use, the stool should be tested for *C. difficile* toxin. When bacterial and viral cultures are negative and diarrhea persists for more than a few days, stools should be examined for ova and parasites. A stool specimen with a pH of less than 6 and the presence of reducing substances may indicate carbohydrate malabsorption or secondary lactase deficiency. Stool electrolyte measurements may help identify children with secretory diarrhea.

The serum bicarbonate (HCO_3) may be useful when combined with other clinical signs. In the presence of metabolic acidosis, an anion gap may be helpful to distinguish between types of metabolic imbalance. A complete blood count (CBC), serum electrolytes, and creatinine and BUN levels should be obtained for the child who has moderate-to-severe dehydration or who requires hospitalization. Urine specific gravity should be determined if dehydration is suspected. The hemoglobin, hematocrit, creatinine, and BUN levels are usually elevated in acute diarrhea and should normalize with rehydration.

Therapeutic Management. The major goals in the management of acute diarrhea include (1) assessment of fluid and electrolyte imbalance, (2) rehydration, (3) maintenance fluid therapy, and (4) reintroduction of an adequate diet. Infants and children with acute diarrhea and dehydration should be treated first with ORT. ORT is more effective, safer, less painful, and less costly than IV rehydration. ORT is the treatment of choice for most cases of dehydration caused by diarrhea (Kotloff, 2020). ORSs enhance and promote the reabsorption of sodium and water, and studies indicate that these solutions greatly reduce vomiting, volume loss from diarrhea, and the duration of the illness. ORSs, including reduced-osmolarity ORS, are available in Canada as commercially prepared solutions and are successful in treating the majority of infants with dehydration (Figure 46.2).

After rehydration, ORS may be used during maintenance fluid therapy by alternating the solution with a low-sodium fluid such as breast milk, lactose-free formula, or half-strength lactose-containing formula. In older children, ORS can be given and a regular diet continued.

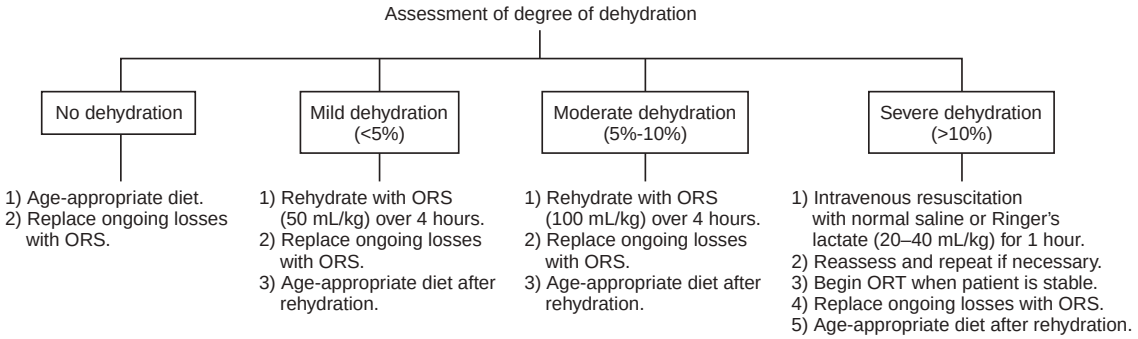

Fig. 46.2 Algorithm for managing acute gastroenteritis in children. *ORS,* Oral rehydration solution; *ORT,* oral rehydration therapy. (From Leung, A., Prince, T., & Canadian Paediatric Society, Nutrition and Gastroenterology Committee. [2006]. Oral rehydration therapy and early refeeding in the management of childhood gastroenteritis. *Paediatrics & Child Health, 11*[8], 529.)

Ongoing stool losses should be replaced on a 1:1 basis with ORS. If the stool volume is not known, approximately 10 mL/kg of ORS should be given for each diarrheal stool.

Solutions for oral hydration are useful in most cases of dehydration, and vomiting is not a contraindication. A child who is vomiting should be given an ORS at frequent intervals and in small amounts. For young children the caregiver may give the fluid with a spoon or small syringe in 5- to 10-mL increments every 1 to 5 minutes. An ORS may also be given via NG or gastrostomy tube infusion. Infants without clinical signs of dehydration do not need ORT. However, they should receive the same fluids recommended for infants with signs of dehydration in the maintenance phase and for ongoing stool losses. The CPS suggests the use of probiotics to reduce the risk of antibiotic-associated diarrhea in children (Marchand & CPS, Nutrition and Gastroenterology Committee, 2012/2019).

! NURSING ALERT

Diarrhea is not managed by encouraging intake of clear fluids by mouth, such as fruit juices, carbonated soft drinks, and gelatin. These fluids usually have high carbohydrate content, very low electrolyte content, and high osmolality. Caffeinated soft drinks should be avoided because caffeine is a mild diuretic and may lead to increased loss of water and sodium. Chicken or beef broth is not given because it contains excessive sodium and inadequate carbohydrate. The BRAT diet (bananas, rice, applesauce, and toast or tea) is contraindicated for the child and especially for the infant with acute diarrhea because this diet has little nutritional value (low in energy and protein), is high in carbohydrates, and is low in calories.

Early reintroduction of nutrients is desirable and is gaining more widespread acceptance in treatment of acute diarrhea. Continued feeding or early reintroduction of a normal diet has no adverse effects; it lessens the severity and duration of the illness and improves weight gain when compared with a slower reintroduction of foods (Kotloff, 2020). Infants who are breastfeeding should continue to do so, and ORS should be used to replace ongoing losses in these infants. Formula-fed infants should resume their formula; it should not be diluted or mixed with additional water. In toddlers there is no contraindication to continuing soft or pureed foods. Older children who consume a regular diet, including milk, can be offered their normal foods after rehydration has been achieved. A diet of easily digestible foods such as cereals, cooked vegetables, and meats is adequate for the older child. Foods with complex carbohydrates (rice, wheat, potatoes, bread, and cereals), fresh fruits, lean meats, yogurt, and vegetables should be reintroduced while ORS is given to replace ongoing losses from emesis or stools and for maintenance (Kotloff, 2020).

In cases of severe dehydration and shock, IV fluids are initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to (1) meet ongoing daily physiological losses, (2) replace previous deficits, and (3) replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, those with uncontrollable vomiting, those who are unable to drink for any reason (e.g., extreme fatigue, coma), and those with severe gastric distension.

The IV solution is selected on the basis of what is known about the probable type and cause of the dehydration. The type of fluid normally used is a saline solution containing 5% dextrose in water. Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, rapid replacement is contraindicated in hypertonic dehydration because of the risk for water intoxication.

After the severe effects of dehydration are under control, specific diagnostic and therapeutic measures are initiated to detect and treat the cause of the diarrhea. The use of antibiotic therapy in children with acute gastroenteritis is controversial. Antibiotics may shorten the course of some diarrheal illnesses (e.g., those caused by *Shigella* organisms). However, most bacterial diarrheas are self-limiting, and the diarrhea often resolves before the causative organism can be determined. Antibiotics may prolong the carrier period for bacteria such as *Salmonella*. However, they may be considered in patients who are younger than 3 months of age, on immunosuppressive medication, or have clinical signs of shock, severe malnutrition, dysentery, suspected cholera, or suspected giardiasis. Antimotility medications such as loperamide are not recommended in children. Because of the self-limiting nature of vomiting and its tendency to improve when dehydration is corrected, antiemetic medications such as the phenothiazines are not recommended because of their adverse effects; however, ondansetron has few adverse effects and may be administered if vomiting persists and interferes with ORT (Doré-Bergeron et al., 2018; Kotloff, 2020).

Nursing Care. The management of most cases of acute diarrhea takes place in the home with education of the caregiver. Caregivers are taught to monitor for signs of dehydration (especially the number of wet diapers or voidings) and the amount of fluids taken by mouth and to assess the frequency and amount of stool losses. Education relating to ORT, including the administration of maintenance fluids and replacement of ongoing losses, is important (see Clinical Reasoning Case Study: Diarrhea). ORS should be administered in small quantities at frequent intervals. Vomiting is not a contraindication to ORT unless it is severe. Information about the introduction of a regular diet is essential. Parents

need to know that a slightly higher stool output initially occurs with continuation of a normal diet and with ongoing replacement of stool losses. The benefits of a better nutritional outcome with fewer complications and a shorter duration of illness outweigh the potential increase in stool frequency. Parents' concerns should be addressed to ensure they will carry out the treatment plan. See Nursing Process: Diarrhea available on Evolve.

CLINICAL REASONING CASE STUDY

Diarrhea

A mother brings her 8-month-old infant, Mary, to the primary care clinic. The mother reports that Mary has had a "cold" for about 2 days and this morning she began to vomit and has had diarrhea for the past 8 hours. The mother states that Mary is still breastfeeding but that she is not taking as much fluid as usual and she is having three times as many stools as usual (the stools are watery in consistency). The nurse practitioner's assessment of Mary finds that her temperature is 38.0°C, her pulse and blood pressure are in the normal range, her mucous membranes are moist, and she has tears when she cries. The nurse practitioner also notes that Mary's weight has not changed from when she was seen in the clinic 2 weeks ago for her well-child visit.

Questions

1. What evidence should you consider regarding this condition?
2. What additional information is required at this time?
3. How will the nurse practitioner determine the level of dehydration?
4. How is acute diarrhea managed?
5. List the nursing intervention(s) that have the highest priority.
6. Identify important patient-centred outcomes with reference to your nursing interventions.

If the child with acute diarrhea and dehydration is hospitalized, an accurate weight must be obtained, and intake and output must be carefully monitored. The child may be placed on parenteral fluid therapy with reinstitution of oral fluids and soft foods; keeping the child with gastroenteritis NPO for a long period is usually avoided to prevent changes in intestinal permeability as a result of infection. Monitoring the IV infusion is an important nursing function. The nurse must ensure that the correct fluid and electrolyte concentration is infused, the flow rate is adjusted to deliver the desired volume in a given time, and the IV site is maintained.

Accurate measurement of output is essential to determine whether renal blood flow is sufficient to permit the addition of potassium to the IV fluids. The nurse is responsible for examination of stools and collection of specimens for laboratory examination (see Collection of Specimens, Chapter 44). Care should be taken when obtaining and transporting stools to prevent possible spread of infection; stool specimens should be transported to the laboratory in appropriate containers and media according to hospital policy. A clean tongue depressor can be used to obtain specimens for laboratory examination or as an applicator for transfer to a culture medium.

Diarrheal stools are highly irritating to the skin, thus extra care is needed to protect the skin of the perianal and perineal region from excoriation (see Diaper Dermatitis, Chapter 52). Taking a rectal temperature should be avoided because this can stimulate the bowel, increasing passage of stool.

Support for the child and family involves the same care and consideration given all hospitalized children (see Chapter 43). Parents need to be kept informed of the child's progress and instructed in the use of frequent and proper **hand hygiene** and the disposal of soiled diapers, clothes, and bed linen. If *C. difficile* is the infecting agent, hands must be washed with soap and water and not with alcohol-based cleanser. Everyone caring for the child must be aware of "clean" areas and "dirty" areas, especially in the hospital, where the sink in the child's room is used for many purposes. Soiled diapers and linens should be discarded in receptacles close to the bedside.

Prevention. The best intervention for diarrhea is prevention. The fecal–oral route spreads most infections, and parents need information about preventive measures such as personal hygiene, protection of the water supply from contamination, and careful food preparation. Meticulous attention to perianal hygiene, disposal of soiled diapers, proper hand hygiene, and isolation of infected persons also minimize the transmission of infection (see Infection Control, Chapter 44).

NURSING ALERT

To reduce the risk of bacteria transmitted via food, encourage parents to:

- **Clean:** Wash hands, utensils, and work areas with hot, soapy water after contact with raw meat to keep bacteria from spreading; sanitize countertops, cutting boards, and utensils before and after preparing food; and wash raw fruits and vegetables with clean, running water before eating.
- **Chill:** Keep cold food at or below 4°C; thaw food in the refrigerator; never thaw food on the counter or let it sit out of the refrigerator for more than 2 hours.
- **Separate:** Use one cutting board for raw meat, poultry, and seafood, and use a different cutting board for food that is ready to eat or cooked; keep raw food away from other food while shopping, and while storing, preparing, and serving foods; place raw meat, poultry, and seafood in containers on the bottom shelf of the refrigerator.
- **Cook:** Cook raw meat, poultry, fish, and seafood no more than 2 to 3 days after purchasing; check ground meat with a fork to make certain no pink is showing before taking a bite; cook all dishes made with ground meat until brown or grey inside or to an internal temperature of 71°C (Government of Canada, 2021b).

Parents also need information about preventing diarrhea in their child while travelling. They should be cautioned against giving children adult medications that are used to prevent traveller's diarrhea. Until vaccines or other prophylactic measures are proven to be safe for children, the best measure during travel to areas where water may be contaminated is to allow children to drink only bottled water and carbonated beverages (from the container through a straw supplied from home). Tap water, ice, unpasteurized dairy products, raw vegetables, unpeeled fruits, meats, and seafood should also be avoided.

To prevent contraction of rotavirus and associated diarrhea, two rotavirus vaccines are available for children. Human-bovine reassortant rotavirus vaccine (RotaTeq) and live-attenuated human rotavirus vaccine (Rotarix) may be used to prevent this infectious diarrheal disease (see Immunizations, Chapter 35). The CPS recommends that all babies be vaccinated (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2020). Population-based studies show a reduction of diarrhea-associated hospitalizations by as much as 87 to 96% in the years after rotavirus vaccination (Esona & Gautam, 2015). Breastfeeding during the first 6 months of life has been found to have a protective effect against rotavirus infection.

Constipation

Constipation is an alteration in the frequency, consistency, or ease of passing stool. Parents often define constipation as passing less than three stools per week. It is defined as infrequent, difficult, painful, or incomplete evacuation of hard stools (Rowan-Legg & CPS, Community Paediatrics Committee, 2011/2018). It may also be defined

as painful bowel movements, which are often blood streaked or include the retention of stool, with or without soiling, even with a stool frequency of more than three stools per week. However, the frequency of bowel movements is not considered a diagnostic criterion because it varies widely among children. Having extremely long intervals between defecation is termed **obstipation**. Constipation with fecal soiling is referred to as **encopresis**.

Constipation may arise secondary to a variety of organic disorders or in association with a wide range of systemic disorders. Structural disorders of the intestine, such as strictures, ectopic anus, and Hirschsprung disease (HD), may be associated with constipation. Systemic disorders associated with constipation include hypothyroidism, hypercalcemia resulting from hyperparathyroidism or vitamin D excess, and chronic lead poisoning. Constipation may be associated with medications such as antacids, diuretics, antiepileptics, antihistamines, opioids, and iron supplementation. Spinal cord lesions may be associated with loss of rectal tone and sensation. Affected children are prone to chronic fecal retention and overflow incontinence.

The majority of children have **idiopathic** or *functional constipation* since no underlying cause can be identified. Chronic constipation may occur as a result of environmental or psychosocial factors or a combination of the two. Transient illness, withholding and avoidance secondary to painful or negative experiences with stooling, and dietary intake with decreased fluid and fibre all play a role in the etiology of constipation.

Newborn Period. Normally the newborn passes a first meconium stool within 24 to 36 hours of birth. Any newborn who does not do so should be assessed for evidence of intestinal atresia or stenosis, HD, hypothyroidism, meconium plugs, or meconium ileus. *Meconium plugs* are caused by meconium that has reduced water content and are usually evacuated after digital examination but may require irrigation with a hypertonic solution or contrast medium. *Meconium ileus*, the initial manifestation of cystic fibrosis, is the luminal obstruction of the distal small intestine by abnormal meconium. Treatment is the same as for a meconium plug; early surgical intervention may be needed to evacuate the small intestine.

Infancy. The onset of constipation frequently occurs during infancy and may result from organic causes such as HD, hypothyroidism, and strictures. It is important to differentiate these conditions from functional constipation. Constipation in infancy is often related to dietary practices. It is less common in breastfed infants, who have softer stools than bottle-fed infants. Breastfed infants may also have fewer stools because of more complete use of breast milk with little residue. When constipation occurs with a change from human milk or modified cow's milk to whole cow's milk, simple measures, such as adding or increasing the amount of cereal, vegetables, and fruit in the infant's diet, usually resolve the issue. When a bottle-fed infant passes a hard stool that results in an anal fissure, stool-withholding behaviours may develop in response to pain on defecation (see Clinical Reasoning Case Study: Constipation).

Childhood. Most constipation in early childhood is the result of environmental changes or normal development when a child begins to attain control over bodily functions. A child who has experienced discomfort during bowel movements may deliberately try to withhold stool. Over time, the rectum accommodates to the accumulation of stool, and the urge to defecate passes. When the bowel contents are ultimately evacuated, the accumulated feces are passed with pain, thus reinforcing the desire to withhold stool.

Constipation in school-age children may represent an ongoing issue or a first-time event. The onset of constipation at this age is often the result of environmental changes, stresses, and changes in toileting patterns. A common cause of new-onset constipation at school entry is fear of using the school bathrooms, which are noted for their lack of privacy. Early and hurried departure for school immediately after breakfast may also impede bathroom use.

CLINICAL REASONING CASE STUDY

Constipation

Jung, an 8-month-old infant, is seen by the pediatric nurse practitioner for his well-child visit. Jung's mother states that he usually has one hard stool every 4 to 5 days, which causes discomfort when the stool is passed. He has also had one episode of diarrhea and two episodes of ribbonlike stools. Abdominal distension and vomiting have not accompanied the constipation, and Jung's growth has been appropriate. Currently his diet consists of cow's milk formula only. Jung's mother reports that the infrequent passage of hard stools began approximately 6 weeks ago when she stopped breastfeeding.

Questions

1. What evidence should you consider regarding this condition?
2. What additional information is required at this time?
3. What are the causes of constipation in infants?
4. List the nursing intervention(s) that should be implemented and identify which have the highest priority.
5. Identify important patient-centred outcomes with reference to your nursing interventions.

Therapeutic Management. The goals in treating constipation are to produce soft, painless stools and to prevent the reaccumulation of feces. The management of simple constipation consists of a plan to promote regular bowel movements. Often this is as simple as changing the diet to provide more fibre and fluids, avoiding foods known to be constipating, and establishing a bowel routine that allows for regular passage of stool.

The process of bowel retraining is often used for functional constipation. This includes disimpaction, prolonged laxative treatment and behaviour therapy to achieve regular evacuation and avoid recurrent constipation, dietary changes (primarily increasing fibre content) to maintain soft stools, and gradual tapering and withdrawal of laxatives as tolerated (Rowan-Legg & CPS, Community Paediatrics Committee, 2011/2018; Sood, 2021). Fecal disimpaction may be necessary at the outset of treatment (Rowan-Legg & CPS, Community Paediatrics Committee, 2011/2018). Disimpaction can be achieved by either oral or rectal medication but not through digital disimpaction. Once the impacted stool has been removed a maintenance schedule of laxatives is initiated. The child is treated with a maintenance regimen of oral osmotic laxatives to "retrain" the bowel and avoid reimpaction, which could restart the constipation cycle (Sood, 2021). Stool-softening agents such as docusate or lactulose may also be helpful. Polyethylene glycol (PEG) 3350 without electrolytes is a chemically inert polymer that is used as a laxative. It is tolerated well by children because it can be mixed in a beverage of choice (Rowan-Legg & CPS, Community Paediatrics Committee, 2011/2018).

Behaviour therapy involves developing a toilet sitting schedule. The child should have a routine scheduled toilet sitting for 3 minutes to 10 minutes (age dependent), once or twice a day. A footstool to support the legs is useful to effectively increase intra-abdominal pressure (Valsalva). There should be no punishment for not stooling during the toileting time; praise and reward for stooling and the behaviour of toilet sitting can be offered. It is helpful to have children and their

caregivers keep a diary of stool frequency to review at the next appointment. A copy of the Bristol chart (see Figure 46.1) can be helpful for standardizing stool descriptions (Rowan-Legg & CPS, Community Paediatrics Committee, 2011/2018). A balanced and varied diet with a fibre intake of 0.5 g/kg/day (to a maximum of 35 g/day) for all children is also recommended (Rowan-Legg & CPS, Community Paediatrics Committee, 2011/2018).

If other symptoms such as vomiting, abdominal distension, or pain and evidence of growth failure are associated with the constipation, the condition should be investigated further.

Nursing Care. Constipation tends to be self-perpetuating. A child who has difficulty or discomfort when attempting to evacuate the bowels has a tendency to retain the bowel contents, and this may initiate a vicious cycle. Nursing assessment begins with an accurate history of bowel habits; diet; events associated with the onset of constipation; medications or other substances that the child may be taking; and the consistency, colour, frequency, and other characteristics of the stool (see Figure 46.1). If there is no evidence of a pathological condition, the major tasks are to educate the parents regarding normal stool patterns and to participate in the education and treatment of the child.

Parents can benefit from guidance in selecting foods that facilitate bowel movements (Box 46.6). They may need reassurance concerning the prognosis for establishing normal bowel habits. It is also important to discuss their attitudes and expectations regarding toilet habits.

Hirschsprung Disease

Hirschsprung disease (HD) is a congenital anomaly that results in mechanical obstruction from inadequate motility of part of the intestine. It accounts for about one fourth of all cases of newborn obstruction, although it may not be diagnosed until later in infancy or childhood. The incidence is 1 in 5 000 live births (Maqbool & Liacouras, 2020a). It is four times more common in males than in females and may follow a familial pattern in about 10% of cases. HD is usually an isolated **birth defect**, but it has been associated with other syndromes, including Down syndrome. Depending on its presentation, it may be an acute, life-threatening, or chronic condition.

BOX 46.6 High-Fibre Foods

Bread, Grains
Whole-grain bread or rolls
Whole-grain cereals
Bran
Unrefined (brown) rice

Vegetables
Raw vegetables, especially broccoli, cabbage, carrots, cauliflower, celery, lettuce, and spinach
Cooked vegetables, such as those listed previously and asparagus, beans, Brussels sprouts, corn, potatoes, rhubarb, squash, string beans, and turnips

Fruits
Raw fruits, especially those with skins or seeds, other than ripe banana or avocado
Raisins, prunes, or other dried fruits

Miscellaneous
Nuts, seeds, legumes, popcorn
High-fibre snack bars

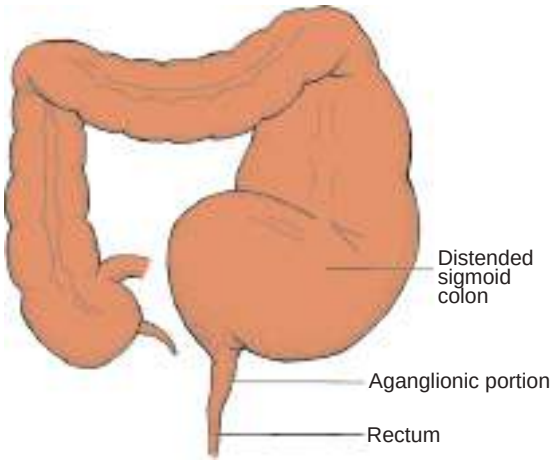

Fig. 46.3 Hirschsprung disease.

Pathophysiology. The pathology of HD relates to the absence of ganglion cells in the affected areas of the intestine, resulting in a loss of the rectosphincteric reflex and an abnormal microenvironment of the cells of the affected intestine. The term *congenital aganglionic megacolon* describes the primary defect, which is the absence of ganglion cells in the myenteric plexus of Auerbach and the submucosal plexus of Meissner (Figure 46.3).

The absence of ganglion cells in the affected bowel results in a lack of enteric nervous system stimulation, which decreases the ability of the internal sphincter to relax. Unopposed sympathetic stimulation of the intestine results in increased intestinal tone. In addition to the contraction of the abnormal bowel and the resulting lack of peristalsis, there is a loss of the rectosphincteric reflex. Normally, when a stool bolus enters the rectum, the internal sphincter relaxes and the stool is evacuated. In HD the internal sphincter does not relax. In most cases, the aganglionic segment includes the rectum and some portion of the distal colon. In 80% of cases, the aganglionosis is restricted to the internal sphincter, rectum, and a few centimetres of the sigmoid colon and is termed *short-segment disease* (Liang et al., 2014; Maqbool & Liacouras, 2020a). However, the entire colon or part of the small intestine may be involved; this is considered *long-segment disease*. Occasionally, skip segments or total intestinal aganglionosis may occur. Rarely, total colonic aganglionosis, in which there is no innervation of the large and small intestine from the anus to the ileocecal valve, may occur.

Diagnostic Evaluation. Most children with HD are diagnosed in the first few months of life. Clinical manifestations vary according to the age when symptoms are recognized and the presence of complications such as enterocolitis (Box 46.7). A newborn usually is seen with distended abdomen, feeding intolerance with bilious vomiting, and delay in the passage of meconium. Typically, 99% of normal-term infants pass meconium in the first 48 hours of life, whereas fewer than 10% of infants with HD do so.

The history is an important part of diagnosis and typically includes a chronic pattern of constipation. On examination, the rectum is empty of feces, the internal sphincter is tight, and leakage of stool and accumulated gas may occur if the aganglionic segment is short. To confirm the diagnosis, rectal biopsy is performed either surgically to obtain a full-thickness biopsy specimen or by suction biopsy for histological evidence of the absence of ganglion cells.

Therapeutic Management. After the child is stabilized with fluid and electrolyte replacement if needed, surgery is performed, which has a high rate of success (Maqbool & Liacouras, 2020a). Surgical

BOX 46.7 Clinical Manifestations of Hirschsprung Disease

Newborn Period
Failure to pass meconium within 24 to 48 hours after birth
Refusal to feed
Bilious vomiting
Abdominal distension

Infancy
Growth failure
Constipation
Abdominal distension
Episodes of diarrhea and vomiting
Signs of enterocolitis
Explosive, watery diarrhea
Fever
Appears significantly ill

Childhood (Symptoms Appear More Chronic)
Constipation
Ribbonlike, foul-smelling stools
Abdominal distension
Visible peristalsis
Easily palpable fecal mass
Undernourished, anemic appearance

management consists primarily of the removal of the aganglionic portion of the bowel to relieve obstruction, restore normal motility, and preserve the function of the external anal sphincter. With earlier diagnosis, the proximal bowel may not be extremely distended, thus allowing for a primary pull-through or one-stage procedure and eliminating the need for a temporary colostomy. The transanal Soave endorectal pull-through procedure is often performed and consists of pulling the end of the normal bowel through the muscular sleeve of the rectum, from which the aganglionic mucosa has been removed. Simpler operations such as an anorectal myomectomy may be indicated in very short–segment disease.

Prognosis. After the pull-through procedure, anal stricture and incontinence may occur and require further therapy, including dilations or bowel retraining therapy. Constipation and fecal incontinence are chronic conditions in a small proportion of patients after surgical correction for HD (Maqbool & Liacouras, 2020a).

Nursing Care. The nursing concerns depend on the child's age and the type of treatment. If the disorder is diagnosed during the newborn period, the main objectives are to (1) help the parents adjust to a congenital defect in their child, (2) foster infant–parent bonding, (3) prepare parents for the medical-surgical intervention, and (4) assist them to assume care of the child after surgery.

Preoperative care. The child's preoperative care depends on the age and clinical condition. A child who is malnourished may not be able to withstand surgery until their physical status improves. Often this involves symptomatic treatment with enemas; a low-fibre, high-calorie, and high-protein diet; and, in severe situations, the use of **total parenteral nutrition (TPN)**.

Physical preoperative preparation includes the same measures that are common to any surgery (see Surgical Procedures, Chapter 44). In the newborn, whose bowels are relatively sterile, no additional preparation is necessary. However, in other children, preparation for the pull-through procedure involves emptying the bowel with saline enemas and decreasing bacterial flora with oral or systemic antibiotics and colonic irrigations using antibiotic solution. Enterocolitis is the most serious complication of HD.

Emergency preoperative care includes frequent monitoring of vital signs and blood pressure for signs of shock; monitoring fluid and electrolyte replacements and plasma or other blood derivatives; and observing for symptoms of bowel perforation, such as fever, increasing abdominal distension, vomiting, increased tenderness, irritability, dyspnea, and cyanosis.

Because progressive distension of the abdomen is a serious sign, the nurse needs to measure abdominal circumference with a paper tape measure, usually at the level of the umbilicus or at the widest part of the abdomen. The point of measurement is marked with a pen to ensure reliability of subsequent measurements. Abdominal measurement can be obtained along with the vital sign measurements and is recorded in serial order so that any change becomes obvious. To reduce stress to the acutely ill child when frequent measurements of abdominal circumference are needed, the tape measure can be left in place beneath the child rather than removed each time.

The child's age dictates the type and extent of psychological preparation. When a colostomy is performed, the child who is of preschool age is told about the procedure in concrete terms with the use of visual aids (see Chapter 43). It is important to time explanations appropriately to prevent the anxiety and confusion that could result from too much information. It is also important to stress to parents and older children that the colostomy for HD is temporary, unless so much bowel is involved that a permanent ileostomy must be performed. In most instances the extent of bowel resection is known before surgery, although the nurse should be aware of cases when doubt exists concerning repair. The nurse should remember that, although a temporary colostomy is favourable in terms of future health and adjustment, it requires additional surgery, which may be stressful to parents and children.

Postoperative care. Postoperative care is the same as that for any child or infant with abdominal surgery (see Surgical Procedures, Chapter 44). The nurse involves the parents in the care of the child, allowing them to help with feedings and observe for signs of wound infection or irregular passage of stool. Some children will require daily anal dilatations in the postoperative period to avoid anastomotic strictures; parents are often taught to perform the procedure in the home (Temple et al., 2012). When a colostomy is part of the corrective procedure, skin and stomal care is a major nursing task (see Ostomies, Chapter 44).

Discharge care. After surgery, parents need instruction concerning colostomy care. Even a preschooler can be included in the care by handing articles to the parent, rolling up the colostomy pouch after it is emptied, or applying barrier preparations to the surrounding skin. Although the diagnosis of HD is less frequent in school-age children or adolescents, children this age can often be involved in colostomy care to the point of total responsibility.

Some institutions and communities have enterostomal therapists who provide expert assistance in planning home care. If families require financial assistance and psychological support, referral to a social worker, home health care agency, or community health nurse can provide continuity of care.

Vomiting

Vomiting is the forceful ejection of gastric contents through the mouth. It is a well-defined, complex, coordinated process that is under CNS control and is often accompanied by nausea and retching. Vomiting has many causes including acute infectious diseases, increased

intracranial pressure, toxic ingestions, food intolerances and allergies, mechanical obstruction of the GI tract, metabolic disorders, kidney disease, and psychogenic issues (Singhi et al., 2013). Vomiting is common in childhood, is usually self-limiting, and requires no specific treatment. However, complications may occur, including acute fluid volume loss (dehydration) and electrolyte disturbances, malnutrition, aspiration, and Mallory-Weiss syndrome (small tears in the distal esophageal mucosa).

Characteristics of the emesis and pattern of vomiting help determine the cause. The colour and consistency of the emesis vary according to the cause. Green bilious vomiting suggests bowel obstruction. Curdled stomach contents, mucus, or fatty foods that are vomited several hours after ingestion suggest poor gastric emptying or high intestinal obstruction. Gastric irritation by certain medicines, foods, or toxic substances may cause vomiting. Vomiting is also a response to psychological stress due to a rise in adrenaline levels that stimulates the chemoreceptor trigger zone. Forceful vomiting is associated with pyloric stenosis. Cyclic vomiting is a rare disorder characterized by bouts of vomiting that can last from hours to several days but between bouts, the child appears healthy and participates in normal activities. There is a lack of research on this syndrome regarding the etiology as well as evaluation of treatment protocols (Rashid et al., 2016).

Associated symptoms also help identify the cause. Fever and diarrhea accompanying vomiting suggest an infection. Constipation associated with vomiting suggests an anatomical or functional obstruction. Localized abdominal pain and vomiting often occur with appendicitis, pancreatitis, or peptic ulcer disease.

Therapeutic Management. Management is directed toward detection and treatment of the cause of the vomiting and prevention of complications, such as dehydration and malnutrition. Fluids are administered in the same manner as and in a similar electrolyte composition to those administered for diarrhea. Although most children respond to these measures, antiemetic medications may be needed. Antiemetics such as ondansetron (Zofran) and trimethobenzamide (Tigan) block receptors in the chemoreceptor trigger zone; others such as metoclopramide (Reglan) enhance gastroduodenal peristalsis; still others such as promethazine (Phenergan) compete for H_1-receptor sites (Doré-Bergeron et al., 2018). For children who are prone to motion sickness, it is helpful to administer an appropriate dose of dimenhydrinate (Gravol) before a trip.

Nursing Care. The major focus of nursing care is observing and reporting vomiting behaviour and associated symptoms and implementing measures to reduce the vomiting. Accurate assessment of the type of vomiting, the appearance of the vomitus, and the child's behaviour in association with the vomiting helps to establish a diagnosis.

The cause of the vomiting determines the nursing interventions. When the vomiting is a manifestation of improper feeding methods, establishing proper techniques through teaching and example usually corrects the situation. If vomiting is believed to be an indication of obstruction, food is usually withheld, or special feeding techniques are implemented. In situations in which vomiting is related to concurrent infection, dietary indiscretion, or emotional factors, efforts are directed toward maintaining hydration or preventing dehydration.

The thirst mechanism is the most sensitive guide to fluid needs, and ad libitum administration of a glucose-electrolyte solution to an alert child restores water and electrolytes satisfactorily. It is important to include carbohydrate to spare body protein and avoid ketosis resulting from exhaustion of glycogen stores. Small, frequent feedings of fluids or foods are preferred. After vomiting has stopped, more liberal amounts of fluids are offered, followed by gradual resumption of the regular diet.

The vomiting infant or child should be positioned on their side or semi-reclining to prevent aspiration and should be observed for evidence of dehydration. Careful monitoring of fluid and electrolyte status is necessary to prevent an electrolyte disturbance.

Gastroesophageal Reflux

Gastroesophageal reflux (GER) is defined as the transfer of gastric contents into the esophagus. This phenomenon is physiological, occurring throughout the day, most frequently after meals and at night. It is important to differentiate GER from *gastroesophageal reflux disease (GERD).* GERD represents symptoms or tissue damage that results from GER. The peak incidence of GER occurs at 4 months of age and generally resolves spontaneously in most infants before 12 months of age (Khan & Matta, 2020). GER becomes a disease when complications (e.g., failure to thrive, respiratory conditions, or dysphagia) develop (Box 46.8).

Certain conditions predispose children to a high prevalence of GERD, including neurological impairment, hiatal hernia, repaired esophageal atresia, and morbid obesity (Khan & Matta, 2020). *Sandifer syndrome* is an uncommon condition, usually occurring in young children, characterized by repetitive stretching and arching of the head and

BOX 46.8 Clinical Manifestations and Complications of Gastroesophageal Reflux

Symptoms in Infants

May have no observable clinical signs
Spitting up, regurgitation, vomiting (may be forceful)
Excessive crying, irritability, arching of the back with neck extension, stiffening
Feeding refusal, weight loss, growth failure
Respiratory issues (cough, wheeze, stridor, gagging, choking with feedings)
Hematemesis
Apnea or apparent life-threatening event

Symptoms in Children

Heartburn
Dyspepsia, abdominal pain
Noncardiac chest pain
Chronic cough
Dysphagia
Nocturnal bronchospasm and asthma
Recurrent pneumonia, pneumonitis

Complications

Esophagitis
Esophageal stricture
Laryngitis
Recurrent pneumonia
Anemia
Barrett's esophagus

Adapted from Rudolph, C. D., et al. (2001). Guidelines for evaluation and treatment of gastroesophageal reflux in infants and children: Recommendations of the North American Society for Pediatric Gastroenterology and Nutrition. *Journal of Pediatric Gastroenterology & Nutrition, 32*(Suppl 2), S1–S31.

neck that can be mistaken for a seizure. This manoeuvre likely represents a physiological neuromuscular response attempting to prevent acid refluxate from reaching the upper portion of the esophagus (Khan & Matta, 2020).

Pathophysiology. Although the pathogenesis of GER is multifactorial, its primary causative mechanism likely involves inappropriate transient relaxation of the LES. Factors that increase abdominal pressure, such as coughing and sneezing, scoliosis, and overeating, may contribute to GERD. Esophageal symptoms are caused by inflammation from the acid in the gastric refluxate, whereas reactive airway disease may result from stimulation of airway reflexes by the acid refluxate.

Diagnostic Evaluation. The history and physical examination are usually sufficiently reliable to establish the diagnosis of GER. Focused diagnostic testing, depending on the presentation and the differential diagnosis, may be used to supplement the initial examination (Khan & Matta, 2020). Some of the testing that might be done include contrast (usually barium) radiographic study of the esophagus and upper GI tract, 24-hour intraesophageal pH monitoring, and endoscopy with biopsy.

Therapeutic Management. Therapeutic management of GER depends on its severity. No therapy is needed for the infant who is thriving and has no respiratory complications. Avoidance of certain foods that exacerbate acid reflux (e.g., caffeine, citrus, tomatoes, alcohol, peppermint, and spicy or fried foods), lifestyle modifications in older children (e.g., weight control if indicated; small, more frequent meals), and feeding maneuvers in infants (e.g., thickened feedings) can improve mild GER symptoms.

In symptomatic bottle-fed infants, feeding manoeuvres such as thickened feedings if on a commercial formula and upright positioning can improve mild GER symptoms. Feedings thickened with 15 mL of rice or oat cereal per 30 mL of formula may be recommended. This supplementation may benefit infants who are underweight as a result of GERD. However, caution should be exercised when managing preterm infants because of the possible association between xanthan gum–based thickened feeds and necrotizing enterocolitis (Khan & Matta, 2020). The additional calories are not beneficial in infants who are overweight. These infants may benefit from prethickened formulas that are now commercially available. NG feedings may be necessary for infants with severe reflux and growth failure until surgery can be performed.

Seated position worsens infant reflux and should be avoided in infants with GER. When awake and observed, the prone position or upright carried position can be used to minimize reflux. Elevating the head of the bed may also decrease GER. Prone positioning of infants also decreases episodes of GER, but because of the risk for sudden infant death syndrome, all infants should sleep in the supine position (Khan & Matta, 2020). The CPS recommends supine positioning for sleep (see Chapter 35). If the prone position is used, parents need to be cautioned to avoid placing the child on soft bedding. A weight loss program may be necessary for children with GERD symptoms that occur as a result of obesity.

Pharmacological therapy may be used to treat infants and children with GERD. Both H_2-receptor antagonists (cimetidine [Tagamet], ranitidine [Zantac], or famotidine [Pepcid]) and proton pump inhibitors (PPIs; esomeprazole [Nexium], lansoprazole [Prevacid], omeprazole [Prilosec], pantoprazole [Protonix], and rabeprazole [Aciphex]) reduce gastric hydrochloric acid secretion and may stimulate some increase in LES tone. Use of available prokinetic medications (e.g., metoclopramide) remains controversial. Clinical practice guidelines recommend the use of PPIs over the H_2-receptor antagonists to alleviate symptoms and to heal esophagitis (Rosen et al., 2018).

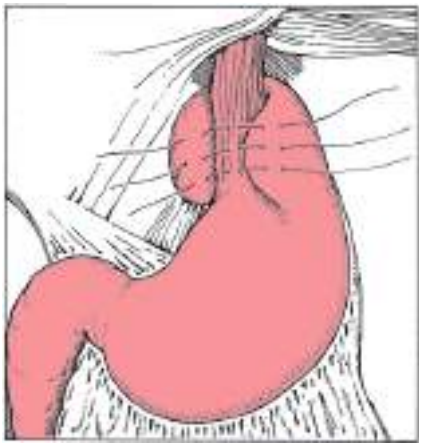

Fig. 46.4 Nissen fundoplication sutures passing through esophageal musculature. (Redrawn from Campbell, A., & Ferrara, B. [1993]. Toupet partial fundoplication: Correcting, preventing gastroesophageal reflux. *AORN Journal, 57*[3], 671–679. Copyright 1993, with permission from Elsevier.)

Surgical management of GER is reserved for children with severe complications, such as recurrent aspiration pneumonia, apnea, severe esophagitis, or growth failure, and for children who have failed to respond to medical therapy. The *Nissen fundoplication* (Figure 46.4) is the most common surgical procedure, which is commonly performed laparoscopically with outcomes of decreased time to feedings, better cosmetic results, less pain, and fewer complications (Rosen et al., 2018). This surgery involves passage of the gastric fundus behind the esophagus to encircle the distal esophagus. Long-term complications following fundoplication include breakdown of the wrap, small bowel obstruction, gas-bloat syndrome, infection, retching, and dumping syndrome.

Nursing Care. Nursing care is directed at (1) identifying children with symptoms suggestive of GER, (2) educating parents in home care, including feeding, positioning, and medications, and (3) if appropriate, providing care for the child undergoing surgical repair (see Surgical Procedures, Chapter 44). Postoperative nursing care after the fundoplication is similar to that of other laparoscopy or open abdominal surgeries.

Early in the treatment program, parents should be reassured that most infants and children outgrow GER and often conservative lifestyle changes are sufficient. Parents need support and reassurance to implement lifestyle changes. To help parents cope with the inconvenience of caring for a child who spits up frequently, simple measures such as using bibs and protective cloths during and after feedings and prone positioning when holding the infant after feeding are beneficial. It is important to educate and reassure parents about positioning. In the past, upright positioning was encouraged during sleeping for both infants and older children. However, the supine position for sleeping continues to be recommended. Parents should not place infants on their sides as an alternative to fully supine sleeping.

Rescheduling of the family's routine may be required to accommodate more frequent feeding times. If parents thicken formula with cereal, they should also enlarge the nipple opening for easier sucking. Breastfeeding should continue, and the breastfeeding parent may provide more frequent feeding times or express the milk for thickening with rice cereal. Parents should avoid feeding the child spicy foods or any foods that aggravate symptoms in general. Children should also avoid vigorous play after feedings, and feeding should occur just before bedtime.

When regurgitation is severe and growth is restricted, continuous NG tube or gastrostomy feedings may be considered; these feedings decrease the amount of emesis and provide constant buffering of gastric acid. Caregivers require special preparation when this type of nutritional therapy is indicated. See Chapter 44 for more information on tube feedings.

The nurse can support the family by providing information about all aspects of treatment. Parents often require specific information about the medications given for GERD. PPIs are most effective when administered 30 minutes before breakfast so that the peak plasma concentrations occur with mealtime. If they are given twice a day, the second best time for administration is 30 minutes before the evening meal. Parents need to be reassured of their efficacy because it takes several days of administration to achieve a steady state of acid suppression. A number of new formulations available in PPIs allow for more efficient administration. Some preparations are available in dissolvable pills. Powder and granule preparations are available as well. Many pharmacies compound the medication in a liquid form for administration.

INTESTINAL PARASITIC DISEASES

Intestinal parasitic diseases, including helminths (worms) and protozoa, constitute the most frequent infections in the world. In Canada, the incidence of intestinal parasitic disease, especially giardiasis, has increased among young children who attend day care centres. Young children are especially at risk because of typical hand–mouth activity and uncontrolled fecal activity.

Intestinal parasitic diseases in humans are caused by various infecting organisms. This discussion is limited to the two common parasitic infections among children in Canada: giardiasis and pinworms. Table 46.6 describes the outstanding features of selected helminths that belong to the family of nematodes.

Giardiasis

Giardiasis is caused by the protozoan *Giardia lamblia* (also called *Giardia intestinalis, Giardia duodenalis,* and *Lamblia intestinalis*) and is sometimes called "beaver fever." Giardiasis occurs worldwide. The potential for transmission is great because the cysts—the nonmotile

TABLE 46.6 Selected Intestinal Parasites

Clinical Manifestations	Comments
Ascariasis—*Ascaris lumbricoides* (Common Roundworm)	
Light infections: asymptomatic	Transferred to mouth by way of contaminated food, fingers, or toys
Heavy infections: anorexia, irritability, nervousness, enlarged abdomen, weight loss, fever, intestinal colic	Largest of the intestinal helminths
	Affects principally young children 1–4 yr of age
Severe infections: intestinal obstruction, appendicitis, perforation of intestine with peritonitis, obstructive jaundice, lung involvement—pneumonitis	Prevalent in warm climates
Hookworm Disease—*Necator americanus*	
Light infections in well-nourished individuals: no issues	Transmitted by discharging eggs on the soil, which are picked up, causing infection from direct skin contact with contaminated soil
Heavier infections: mild to severe anemia, malnutrition	
May be itching and burning followed by erythema and a papular eruption in areas to which the organism migrates	Wearing shoes is recommended, although children playing in contaminated soil expose many skin surfaces
Strongyloidiasis—*Strongyloides stercoralis* (Threadworm)	
Light infection: asymptomatic	Transmission is same as for hookworm (direct contact with human skin), except autoinfection (organism can complete its life cycle in humans) is common
Heavy infection: respiratory signs and symptoms; abdominal pain, distension; nausea and vomiting; diarrhea—large, pale stools, often with mucus	Older children and adults affected more often than young children
Threat to life in children with weakened immunological defences	Severe infections may lead to severe nutritional deficiency
Elevated eosinophils may be the only manifestation	Prevalent in warm climates
Visceral Larva Migrans—*Toxocara canis* (Dogs); Intestinal Toxocariasis—*Toxocara cati* (Cats)	
Depends on reactivity of infected individual	Transmitted by ingestion of or contact with soil containing eggs from feces of infected dog or cat
May be asymptomatic except for eosinophilia	Dogs and cats should be kept away from areas where children play; sandboxes are especially common transmission areas
Specific diagnosis difficult	More prevalent in hot, humid environments where eggs remain in soil
	Periodic deworming of diagnosed dogs and cats
	Control of dog and cat population
	Continued education and laws to prevent indiscriminate canine and feline defecation
Trichuriasis—*Trichuris trichiura* (Whipworm)	
Light infections: asymptomatic	Transmitted from contaminated soil or from vegetables grown in soil where eggs are present
Heavy infections: abdominal pain and distension, diarrhea	Most frequent in warm, moist climates
	Occurs most often in undernourished children living in unsanitary conditions

BOX 46.9 Clinical Manifestations of Giardiasis

Infants and young children:
- Diarrhea
- Vomiting
- Anorexia
- Growth failure

Children older than 5 years of age:
- Abdominal cramps
- Intermittent loose stools
- Constipation
- Stools may be malodourous, watery, pale, and greasy

Most infections resolve spontaneously in 4 to 6 weeks

Rarely, chronic form occurs:
- Intermittent loose, foul-smelling stools
- Possibility of abdominal bloating, flatulence, sulphur-tasting belches, epigastric pain, vomiting, headache, and weight loss

stage of the protozoa—can survive in the environment for months. Chief modes of transmission are person to person, food, and animals, especially puppies. Contaminated water, especially in mountain lakes and streams, and swimming or wading pools frequented by diapered infants are common sources of transmission. In children, person-to-person transmission is the most likely cause. Child care centres and institutions providing care for persons with developmental disabilities are common sites for urban giardiasis, and the children may pass cysts for months. Although individuals infected with giardiasis may be asymptomatic, common symptoms include abdominal cramps and diarrhea (Box 46.9).

Diagnosis of giardiasis may be made by microscopic examination of stool specimens or duodenal fluid or by identification of *G. lamblia* antigens in these specimens using techniques such as enzyme immunoassay (EIA). Because the *Giardia* organisms live in the upper intestine and are excreted in a highly variable pattern, repeated microscopic examination of stool specimens may be required to identify *trophozoites* (active parasites) or cysts. Duodenal specimens are obtained by direct aspiration, biopsy, or the *string* test. In the string test, the child swallows a gelatin capsule with a nylon string attached. Several hours later, the string is withdrawn, and the contents are sent for laboratory analysis. With the availability of EIA techniques to identify *Giardia* antigens in stool specimens, other tests are being used less often.

Therapeutic Management. The medications of choice for treatment of giardiasis are metronidazole (Flagyl), tinidazole (Tindamax), paromomycin (Humatin), and nitazoxanide (Alinia). Tinidazole is said to have an 80 to 100% cure rate after a single dose and has fewer adverse effects than metronidazole. Metronidazole and tinidazole have a metallic taste and GI adverse effects, including nausea and vomiting; nitazoxanide has no bitter taste and should be taken with food to avoid GI symptoms (AAP, Committee on Infectious Diseases, 2018).

Nursing Care. The most important nursing consideration in prevention of giardiasis is education of parents, child care centre staff, and those who are entrusted with the daily care of small children regarding appropriate sanitation practices. Attention to meticulous sanitary practices during diaper changes is essential (Figure 46.5). In addition, young children who are infected or who have diarrhea should be discouraged from swimming in community or private pools until they are infection free. Lakes and streams may contain high numbers of *Giardia* spore cysts, which can be swallowed in the water. Children should be discouraged from swimming in stagnant bodies of water and in water where children who are known to be infected are swimming. After children are infected, family education regarding medication administration is essential.

Fig. 46.5 Prevention of giardiasis, especially in day care centres, requires sanitary practices during diaper changes, such as discarding paper diapers in a covered receptacle, changing paper covers on the diaper-changing surface, and having facilities for hand hygiene nearby. Note: Soiled cloth diapers and clothing should be stored in a plastic bag for transport home.

Enterobiasis (Pinworms)

Enterobiasis, or pinworms, caused by the nematode *Enterobius vermicularis*, is a common helminthic infection in Canada. It is universally present in temperate climatic zones and may infect more than 30% of all children at any one time. Crowded conditions such as in classrooms and day care centres favour transmission.

Infection begins when the eggs are ingested or inhaled (they float in the air). The eggs hatch in the upper intestine and then mature and migrate through the intestine. After mating, adult females migrate out the anus and lay eggs. The movement of the worms on skin and mucous membrane surfaces causes intense itching. As the child scratches, eggs are deposited on the hands and underneath the fingernails. The typical hand-to-mouth activity of youngsters makes them especially prone to reinfection. Pinworm eggs persist in the indoor environment for 2 to 3 weeks, contaminating anything they contact, such as toilet seats, doorknobs, bed linen, underwear, and food. Except for the intense rectal itching associated with pinworms, the clinical manifestations are nonspecific (Box 46.10).

Diagnostic Evaluation. Diagnosis is most commonly made from the tape test (see Nursing Care). Repeated tests to collect eggs may be necessary, and if there is a possibility that other family members may be infected, a tape test should be performed on them as well.

Therapeutic Management. The medications available for treatment of pinworms include mebendazol (Vermox) and nonprescription pyrantel pamoate (Combatrin). The medication of choice is mebendazole,

BOX 46.10 Clinical Manifestations of Pinworms

Intense perianal itching (principal symptom); evidence of itching in young children includes the following:
- General irritability
- Restlessness
- Poor sleep
- Bed-wetting
- Distractibility
- Short attention span

Perianal dermatitis and excoriation secondary to itching
If worms migrate, possible vaginal (vulvovaginitis) and urethral infection

which is safe, effective, and convenient, with few adverse effects; however, it is not recommended for children younger than 2 years of age. If pyrvinium pamoate is prescribed, parents should be advised that the medication stains stool and vomitus bright red, as well as clothing or skin that comes in contact with it. Because pinworms are easily transmitted, all household members are treated. The dose of antiparasitic medication should be repeated in 2 weeks to completely eradicate the parasite and prevent reinfection.

Nursing Care. Nursing care is directed at identifying the parasite, eradicating the organism, and preventing reinfection. Parents need clear, detailed instructions for the tape test. A loop of transparent (not "frosted" or "magic") tape, sticky side out, is placed around the end of a tongue depressor, which is then firmly pressed against the child's perianal area. A convenient, commercially prepared tape is also available for this purpose. Pinworm specimens are collected in the morning as soon as the child awakens and *before* they have a bowel movement or bathe. The procedure may need to be performed on three or more consecutive days before eggs are collected. Parents should be instructed to place the tongue blade in a glass jar or loosely in a plastic bag so that it can be brought in for microscopic examination. For specimens collected in the hospital, health care provider's office, or clinic, the tape is placed smoothly on a glass slide, sticky side down, for examination.

Adherence to the medication regimen is usually excellent because the duration of treatment is typically only one dose. However, the family should be reminded of the need to take a second dose in 2 weeks to ensure eradication of the eggs.

To prevent reinfection, washing all clothes and bed linens in hot water and vacuuming the house may be recommended. However, there is little documentation on the effectiveness of these measures because pinworms survive on many surfaces. Helpful suggestions include hand hygiene after toileting and before eating, keeping the child's fingernails short to minimize the chance of ova collecting under the nails, dressing children in one-piece sleeping outfits, and daily showering rather than tub bathing. Families should be informed that recurrence is common. Repeated infections should be treated in the same manner as the first one.

INFLAMMATORY DISORDERS

Acute Appendicitis

Appendicitis, inflammation of the *vermiform appendix* (blind sac at the end of the cecum), is the most common cause of emergency abdominal surgery in childhood. The peak age of children with appendicitis is between 10 and 18 years, it is rare in children younger than 5 years of age (Aiken, 2020). Classically, the first symptom of appendicitis is periumbilical pain, followed by nausea, right lower quadrant pain, and later vomiting with fever. More than 50% of patients have an atypical presentation (Aiken, 2020). Perforation of the appendix can occur within approximately 48 hours after the first sign of pain. At the time of initial presentation, about one third of all cases involve an already perforated appendix. Complications from appendiceal perforation include major abscess, phlegmon, enterocutaneous fistula, peritonitis, and partial bowel obstruction. A *phlegmon* is an acute suppurative inflammation of subcutaneous connective tissue that spreads.

Etiology. The cause of appendicitis is obstruction of the lumen of the appendix, usually by hardened fecal material (fecalith). Swollen lymphoid tissue, frequently occurring after a viral infection, can also obstruct the appendix. Another rare cause of obstruction is a parasite such as *Enterobius vermicularis*, or pinworms, which can obstruct the appendiceal lumen.

Pathophysiology. With acute obstruction, the outflow of mucus secretions is blocked, and pressure builds within the lumen, resulting in compression of blood vessels. The resulting ischemia is followed by ulceration of the epithelial lining and bacterial invasion. Subsequent necrosis causes perforation or rupture with fecal and bacterial contamination of the peritoneal cavity. The resulting inflammation spreads rapidly throughout the abdomen (*peritonitis*), especially in young children, who are unable to localize infection. Progressive peritoneal inflammation results in functional intestinal obstruction of the small bowel (*ileus*) because intense GI reflexes severely inhibit bowel motility. Because the peritoneum represents a major portion of total body surface, the loss of ECF to the peritoneal cavity leads to electrolyte imbalance and hypovolemic shock.

Diagnostic Evaluation. Diagnosis is not always straightforward. Fever, vomiting, abdominal pain, and an elevated white blood cell (WBC) count are associated with appendicitis but are also seen in IBD, pelvic inflammatory disease, gastroenteritis, urinary tract infection, right lower lobe pneumonia, mesenteric adenitis, Meckel diverticulum, and intussusception. Prolonged symptoms and delayed diagnosis often occur in younger children, in whom the risk of perforation is greatest because of their inability to verbalize their symptoms. In addition to fever, signs of peritonitis include sudden relief from pain after perforation, subsequent increase in pain (usually diffuse and accompanied by rigid guarding of the abdomen), progressive abdominal distension, tachycardia, rapid shallow breathing, pallor, chills, and irritability.

The diagnosis is based primarily on the history and physical examination (Box 46.11). Pain, the cardinal feature, is initially generalized (usually periumbilical); however, it usually descends to the lower right quadrant. The most intense site of pain may be at *McBurney point*, located at a point midway between the anterior superior iliac crest and the umbilicus. Rebound tenderness is not a reliable sign and is extremely painful to the child. Referred pain, elicited by light percussion around the perimeter of the abdomen, indicates peritoneal irritation. Movement such as riding over bumps in an automobile or on a stretcher aggravates the pain. In addition to pain, significant clinical manifestations include fever, a change in behaviour, anorexia, and vomiting.

Laboratory studies usually include a CBC, urinalysis (to rule out a urinary tract infection), and, in adolescent females, serum human chorionic gonadotropin (to rule out an ectopic pregnancy). A WBC count greater than 10×10^6/L and an elevated C-reactive protein (CRP) are common but are not necessarily specific for appendicitis. An elevated percentage of bands (often referred to as "a shift to the left") may

BOX 46.11 Clinical Manifestations of Appendicitis

- Right lower-quadrant abdominal pain
- Fever
- Rigid abdomen
- Decreased or absent bowel sounds
- Vomiting (typically follows onset of pain)
- Constipation or diarrhea may be present
- Anorexia
- Tachycardia; rapid, shallow breathing
- Pallor
- Lethargy
- Irritability
- Stooped posture (guarding)

indicate an inflammatory process. CRP is an acute-phase reactant that rises within 12 hours of the onset of infection.

Ultrasound has emerged as the first-choice tool for children requiring an imaging study in the evaluation of suspected acute appendicitis. Ultrasound is effective in pediatric centres experienced with the technique and is often more readily available and quicker, and avoids the use of sedation, contrast agents, and radiation exposure. Computed tomography (CT) scanning is the gold standard imaging study for evaluating children with suspected appendicitis, but it is often not as easily accessed and there are the negative effects of exposure to ionizing radiation (Aiken, 2020).

! NURSING ALERT

Signs of peritonitis, in addition to fever, include sudden relief from pain after perforation; subsequent increase in pain (usually diffuse and accompanied by rigid guarding of the abdomen); progressive abdominal distension; tachycardia; rapid, shallow breathing; pallor; chills; irritability; and restlessness.

Therapeutic Management. Treatment of appendicitis before perforation includes rehydration, antibiotics, and surgical removal of the appendix (appendectomy). Laparoscopic surgery is now commonly used to treat nonperforated acute appendicitis, and some surgeons will use laparoscopy with a perforated appendix (Aiken, 2020). Recovery is rapid and, if no complications occur, the hospital stay is short. Antibiotics should be initiated promptly once the diagnosis of appendicitis is made or highly suspected, as they lower the risk of postoperative complications.

Nonsurgical treatment for ruptured appendix is becoming more common. Advantages of the antibiotic-alone/nonoperative approach in acute appendicitis include avoidance of surgical complications and the risk of general anaesthesia, as well as not undergoing an operative procedure. Children who are selected for this type of treatment usually receive 1 to 2 days of IV broad-spectrum antibiotics and pain control. If the child demonstrates clinical recovery by resolution of pain and fever and is tolerating a general diet, they are discharged to complete 7 to 10 days of oral antibiotics (Aiken, 2020).

Ruptured appendix. Management of the child diagnosed with peritonitis caused by a ruptured appendix often begins preoperatively with IV administration of fluid and electrolytes, systemic antibiotics, and NG compression. Postoperative management includes IV fluids, continued administration of antibiotics, and NG suction for abdominal decompression until intestinal activity returns. Sometimes surgeons close the wound after irrigation of the peritoneal cavity. Other times, they leave the wound open (delayed closure) to prevent wound infection. A Penrose drain may be used to permit transperitoneal drainage.

Nursing Care. Because abdominal pain is the most common childhood discomfort with appendicitis, it is important to assess the severity of pain (see Pain Assessment, Chapter 34). One of the most reliable estimates is the degree of change in behaviour. The younger, nonverbal child will assume a rigid, motionless, side-lying posture with the knees flexed on the abdomen, and there is decreased range of motion of the right hip. Older children may exhibit all of these behaviours along with abdominal pain. They can always indicate a point at which the pain is worse than at any other location.

! NURSING ALERT

In any instance when appendicitis is suspected, be aware of the danger of administering laxatives or enemas or applying heat to the area. Such measures stimulate bowel motility and increase the risk of perforation.

Postoperative care. Postoperative care for the nonperforated appendix is the same as for most abdominal procedures. Care of the child with a ruptured appendix and peritonitis is more complex, and the course of recovery is considerably longer. The child is maintained on IV fluids, nothing per mouth (NPO), and the NG tube is kept on low continuous gastric decompression until there is evidence of intestinal activity. Listening for bowel sounds and observing for other signs of bowel activity (e.g., passage of flatus or stool) are part of the routine assessment. Management of IV therapy is the same as for any child receiving fluids and parenteral antibiotics. A drain is often placed in the wound during surgery, and frequent dressing changes with meticulous skin care are essential to prevent excoriation of the area surrounding the surgical site. Wound care includes irrigation with antibacterial solution. Early ambulation with adequate pain management assists in preventing many of the complications associated with prolonged bed rest and immobility (e.g., venous stasis, bowel hypomotility, abdominal pain from intestinal gas).

Management of pain from the incision and repeated dressing changes and irrigations are an essential part of the child's care. Because pain is continuous during the first few postoperative days, analgesics are given regularly to control pain. Procedures are performed when the analgesics are at peak effect.

Psychological care of the child and parents is similar to that used in other **emergency** situations. Parents and older children may want to express their feelings and concerns regarding the events surrounding the illness and hospitalization. The nurse can provide education and psychosocial support to promote adequate coping and alleviate anxiety for both the child and the family. (See Nursing Care Plan: The Child with Appendicitis, available on Evolve.)

Meckel Diverticulum

Meckel diverticulum is a remnant of the fetal omphalomesenteric duct that connects the yolk sac with the primitive midgut during fetal life. Normally this structure is obliterated by the seventh to eighth week of gestation, when the placenta replaces the yolk sac as the source of nutrition for the fetus (Kennedy et al., 2020). Failure of obliteration may result in an *omphalomesenteric fistula*, a fibrous band connecting the small intestine to the umbilicus, known as *Meckel diverticulum*.

Meckel diverticulum is a true diverticulum because it arises from the antimesenteric border of the small intestine and contains all layers of the intestinal wall. The diverticulum is usually found within 40 to 50 cm of the ileocecal valve and averages 1 to 10 cm in length. Meckel

diverticulum is found in approximately 2% of the general population, generally presents before the age of 2 years, and is found twice as commonly in females (Kennedy et al., 2020).

Pathophysiology. Bleeding, obstruction, or inflammation causes the symptomatic complications of Meckel diverticulum. Bleeding, which is the most common issue in children, is caused by peptic ulceration or perforation because of the unbuffered acidic secretion. Several mechanisms can cause obstruction, such as intussusception or entanglement of the small intestine.

Diagnostic Evaluation. Diagnosis is usually based on the history, physical examination, and a specialized radiographic study but can be difficult to diagnose. A technetium-99m pertechnetate scan (Meckel scan) can detect the presence of gastric mucosa with an overall diagnostic accuracy of 85%. CT scanning, wireless capsule endoscopy, and mesenteric angiography may be used to investigate complications (Kennedy et al., 2020). Laboratory studies are usually part of the general workup to rule out any bleeding disorder and evaluate the severity of the anemia.

The most common clinical presentation in children includes painless rectal bleeding, abdominal pain, or signs of intestinal obstruction (Box 46.12). Bleeding, which may be mild or profuse, often appears as dark red or "currant jelly" stools; it may be significant enough to cause hypotension. Blood studies are performed to screen for bleeding disorders and anemia.

Therapeutic Management. The standard treatment is surgical removal of the diverticulum. When severe hemorrhage increases the surgical risk, interventions to correct hypovolemic shock, such as blood replacement, IV fluids, and oxygen, may be necessary. Antibiotics may be used preoperatively to control infection. If intestinal obstruction has occurred, appropriate preoperative measures are used to reverse electrolyte imbalances and minimize abdominal distension.

Prognosis. If this condition is diagnosed and treated early, full recovery is likely. The mortality rate of untreated Meckel diverticulum is approximately 6% (Caracappa et al., 2014). Complications of untreated Meckel's diverticulum include GI hemorrhage and bowel obstruction.

Nursing Care. Nursing care is the same as for any child undergoing abdominal surgery (see Chapter 43). When intestinal bleeding is present, specific preoperative considerations include frequent monitoring of vital signs, including blood pressure and recording the approximate amount of blood lost in stools. Pain management is essential to preoperative and postoperative care of the child with this condition.

Postoperatively, the child requires IV fluids and an NG tube for decompression and evacuation of gastric secretions; laparoscopic surgery may avoid the necessity for an NG tube. Signs of return of normal bowel function should be monitored in the postoperative period. Because the onset of illness is usually rapid, psychological support is important, as in other acute conditions, such as appendicitis. It is important to remember that rectal bleeding is usually traumatic to both the child and the parents and may significantly affect their emotional reaction to hospitalization and surgery.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) should not be confused with irritable bowel syndrome (IBS). IBD is a term used for two forms of chronic intestinal inflammation: ulcerative colitis (UC) and Crohn disease (CD). Although UC and CD have similar epidemiological, immunological, and clinical features, they are distinct disorders (Table 46.7).

In addition to GI symptoms, both CD and UC are characterized by extraintestinal and systemic inflammatory responses. Exacerbations and remissions without complete resolution are also characteristics of IBD. Growth failure, which is particularly common in CD, is an important challenge unique to the pediatric population. CD is more disabling, has more serious complications, and has less effective medical and surgical treatment than UC.

Approximately 0.7% of the Canadian population has IBD, which is one of the highest incidence and prevalence rates of IBD yet reported. IBD affects all age groups, with adolescents and young adults at highest risk of diagnosis (Kaplan et al., 2019).

Etiology. Despite decades of research, the etiology of IBD is not completely understood, and there is no known cure. There is evidence to indicate a multifactorial etiology. Research has focused on theories of defective immunoregulation of the inflammatory response to bacteria or viruses in the GI tract in individuals with a genetic predisposition. In CD the chronic immune process is characterized by a T-helper-1 cytokine profile, whereas in UC the response is more humoral and mediated by T-helper-2 cells (Stein & Baldassano, 2020).

Environmental factors also appear to play a role in the development of IBD. Breastfeeding decreases the risk of developing CD, whereas infantile diarrhea seems to increase the risk. Cigarette smoking also

Similar to appendicitis
May be vague and recurrent

Bloody Stools*
Painless
Bright or dark red with mucus ("currant jelly" stool)
In infants, bleeding may be accompanied by pain

Sometimes
Severe anemia
Shock

*Often an initial sign.

TABLE 46.7 Clinical Manifestations of Inflammatory Bowel Diseases

Characteristics	Ulcerative Colitis	Crohn Disease
Rectal bleeding	Common	Uncommon
Diarrhea	Often severe	Moderate to severe
Pain	Less frequent	Common
Anorexia	Mild or moderate	May be severe
Weight loss	Moderate	May be severe
Growth delay	Usually mild	May be severe
Anal and perianal lesions	Rare	Common
Fistulas and strictures	Rare	Common
Rashes	Mild	Mild
Joint pain	Mild to moderate	Mild to moderate

appears to be a risk factor for CD but appears to be protective against UC (Stein & Baldassano, 2020).

Pathophysiology of Ulcerative Colitis. The inflammation is limited to the colon and rectum, with the distal colon and rectum most severely affected. Inflammation affects the mucosa and submucosa and involves continuous segments along the length of the bowel with varying degrees of ulceration, bleeding, and edema. The presentation may be mild, moderate, or severe, depending on the extent of mucosal inflammation and systemic symptoms. Children with UC usually are seen with diarrhea, rectal bleeding, and abdominal pain, often associated with tenesmus and urgency. Thickening of the bowel wall and fibrosis are unusual, but long-standing disease can result in shortening of the colon and strictures. Extraintestinal manifestations are less common in UC than in CD. Toxic megacolon is the most dangerous form of severe colitis.

Pathophysiology of Crohn Disease. The chronic inflammatory process of CD involves any part of the GI tract from the mouth to the anus but most often affects the terminal ileum. The disease involves all layers of the bowel wall (*transmural*) in a discontinuous fashion, meaning that between areas of intact mucosa there are areas of affected mucosa (*skip lesions*). The most common symptoms are abdominal pain, diarrhea, and decrease in appetite resulting in weight loss. Perianal disease, including skin tags, fistulas, and abscesses, occur in CD. Fever, growth delay, and delayed sexual development are seen commonly. Mild GI symptoms, poor growth, and extraintestinal manifestations may be present for several years before overt GI symptoms occur. The inflammation may result in ulcerations, fibrosis, adhesions, stiffening of the bowel wall, stricture formation, and fistulas to other loops of bowel, bladder, vagina, or skin. Extraintestinal manifestations include erythema nodosum, pyoderma gangrenosum, arthralgia and arthritis, uveitis and episcleritis, sclerosing cholangitis, autoimmune hepatitis, nephrolithiasis, and pneumonitis.

Diagnostic Evaluation. The diagnosis of UC and CD is derived from the history, physical examination, laboratory evaluation, and other diagnostic procedures. Laboratory tests include a CBC to evaluate anemia and an erythrocyte sedimentation rate (ESR) or CRP to assess the systemic reaction to the inflammatory process. Levels of total protein, albumin, iron, zinc, magnesium, vitamin B_{12}, and fat-soluble vitamins may be low in children with CD. Stools are examined for blood, leukocytes, and infectious organisms. A serological panel is often used in combination with clinical findings to diagnose IBD and to differentiate between CD and UC.

In patients with CD, an upper GI series with small bowel follow-through assists in assessing the existence, location, and extent of disease. Upper endoscopy and colonoscopy with biopsies are an integral part of diagnosing IBD. Endoscopy allows direct visualization of the surface of the GI tract so that the extent of inflammation and narrowing can be evaluated. CT and ultrasound also may be used to identify bowel wall inflammation, intra-abdominal abscesses, and fistulas. Colonoscopy can be used to confirm the diagnosis and evaluate the extent of the disease. Discrete ulcers are commonly seen in patients with CD, whereas microulcers and diffuse abnormalities and inflammation are seen in patients with UC (Stein & Baldassano, 2020). CD lesions may pierce the walls of the small intestine and colon, creating tracts called *fistulas* between the intestine and adjacent structures such as the bladder, anus, vagina, or skin.

Therapeutic Management. The course of IBD continues to be unpredictable with flareups that can severely impair physical and social functioning. The goals of therapy are to (1) control the inflammatory process to reduce or eliminate the symptoms, (2) obtain long-term remission, (3) promote healthy growth and development, and (4) promote a lifestyle that allows the child to maintain relationships and activities with peers. Treatment is individualized and managed according to the type and severity of the disease, its location, and the response to therapy. CD is more disabling, has more serious complications, and is often less amenable to medical and surgical treatment than is UC. Because UC is confined to the colon, a colectomy may cure UC.

Medical treatment. The goal of any treatment regimen is first to induce remission of acute symptoms and then to maintain remission over time. Treatment with 5-aminosalicylates (5-ASAs) is effective in the induction and maintenance of remission in mild to moderate UC. Mesalamine, olsalazine, and balsalazide are now preferred over sulfasalazine because of reduced adverse effects (headache, nausea, vomiting, neutropenia, and oligospermia). Suppository and enema preparations of mesalamine are used to treat left-sided colitis. These medications decrease inflammation by inhibiting prostaglandin synthesis. 5-ASAs can be used to induce remission in mild CD.

Corticosteroids, such as prednisone and prednisolone, are indicated in induction therapy in children with moderate to severe UC and CD. These agents inhibit the production of adhesion molecules, cytokines, and leukotrienes. Although these medications reduce the acute symptoms of IBD, they have adverse effects that relate to long-term use, including growth suppression (adrenal suppression), weight gain, and decreased bone density. High doses of IV corticosteroids may be administered in acute episodes and tapered according to clinical response. Budesonide, a synthetic corticosteroid, is designed for controlled release in the ileum and is indicated for ileal and right-sided colitis; budesonide has fewer adverse effects than prednisone and prednisolone. Rectal steroid therapy (enemas and foam-based preparations) is available for both induction and maintenance therapy in left-sided colitis.

Immunomodulators, such as azathioprine and its metabolite 6-mercaptopurine (6-MP), are used to induce and maintain remission in children with IBD who are steroid resistant or steroid dependent and in treating chronic draining fistulas. They block the synthesis of purine, thus inhibiting the ability of DNA and RNA to hinder **lymphocyte** function, especially that of T cells. Adverse effects include infection, pancreatitis, hepatitis, bone marrow toxicity, arthralgia, and malignancy. Methotrexate has also been shown to be useful in inducing and maintaining remission in CD patients unresponsive to standard therapies. Cyclosporine and tacrolimus have both been shown to be effective in inducing remission in severe steroid-dependent UC. 6-MP or azathioprine is then used to maintain remission. Patients on immunomodulating medications require regular monitoring of their CBC and differential to assess for changes that reflect suppression of the immune system, since many of the adverse effects can be prevented or managed by dose reduction or discontinuation of medication.

Antibiotics, such as metronidazole and ciprofloxacin, may be used as an adjunctive therapy to treat complications, such as perianal disease or small bowel bacterial overgrowth, in CD. Adverse effects of these medications are peripheral neuropathy, nausea, and a metallic taste.

Biological therapies are complex molecular structures derived from living cells that act to regulate inflammatory and anti-inflammatory cytokines like tumour necrosis factor-alpha (TNF-α), which is believed to influence active inflammation. Biological therapy has rapidly advanced in recent years and there are now multiple medication options for the treatment of children with both CD and UC. These treatments are quickly supplanting traditional treatments, especially when first-line therapy is not successful. Biologics have revolutionized the treatment of IBD and most children are able to achieve remission of symptoms (Crohn's and Colitis Canada, 2019). Biologics are generally

well tolerated but are costly and require either subcutaneous injection or IV administration.

Emerging therapies for IBD that are currently being investigated include cannabis use, fecal transplantation, and stem-cell therapy. While these show varying degrees of promise, none are currently approved as therapy for children in Canada (Crohn's and Colitis Canada, 2019).

Nutritional support. Nutritional support is important in the treatment of IBD. Growth failure is a common serious complication, especially in CD. It is characterized by weight loss, alteration in body composition, restricted height, and delayed sexual maturation. Malnutrition causes the growth failure, and its etiology is multifactorial. Malnutrition occurs as a result of inadequate dietary intake, excessive GI losses, malabsorption, medication–nutrient interaction, and increased nutritional requirements. Inadequate dietary intake occurs with anorexia and episodes of increased disease activity. Excessive loss of nutrients (protein, blood, electrolytes, and minerals) occurs secondary to intestinal inflammation and diarrhea. Carbohydrate, lactose, fat, vitamin, and mineral malabsorption and vitamin B_{12} and folic acid deficiencies occur with disease episodes and with medication administration and when the terminal ileum is resected. Nutritional requirements are increased with inflammation, fever, fistulas, and periods of rapid growth (e.g., adolescence).

The goals of nutritional support include (1) correction of nutrient deficits and replacement of ongoing losses, (2) provision of adequate energy and protein for healing, and (3) provision of adequate nutrients to promote normal growth. Nutritional support includes both enteral and parenteral nutrition. A well-balanced, high-protein, high-calorie diet is recommended for children whose symptoms do not prohibit an adequate oral intake. There is little evidence that avoiding specific foods influences the severity of the disease. Supplementation with multivitamins, iron, and folic acid is recommended.

Special enteral formulas, given either by mouth or continuous enteral (NG or gastrostomy) infusion (often at night), may be required. Elemental formulas are completely absorbed in the small intestine with almost no residue. Several studies have demonstrated that a diet consisting only of elemental formula not only improved nutritional status but also induced disease remission, either without steroids or with a diminished dosage of steroids required. An elemental diet is a safe and potentially effective primary therapy for patients with CD. Unfortunately, remission is not sustained when enteral feedings are discontinued unless maintenance medications are added to the treatment regimen.

TPN has also improved nutritional status in patients with IBD. Short-term remissions have been achieved after TPN, although complete bowel rest has not reduced inflammation or added to the benefits of improved nutrition by TPN. Nutritional support is less likely to induce a remission in UC than in CD. However, improvement of nutritional status is important in preventing deterioration of the patient's health status and in preparing them for surgery.

Surgical treatment. Surgery is indicated for UC when medical and nutritional therapies fail to prevent complications. Surgical options include a subtotal colectomy and ileostomy, leaving a rectal stump as a blind pouch. A reservoir pouch is created in the configuration of a J or S to help improve continence postoperatively. An ileoanal pull-through preserves the normal pathway for defecation. *Pouchitis*, an inflammation of the surgically created pouch, is the most common late complication of this procedure and has been reported to occur in up to 50% of cases. Metronidazole and ciprofloxacin are effective in treating pouchitis. Ciprofloxacin has fewer adverse effects. In many cases UC can be cured with a total colectomy.

Surgery may be required in children with CD when complications cannot be controlled by medical and nutritional therapy. Segmental intestinal resections are performed for small bowel obstructions, strictures, or fistulas. Partial colonic resection is not curative, and the disease often recurs.

Prognosis. IBD is a chronic disease. Relatively long periods of quiescent disease may follow exacerbations. The outcome of the disease is influenced by the regions and severity of involvement, as well as by appropriate therapeutic management. Malnutrition, growth failure, and bleeding are serious complications. The overall prognosis for UC is good.

The development of colorectal cancer (CRC) is a long-term complication of IBD. Beyond the first decade of disease, the risk of development of colon cancer begins to increase rapidly. The risk of colon cancer may be diminished with surveillance colonoscopies beginning after 8 to 10 years of the disease. Detection of significant dysplasia on biopsy would prompt colectomy (Stein & Baldassano, 2020).

Nursing Care. The nursing considerations in the management of IBD extend beyond the immediate period of hospitalization. These interventions involve continued guidance of families in terms of (1) managing diet, (2) coping with factors that increase stress and emotional lability, (3) adjusting to a disease of remissions and exacerbations, and (4) when indicated, preparing the child and parents for the possibility of diversionary bowel surgery.

Because nutritional support is an essential part of therapy, encouraging the anorectic child to consume sufficient quantities of food is often a challenge. Successful interventions include involving the child in meal planning; encouraging small, frequent meals or snacks rather than three large meals a day; serving meals around medication schedules when diarrhea, mouth pain, and intestinal spasm are controlled; and preparing high-protein, high-calorie foods such as eggnog, milkshakes, cream soups, puddings, or custard (if lactose is tolerated) (see Feeding the Sick Child, Chapter 44). Foods that are known to aggravate the condition should be avoided. Using bran or a high-fibre diet for active IBD is questionable. Bran, even in small amounts, has been shown to worsen the patient's condition. Occasionally the occurrence of aphthous **stomatitis** (mouth ulcers) further complicates adherence to dietary management. Mouth care before eating and the selection of bland foods can help relieve the discomfort of mouth sores.

When NG feedings or TPN are indicated, nurses play an important role in explaining the purpose and expected outcomes of this therapy. The nurse should acknowledge the anxieties of the child and family members and give them adequate time to demonstrate the skills necessary to continue the therapy at home, if needed (see Clinical Reasoning Case Study: Inflammatory Bowel Disease).

The importance of continued medication therapy despite remission of symptoms must be stressed to the child and family members. Failure to adhere to the pharmacological regimen can result in exacerbation of the disease. Unfortunately, exacerbation of IBD can occur even if the child and family adhere to the treatment regimen; this can be difficult for the child and family to cope with.

CLINICAL REASONING CASE STUDY

Inflammatory Bowel Disease

Susan, a 13-year-old girl, was admitted to the hospital because of bloody diarrhea, abdominal pain, and weight loss. After a thorough evaluation, including laboratory tests, radiographic studies, and GI endoscopy procedures, the diagnosis of Crohn disease was made. Medical treatment, including corticosteroid medications and nutritional support, was implemented during this hospitalization.

Susan has improved considerably and is to be discharged home this week. Enteral formula administered by continuous nighttime nasogastric (NG) tube

Continued

CLINICAL REASONING CASE STUDY—CONT'D

infusion will be continued at home, and both Susan and her family are eager to learn how to perform these feedings. You are the nurse who is responsible for Susan's discharge planning.

Questions

1. Evidence—Are there sufficient data to formulate any specific interventions for discharge?
2. Assumptions—Describe some underlying assumptions about the following:
   a. The goals of nutritional support for children with Crohn disease
   b. Teaching required by an adolescent or family member who is administering NG tube feedings at home
   c. Psychosocial issues related to Crohn disease
3. What are the priorities for discharge planning at this time?

Supporting the family. The nurse needs to attend to the emotional components of the disease and assess any sources of stress. Frequently, the nurse can help children adjust to challenges of growth restriction, delayed sexual maturation, dietary restrictions, feelings of being "different" or "sickly," inability to compete with peers, and necessary absence from school during exacerbations of the illness. See Chapter 41 for further information on coping with chronic illness.

If a permanent colectomy-ileostomy is required, the nurse can teach the child and family how to care for the ileostomy. The nurse can also emphasize the positive aspects of the surgery, particularly accelerated growth and sexual development, permanent recovery, eliminated risk of colon cancer in UC, and normality of life despite bowel diversion. Introducing the child and parents to other ostomy patients, especially children who are the same age, can be effective in fostering eventual acceptance. Whenever possible, continent ostomies should be offered as options to the child.

Because of the chronic and often lifelong nature of the disease, families may benefit from the educational services provided by organizations such as the Crohn's and Colitis Foundation of Canada (CCFC) (see Additional Resources at the end of this chapter). Adolescents often benefit by participating in peer-support groups, which are sponsored by the CCFC.

Peptic Ulcer Disease

Peptic ulcer disease (PUD) is a chronic condition that affects the stomach or duodenum. Ulcers are described as gastric or duodenal and as primary or secondary. A *gastric ulcer* involves the mucosa of the stomach; a *duodenal ulcer* involves the pylorus or duodenum. Most primary ulcers are idiopathic or associated with *Helicobacter pylori* infection and tend to be chronic, occurring more frequently in the duodenum (Blanchard & Czinn, 2020). *Secondary ulcers* result from the stress of a severe underlying disease or injury (e.g., severe burns, sepsis, increased intracranial pressure, severe trauma, multisystem organ failure) and are more frequently gastric with an acute onset (Blanchard & Czinn, 2020).

About 1.8 to 5% of children in North America are diagnosed with PUD (Sullivan, 2010). Primary ulcers are more common in children older than 10 years of age, and secondary ulcers are more common in infants and children with underlying disease, and children taking nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, or sodium valproate medications (Sullivan, 2010).

Etiology. The exact cause is unknown, although infectious, genetic, and environmental factors are important. There is a significant relationship between the bacterium *Helicobacter pylori* and ulcers. *H. pylori* is a microaerophilic, Gram-negative, slow-growing, spiral-shaped, and flagellated bacterium known to colonize the gastric mucosa in about half of the population of the world (Blanchard & Czinn, 2020). *H. pylori* synthesizes the enzyme urease, which hydrolyzes urea to form ammonia and carbon dioxide. Ammonia then absorbs acid to form ammonium, thus raising the gastric pH. *H. pylori* may cause ulcers by weakening the gastric mucosal barrier and allowing acid to damage the mucosa. It is believed that it is acquired via the fecal–oral route; this hypothesis is supported by finding viable *H. pylori* in feces.

In addition to ulcerogenic medications, both alcohol and smoking contribute to ulcer formation. There is no conclusive evidence to implicate particular foods such as caffeine-containing beverages or spicy foods, but polyunsaturated fats and fibre may play a role in ulcer formation. Psychological factors may play a role in the development of PUD, and stressful life events, dependency, passiveness, and hostility have all been implicated as contributing factors.

Pathophysiology. Most likely, the pathology is due to an imbalance between the destructive (cytotoxic) factors and defensive (cytoprotective) factors in the GI tract. The toxic mechanisms include acid, pepsin, medications such as Aspirin and NSAIDs, bile acids, and infection with *H. pylori*. The defensive factors include the mucus layer, local bicarbonate secretion, epithelial cell renewal, and mucosal blood flow. The primary mechanism that prevents the development of peptic ulcer is the secretion of mucus by the epithelial and mucous glands throughout the stomach. The thick mucus layer acts to diffuse acid from the lumen to the gastric mucosal surface, thus protecting the gastric epithelium. The stomach and duodenum produce bicarbonate, decreasing acidity on the epithelial cells and thereby minimizing the effects of the low pH. When abnormalities in the protective barrier exist, the mucosa is vulnerable to damage by acid and pepsin. Exogenous factors, such as Aspirin and NSAIDs, cause gastric ulcers by inhibition of prostaglandin synthesis.

Zollinger-Ellison syndrome may occur in children who have multiple, large, or recurrent ulcers. This syndrome is characterized by hypersecretion of gastric acid, intractable ulcer disease, and intestinal malabsorption caused by a gastrin-secreting tumour of the pancreas.

Diagnostic Evaluation. Diagnosis is based on the history of symptoms, physical examination, and diagnostic testing. The focus is on symptoms such as epigastric abdominal pain, periumbilical pain, nocturnal pain, oral regurgitation, heartburn, weight loss, hematemesis, and melena (Box 46.13). History should include questions relating to the use of potentially causative substances such as NSAIDs, corticosteroids, alcohol, and tobacco. Frequently a history of epigastric and periumbilical pain accompanies PUD. However, children often find it difficult to describe the location of their pain and often indicate the location by moving their hand in a circular movement all around the stomach area. The nurse can help differentiate the location by asking the child to point with one finger to the pain. Pain may also be elicited during the examination with palpation. Laboratory tests include a CBC to detect anemia; stool analysis for occult blood; liver function tests (LFTs); ESR or CRP to evaluate inflammation; amylase and lipase to evaluate pancreatitis; and gastric acid measurements to identify hypersecretion.

Radiographic studies such as an upper GI series may be performed to evaluate obstruction or malrotation. An upper endoscopy of the esophagus, stomach, and duodenum is the most reliable procedure to diagnose PUD. A biopsy is taken to determine the presence of *H. pylori*. *H. pylori* can also be diagnosed by a blood test that identifies the presence of the antigen to this organism. The C-urea breath test measures bacterial colonization in the gastric mucosa. This test is used to screen for *H. pylori* in adults and children. Polyclonal and monoclonal stool antigen tests are an accurate noninvasive method for both the initial diagnosis of *H. pylori* and the confirmation of its eradication after treatment. In children, upper endoscopy is recommended to evaluate and confirm *H. pylori* disease (Blanchard & Czinn, 2020).

BOX 46.13 Characteristics of Peptic Ulcer Disease

Newborns

Usually gastric and secondary to stress or critical illness
Newborn commonly has a history of preterm birth, respiratory distress, sepsis, hypoglycemia, or an intraventricular hemorrhage
Perforation may be first sign that massive bleeding may occur
Hematemesis, feeding difficulty, crying episodes, or melena

Infants to 3-Year-Old Children

Most likely to have a secondary ulcer located usually in the stomach or duodenum
Primary ulcers less common and usually located in stomach
Likely to occur in relation to illness, surgery, or trauma
Hematemesis, melena, or perforation

3- to 6-Year-Old Children

Primary or secondary ulcers
Located equally in stomach and duodenum
Perforation more likely in secondary ulcers
Periumbilical pain, poor eating, vomiting, irritability, nighttime waking, hematemesis, melena

Children 6 Years and Older

Usually primary and most often duodenal
More typical of adult type
Chance of recurrence greater
Often associated with *Helicobacter pylori*
Epigastric or vague abdominal pain
Possibly nighttime waking, hematemesis, melena, and anemia

Therapeutic Management. The major goals of therapy for children with PUD are to relieve discomfort, promote healing, prevent complications, and prevent recurrence. Management is primarily medical and consists of administration of medications to treat the infection and reduce or neutralize gastric acid secretion. Antacids are beneficial medications to neutralize gastric acid. Histamine (H_2) receptor antagonists (antisecretory medications) act to suppress gastric acid production. Cimetidine (Tagamet), ranitidine (Zantac), and famotidine (Pepcid) are examples of these medications. They have few adverse effects. Cimetidine has many drug interactions so it must be used with caution.

PPIs, such as omeprazole and lansoprazole, act to inhibit the hydrogen ion pump in the parietal cells, thus blocking the production of acid. These medications have been shown to be effective in children and adolescents but not in infants (van der Pol et al., 2011).

Mucosal protective agents, such as sucralfate and bismuth-containing preparations, may be prescribed for PUD. Sucralfate is an aluminum-containing agent that forms a protective barrier over ulcerated mucosa to protect against acid and pepsin. Bismuth compounds are sometimes prescribed for the relief of ulcers, but they are used less frequently than PPIs. Although these compounds inhibit the growth of microorganisms, the mechanism of their activity is poorly understood. In combination with antibiotics, bismuth is effective against *H. pylori*. Although concern has been expressed about the use of bismuth salts in children because of potential adverse effects, none of these effects has been reported when these compounds have been used in the treatment of *H. pylori* infection. These agents are available in both pill and liquid forms. Because they block the absorption of other medications, they should be given separately from other medications.

Triple-medication therapy is the standard first-line treatment regimen for *H. pylori* (Ertem, 2012). Examples of medication combinations used in triple therapy are (1) bismuth, clarithromycin, and metronidazole; (2) lansoprazole, amoxicillin, and clarithromycin; and (3) metronidazole, clarithromycin, and omeprazole. Common adverse effects of medications include diarrhea and nausea and vomiting. In addition to medications, the child with PUD should be given a nutritious diet and advised to avoid caffeine. Adolescents should be warned about gastric irritation associated with alcohol use and smoking.

Children with an acute ulcer who have developed complications, such as significant hemorrhage, require emergency care. Surgical intervention may be required for complications such as hemorrhage, perforation, or gastric outlet obstruction.

Prognosis. The long-term prognosis for PUD is variable. Many ulcers are treated successfully with medical therapy; however, primary duodenal peptic ulcers often recur. The effect of maintenance medication therapy on long-term morbidity remains to be established with future studies.

Nursing Care. The primary nursing goal is to promote healing of the ulcer through adherence to the medication regimen. If an **analgesic–antipyretic** is needed, acetaminophen, not Aspirin or an NSAID, is used. Seriously ill newborns, infants, and children in critical care units should receive H_2 blockers to prevent stress ulcers. Critically ill children receiving IV H_2 blockers should have their gastric pH values checked at frequent intervals.

The role of stress in ulcer formation should be considered for nonhospitalized children with chronic illnesses. In children, many ulcers occur secondary to other conditions, and the nurse should be aware of family and environmental conditions that may aggravate or precipitate ulcers. Children may benefit from psychological counselling and from learning how to cope constructively with stress.

HEPATIC DISORDERS

Hepatitis

Etiology. The term *hepatitis* is not a diagnosis; it refers to either acute or chronic inflammation of the liver that can result from a number of different causes. These include viruses (e.g., Epstein-Barr, cytomegalovirus, HIV); metabolic conditions (e.g., nonalcoholic fatty liver disease, storage disorders, Wilson disease, alpha-1 antitrypsin deficiency), chemical insult (e.g., medications, toxins, alcohol), anatomical issues (e.g., choledochal duct cyst, biliary atresia), immune-mediated diseases (e.g., autoimmune hepatitis, sclerosing cholangitis), vascular disorders (e.g., Budd-Chiari syndrome, portal vein thrombosis), and neoplasms. Determining the cause of hepatitis is important in determining the treatment and prognosis for the child. Table 46.8 compares the features of hepatitis A virus (HAV), hepatitis B virus (HBV), and hepatitis C virus (HCV), which cause the majority of cases of hepatitis in children.

Hepatitis A. Hepatitis A is the most common form of acute viral hepatitis in most parts of the world. It is a member of the picornavirus family. HAV infection is spread directly or indirectly via the fecal–oral route by ingestion of contaminated foods, direct exposure to infected fecal material, or close contact with an infected person. The virus is particularly prevalent in developing countries with poor living conditions, inadequate sanitation, crowding, and inadequate personal hygiene practices. The spread of HAV has been associated with improper food handling and with high-risk areas such as households with infected persons, residential centres for people with disabilities, and day care centres.

TABLE 46.8 Comparison of Types A, B, and C Hepatitis

Characteristics	Type A	Type B	Type C
Incubation period	15–50 days, average 25–30 days	30–180 days, average 50 days	2 wk–6 mo, average 6–7 wk
Period of communicability	Believed to be later half of incubation period to first week after onset of clinical illness	Variable Virus in blood or other body fluids during late incubation period and acute stage of disease; may persist in carrier state for years to lifetime	Begins before onset of symptoms May persist in carrier state for years
Mode of transmission	Principal route—Fecal–oral Rarely—Parenteral	Principal route—Parenteral Less frequent route—Oral, sexual, any body fluid Perinatal transfer—Transplacental blood (last trimester), at birth, or during breastfeeding, especially if breastfeeding parent has cracked nipples	Principal route—Parenteral Nonparenteral spread possible
Clinical Features			
Onset	Usually rapid, acute	More insidious	Usually insidious
Fever	Common and early	Less frequent	Less frequent
Anorexia	Common	Mild to moderate	Mild to moderate
Nausea and vomiting	Common	Sometimes present	Mild to moderate
Rash	Rare	Common	Sometimes present
Arthralgia	Rare	Common	Rare
Pruritus	Rare	Sometimes present	Sometimes present
Jaundice	Present (many cases anicteric)	Present	Present
Other Features			
Immunity	Present after one attack; no crossover to type B or C	Present after one attack; no crossover to type A or C	Present after one attack; no crossover to type A or B
Carrier state	No	Yes	Yes
Chronic infection	No	Yes	Yes
Prophylaxis			
Immune globulin (Ig)	Passive immunity Successful, especially in early incubation period and pre-exposure prophylaxis	May provide passive immunity Inconsistent benefits; probably of no use	Not currently recommended
HAV vaccine	Two inactivated vaccines are approved for children ages 2–18 yr: Havrix and Vaqta; given in a two-dose schedule (6–12 mo between doses) Twinrix contains HAV and HBV for 18 years or older		
HBV Ig (HBIg)	No benefit	Provides passive immunity Postexposure protection possible (for 3–6 months) if given immediately after definite exposure	No benefit
HBV vaccine	No benefit	Postexposure if given immediately after definite exposure Provides active immunity Universal vaccination recommended for all children (either newborn or school age, depending on province or territory)	No benefit
Mortality Rate	0.1–0.2%	0.5–2.0% in uncomplicated cases; may be higher in complicated cases	1–2.0% in uncomplicated cases; may be higher in complicated case

HAV, Hepatitis A virus; *HBV,* hepatitis B virus.

The average incubation period is about 4 weeks, with a range of 15 to 50 days. Fecal shedding of the virus can occur for 2 to 3 weeks before and for 1 week after the onset of jaundice. During this time, although the individual is asymptomatic, the virus is most likely to be transmitted. Infants with HAV infection are likely to be asymptomatic (anicteric hepatitis). Children often have diarrhea, and their symptoms are frequently attributed to gastroenteritis. Only 1 in 12 young children develops jaundice. HAV infection is self-limiting and does not result in chronic infection or chronic liver disease.

Although some cases may be prolonged, the prognosis is excellent. The HAV vaccine is highly effective. It is available in Canada and is recommended for persons at high risk of exposure or those travelling to an endemic geographical area (Government of Canada, 2021a) (see Chapter 35, Hepatitis A). Usually, the hepatitis A vaccine is effective and is recommended over the immunoglobulin injection for people over 6 months of age. Immunoglobulin is the recommended post-exposure immunoprophylactic agent for infants less than 6 months of age and for those in whom vaccination is contraindicated (previous adverse reactions to hepatitis A vaccine, severe latex allergy, or during a severe illness).

Hepatitis B. The incidence of hepatitis B is declining after the introduction of a universal immunization program. HBV infection rates vary greatly throughout the world. High-prevalence areas have been identified in Africa and Asia; Canada is considered a low-prevalence area. HBV infection can occur as an acute or chronic infection and may range from being asymptomatic and limited to causing fatal fulminant (rapid and severe) hepatitis. Transmission is usually via the parenteral route through the exchange of blood or any bodily secretions or fluids. Infections from blood transfusions have been reduced as a result of blood product–screening procedures. Transplantation of organs, intimate physical contact, transmission from mother to infant, and the splashing of contaminated fluids into the mouth or eyes are other sources of infection. Adults whose occupations are associated with exposure to blood or blood products (such as health care workers) are at increased risk for contracting HBV.

Most HBV infection in children is acquired perinatally. Newborns are at risk for hepatitis if the mother is infected with HBV or was a carrier of HBV during pregnancy. Possible routes of maternal–fetal or maternal–infant transmission include (1) leakage of virus across the placenta late in pregnancy (less than 2% of cases) or during labour, and (2) ingestion of amniotic fluid or maternal blood. Infants who have HBV infection are more than 90% likely to become chronic carriers (Paganelli et al., 2012). In Canada, universal vaccination is recommended for all children (either newborn or of school age, depending on province or territory). In jurisdictions where children do not receive hepatitis B vaccine in infancy, children at increased risk should be given HBV-containing vaccine as soon as possible when the risk is identified (see Chapter 35: Hepatitis B Virus [HBV]) (Government of Canada, 2021a). The incubation period of HBV infection varies from 45 to 160 days.

HBV infection occurs in children and adolescents in the following high-risk groups (see Box 7.4):

- Individuals with hemophilia and others who have received multiple transfusions
- Children and adolescents involved in IV drug use
- Children and adolescents in congregate settings
- Preschool-age children in endemic areas
- Individuals engaged in sexual activity with infected partners

Hepatitis C. The highest risk factor for acquiring HCV is a history of injection drug use. HCV is transmitted through contaminated blood, especially as a result of IV drug use, and from pregnant parent to child. Approximately 5% of infected HCV pregnant parents transmit HCV virus to their fetus, but the rate of parental transmission varies according to the presence or absence of certain cofactors, particularly coinfection with HIV, which increases risk to approximately 75%, and medical conditions (Jensen & Balistereri, 2020) (see Chapter 7). Another common route of infection is by percutaneous exposure, which occurs through transfusion of blood or blood products, transplantation of organs or tissues, or sharing of used needles. Transfusion-associated HCV infection is low.

The clinical course of HCV infection varies. Incubation averages 7 to 9 weeks, with a range of 2 weeks to 6 months. The natural history of the disease in children is not well defined. Some children may be asymptomatic, but hepatitis C can become a chronic condition and can cause cirrhosis and hepatocellular carcinoma. About 85% of individuals infected with HCV develop chronic disease (Jensen & Balistereri, 2020).

Hepatitis D. Hepatitis D is very rare in children in North America but is endemic in other regions of the world, like Mediterranean countries, Latin America, and Eastern Europe. Hepatitis D virus (HDV) is a defective RNA virus that requires the helper function of HBV. HDV infection occurs primarily in hemophiliac patients, people immigrating from endemic regions, and IV drug users. The incubation period is 2 to 8 weeks. Both acute and chronic forms are more severe than HBV infection and can lead to cirrhosis. Testing for HDV infection is only recommended in children who are hepatitis B carriers with evidence of serum hepatitis B surface antigen positivity with elevated liver enzymes despite an undetectable HBV viral load (Coffin et al., 2018).

Hepatitis E. Hepatitis E is considered absent in Canada, the United States, and Western Europe but is endemic in Asia, South America, the Middle East, and Western and Northern Africa. Hepatitis E virus (HEV) infection is enterally transmitted. Transmission may occur through the fecal–oral route or from contaminated water. The incubation period is 2 to 9 weeks. This illness is uncommon in children, does not cause chronic liver disease, is not a chronic condition, and has no carrier state. However, it can be a devastating disease among pregnant persons, with an unusually high case-fatality rate.

Pathophysiology. Pathological changes occur primarily in the parenchymal cells of the liver and result in varying degrees of swelling, infiltration of liver cells by mononuclear cells, and subsequent degeneration, necrosis, and fibrosis. Structural changes within the hepatocyte account for altered liver functions such as impaired bile excretion, elevated transaminase levels, and decreased albumin synthesis. Hepatitis can be self-limited, and complete regeneration of liver cells without scarring may occur. However, some forms of hepatitis do not result in complete return of liver function. These include *fulminant hepatitis*, which is characterized by a severe, acute course and massive destruction of the liver, resulting in liver failure and death in 1 to 2 weeks. *Subacute* or *chronic active hepatitis* is characterized by progressive liver destruction, uncertain regeneration, scarring, and potential cirrhosis.

The progression of liver disease is characterized pathologically by four stages: (1) stage 1 is characterized by mononuclear inflammatory cells surrounding small bile ducts; (2) in stage 2 there is proliferation of small bile ductules; (3) stage 3 is characterized by fibrosis or scarring; and (4) stage 4 is cirrhosis (Angulo & Lindor, 2010).

Clinical Manifestations. The clinical manifestations and course of uncomplicated acute viral hepatitis are similar for most of the hepatitis viruses. Usually the prodromal, or anicteric, phase (absence of jaundice) lasts from 5 to 7 days. Anorexia, malaise, lethargy, and easy fatigability are the most common symptoms and may be mistaken for influenza. Fever may be present, especially in adolescents. Nausea, vomiting, and epigastric or right upper quadrant abdominal pain or

tenderness may occur. Arthralgia and skin rashes may occur and are more likely in children with hepatitis B than those with hepatitis A. The transaminases rather than bilirubin are often elevated in acute hepatitis, and hepatomegaly may be present. Some mild cases of acute viral hepatitis do not cause symptoms or can be mistaken for influenza.

In young children, most of the prodromal symptoms disappear with the onset of jaundice, or the icteric phase. However, many children with acute viral hepatitis never develop jaundice. If jaundice occurs, it is often accompanied by dark urine and pale stools. Pruritus may accompany jaundice and can be bothersome for children.

Children with chronic active hepatitis may be asymptomatic but more commonly have nonspecific symptoms of malaise, fatigue, lethargy, weight loss, or vague abdominal pain. Hepatomegaly may be present, and the transaminases are often very high, with mild-to-severe hyperbilirubinemia.

Fulminant hepatitis is due primarily to HBV or HCV. Many children with fulminant hepatitis develop characteristic clinical symptoms and rapidly develop manifestations of liver failure, including encephalopathy, coagulation defects, ascites, deepening jaundice, and an increasing WBC count. Changes in mental status or personality indicate impending liver failure. Although children with acute hepatitis may have hepatomegaly, a rapid decrease in the size of the liver (indicating loss of tissue caused by necrosis) is a serious sign of fulminant hepatitis. Complications of fulminant hepatitis include GI bleeding, sepsis, renal failure, and disseminated coagulopathy.

Diagnostic Evaluation. Diagnosis is based on the history (especially regarding possible exposure to a hepatitis virus), physical examination, and serological markers (antibodies or antigens) indicating the presence of active infection with hepatitis A, B, or C or previous infection. No serum enzyme is specific for hepatitis, but serum aspartate (AST) and serum aminotransferase (ALT) levels are markedly elevated. Serum bilirubin levels peak 5 to 10 days after clinical jaundice appears. When hepatitis is severe, albumin levels may be depressed, and prothrombin times are often increased. Histological evidence from liver biopsy may be required to establish the diagnosis and assess the severity of the liver disease. Serological markers indicate the antibodies or antigens formed in response to the specific virus and confirm the diagnosis. Serum immunological tests are not available to detect HAV antigen, but there are two HAV antibody tests: anti-HAV immunoglobulin G (IgG) and immunoglobulin M (IgM). Anti-HAV antibodies are present at the onset of the disease and persist for life. A positive anti-HAV antibody test result indicates acute infection, immunity from past infection, passive antibody acquisition (e.g., from transfusion, serum immunoglobulin infusion), or immunization. To diagnose an acute or recent HAV infection, a positive anti-HAV IgM test result that is present with the onset of the disease and that persists for only 2 or 3 days is required.

Diagnosis of hepatitis B is confirmed by the detection of hepatitis B DNA, which also measures viral load, HBV antigens, and the antibodies that are produced in response to the infection. These antibodies and antigens and their significance include the following:

- *HBsAg*—Hepatitis B surface antigen (found on the surface of the virus), indicating ongoing infection or carrier state. In the absence of HBeAg, positive HBsAg denotes a carrier state and is usually associated with a low HBV viral load.
- *Anti-HBs*—Antibody to surface antigen HBsAg, indicating resolving or past infection. In the absence of HBsAg, anti-HBs may be the result of immunization.
- *HBeAg*—Hepatitis Be antigen (another component of the HBV core), indicating active infection. Positive HBeAg is usually associated with a high HBV viral load.
- *Anti-HBe*—Antibody to HBeAg, indicating resolving or past infection

Serum tests for HBV antigens and antibodies are readily available. HBsAg is detectable during acute infection. The presence of HBsAg indicates that the individual has been infected with the hepatitis virus. If the infection is self-limiting, HBsAg disappears in most patients before serum anti-HBs can be detected (termed the *window phase of infection)*. Newborn infection is most likely to occur in infants born to mothers who are HBeAg positive and have a high viral load. In contrast, hepatitis B is much less likely to occur in infants whose mothers are HbsAg positive but HBeAg negative and who have antibodies to HBeAg with a low viral load. Clinical improvement is usually associated with a decrease in or disappearance of these antigens, followed by the appearance of their antibodies and a decrease in HBV viral load.

HCV-RNA is the earliest serological marker for HCV. HCV-RNA can be detected during the incubation period before symptoms of HCV disease are expressed. A positive HCV-RNA result indicates active infection, and persistence of HCV-RNA indicates chronic infection. A negative test result correlates with resolution of the disease. HCV-RNA is also used to determine patient response to antiviral therapy for HCV.

An abdominal ultrasound scan provides measurement of liver size, detection of cystic lesions and stones, and imaging of the gallbladder. Cholescintigraphy radionuclide imaging is used to detect abnormalities in liver uptake, concentration, and excretory function. Finally, a liver biopsy aids in assessing the severity of the disease.

The history of all patients should include questions to seek evidence of (1) contact with a person known to have hepatitis, especially a family member; (2) unsafe sanitation practices, such as contaminated drinking water; (3) ingestion of certain foods, such as clams or oysters (especially from polluted water); (4) multiple blood transfusions; (5) ingestion of hepatotoxic medications, such as salicylates, sulfonamides, antineoplastic agents, acetaminophen, and anticonvulsants; and (6) parenteral administration of illicit drugs or sexual contact with a person who uses these drugs.

Therapeutic Management. Treatment options for viral hepatitis are rapidly evolving. The goals of management include early detection, recognition of chronic liver disease, support and monitoring, and prevention of spread of the disease.

HAV infection is an acute disease that resolves with support and management of symptoms.

Treatment of hepatitis B is not curative and is directed at reducing viral load to prevent further destruction of the liver. Therapy depends on the cause and degree of inflammation. Traditionally, in children and adults, hepatitis B is treated with interferons, naturally occurring proteins that exert antiviral, antiproliferative, and immunomodulatory effects. An interferon formulation, pegylated interferon, can be administered once a week and has been found to sustain plasma levels and enhance viral suppression. Interferon α-$_2$b has immunomodulatory and antiviral effects but needs subcutaneous administration and has adverse effects of retinal changes, marrow suppression, and autoimmune disorders (Jensen & Balistreri, 2020). Newer oral antivirals like lamivudine, adefovir, entecavir, tenofovir, and telbivudine may be used to suppress viral load and thereby reduce ongoing hepatic injury in chronic HBV infection. Effective hepatitis B treatment with oral antivirals requires long-term therapy; medication may never be safely discontinued in some patients. These medications are not specifically approved for use in children but can be obtained with special approval (Coffin et al., 2018).

Treatment of HCV infection now offers an effective cure, which is demonstrated by a sustained undetectable viral load, in over 80% of

chronically infected patients. Many branded combination direct-acting antivirals are marketed and approved in Canada for the treatment of adults. Treatment with these oral medications is generally well tolerated and can cure chronic HCV infection after a course of therapy lasting 8 to 24 weeks. Currently, only a limited number of these combination antiviral products have been approved for children over 12 years of age (Shah et al., 2018).

Prevention. Thorough hand hygiene and routine precautions help prevent the spread of viral hepatitis. Prophylactic use of standard immune globulin is effective in preventing HAV infection in situations of pre-exposure, such as anticipated travel to areas where HAV is prevalent, or in situations of postexposure within 2 weeks during the early part of the incubation period.

Hepatitis B immune globulin (HBIg) is effective in preventing HBV infection after one-time exposure, such as with a needlestick injury or coming in contact with mucous membrane materials, and for newborns whose mother is HBsAg positive and within 72 hours after birth. Immune globulin and HBIg must be administered less than 2 weeks after exposure.

Active immunizations are not available against HCV. It is possible to prevent HDV infection by preventing HBV infection (see Chapter 35, Immunizations).

Prognosis. The prognosis for children with hepatitis varies and depends on the type of virus and the child's age and immune status. HAV usually causes a mild and brief illness with no carrier state. HBV causes a wide spectrum of acute and chronic illness. Approximately 5% of individuals with HBV infection develop chronic hepatitis B each year, and about half of these individuals develop fulminant liver failure, leading to death in the absence of liver transplantation. Hepatocellular carcinoma is a potentially fatal complication of HBV infection. HCV causes acute hepatitis that progresses to chronic hepatitis, but a small number of children go into spontaneous remission and others may develop cirrhosis. Of children with chronic hepatitis C, 25% develop cirrhosis, liver failure, and possible hepatocellular cancer. Viral hepatitis causes approximately 50% of cases of fulminant hepatic failure, and survival varies.

Nursing Care. Nursing care depends on the specific type of viral hepatitis, severity of the illness and symptoms, the medical management, and factors influencing the control and transmission of the disease. Children with viral hepatitis infection are usually cared for at home, and the nurse must explain the medical therapy and infection-control measures to the family. If further assistance is needed for parents to follow through with the therapy, a community health nursing referral may be necessary.

A well-balanced diet and a realistic schedule of rest and activity adjusted to the child's condition should be encouraged. HAV is not infectious within a week after the onset of jaundice, and children may feel well enough to resume school. Parents need to be cautioned about administering any medication to the child, since normal dosages of many medications may become dangerous because of the liver's inability to detoxify and excrete them. Hand hygiene is the single most critical measure in reducing the risk of transmission. The nurse should explain to parents and children the ways in which HAV (oral–fecal route) and HBV (parenteral route) are spread. Routine precautions are carried out in the hospital, and children are not in a single room unless they have fecal incontinence. Toy sharing and sharing of personal items are discouraged.

Nurses caring for young people with HBV infection and a known or suspected history of IV drug use should help these teens realize the dangers of substance use. Nurses need to stress the parenteral mode of transmission of hepatitis and encourage patients to seek counselling through a substance use program.

HBV and HCV are chronic diseases that require frequent monitoring and management. Many communities have interprofessional clinics dedicated to the management of these diseases. The nurse should also address universal vaccination against HBV with the family.

Cirrhosis

The term *cirrhosis* refers to late-stage liver damage that can occur in any chronic disease of the liver. Cirrhosis can also result from acute injury due to infectious, metabolic, autoimmune, or toxic causes. Treatment of the underlying disease process may arrest the continued progression of cirrhosis and, in rare cases, some improvement in the degree of cirrhosis may be observed in children.

Clinical manifestations of cirrhosis in children are similar in all chronic liver disorders. Children may exhibit jaundice, poor growth, anorexia, muscle weakness, and lethargy. Ascites, edema, GI bleeding, anemia, and abdominal pain may be present with impaired intrahepatic blood flow. Pulmonary function may be impaired because of pressure against the diaphragm from hepatosplenomegaly and ascites, or vascular changes in response to chronic liver disease (i.e., hepatopulmonary syndrome). Dyspnea and cyanosis may occur, especially on exertion. Spider angiomas and prominent blood vessels are often present on the upper torso.

Therapeutic Management. The goals of management of cirrhosis include monitoring liver function and managing specific complications, such as esophageal varices and malnutrition. Assessment of the child's degree of liver dysfunction is important so that the child can be evaluated for transplantation at the appropriate time. Liver transplantation has improved the prognosis substantially for many children with cirrhosis. The combination of new immunosuppressive medications and new surgical techniques has resulted in improved survival rates.

Nutritional support is important for children with cirrhosis and malnutrition. Supplements of fat-soluble vitamins and minerals are often required. In some instances, aggressive nutritional support with continuous tube feedings or parenteral nutrition may be needed.

Portal hypertension, which is caused by impaired blood flow in the portal vein through the damaged liver, may lead to esophageal and gastric varicies. Acute hemorrhage of varices is life-threatening and is managed with IV fluids, blood products, vasopressin, and gastric lavage. Balloon tamponade with a Sengstaken-Blakemore tube may be needed. Endoscopic sclerotherapy and endoscopic banding ligation are effective in managing esophageal and gastric varices.

Ascites is treated by sodium restriction and diuretics. Severe ascites with respiratory compromise is treated by administration of albumin or by paracentesis.

Although the full mechanism of hepatic encephalopathy is unknown, failure of the damaged liver to remove endogenous toxins such as ammonia plays a role. Treatment is directed at limiting the ammonia formation and absorption that occur in the bowel, especially with the medications neomycin and lactulose. Because ammonia is formed in the bowel by the action of bacteria on ingested protein, neomycin reduces the number of intestinal bacteria so less ammonia is produced. The fermentation of lactulose by colonic bacteria produces short-chain fatty acids, which lower the colonic pH, thereby inhibiting bacterial metabolism. This decreases the formation of ammonia from bacterial metabolism of protein.

Prognosis. Liver transplantation has revolutionized the approach to liver cirrhosis. Liver failure and cirrhosis are indications for

transplantation. Careful monitoring of the child's condition and quality of life is necessary to evaluate the need for and timing of transplantation (see Family-Centred Care box: End Stage Liver Disease).

FAMILY-CENTRED CARE

End-Stage Liver Disease

In many cases the child and family must cope with an uncertain progression of the disease. The only hope for long-term survival may be liver transplantation. Transplantation can be successful, but the waiting period may be long, and there are many more children in need of organs than there are donors. The procedure is performed only at designated medical centres that are often far from the family's home. The nurse should recognize the unique stresses of coping with end-stage liver disease and waiting for transplantation and assist the family in coping with these stressors. The assistance of social workers and support from other parents can be beneficial.

Currently, liver transplant survival rates in Canadian children are as high as 92 to 97 % for 1-year survival and 87 to 94% for 5-year survival. Living donor transplantation is an option for many children and has been associated with better survival outcomes than with deceased donor transplants (Kehar et al., 2019). Increasing numbers of recipients are reaching their second decade after transplant. The increasing lifespan after transplantation is related to advances in immunosuppressants and surgical techniques as well as improved preoperative, intraoperative, and postoperative care. There still are many more children who need a liver transplant than there are available deceased donors that have size-appropriate livers. The use of reduced-sized grafts, or split-liver donation, from deceased liver donors, or the use of a lobe of the liver from a living donor has decreased the wait time for this population.

Postoperative care for liver transplantation is similar to that for other surgical procedures. There is special emphasis on prevention of infection, as patients are on multiple medications, which cause immunosuppression.

Nursing Care. Nursing care of the child with cirrhosis is determined by the cause of the cirrhosis, the severity of complications, and the prognosis. The prognosis is often poor unless successful liver transplantation occurs. Nursing care of this child is similar to that for any child with a life-threatening illness (see Chapter 41). Hospitalization is required when complications such as hemorrhage, severe malnutrition, or hepatic failure occur. Nursing assessments are directed at monitoring the child's condition, and interventions are aimed at treatment of specific complications. If liver transplantation is an option, the family may need support and assistance to cope.

Biliary Atresia

Biliary atresia (BA) is a progressive inflammatory process that results in both intrahepatic and extrahepatic bile duct fibrosis that leads to eventual ductal obstruction. BA has been detected in 1 in 10 000 to 15 000 live births and is more common in East Asian countries (Hassan & Balistreri, 2020). Associated malformations include polysplenia, intestinal atresia, and malrotation of the intestine. Untreated, BA usually leads to cirrhosis, liver failure, and death within the first 2 years of life. BA is the leading cause of liver failure and liver transplant for Canadian children, accounting for 75% of pediatric transplants by 2 years of age and 50% of all transplants before 18 years of age.

Etiology and Pathophysiology. The exact cause of BA is unknown; it has been suggested that immune mechanisms or viral injury could cause the progressive inflammation that leads to complete obliteration of the bile ducts. BA is not seen in fetuses, stillborns, or newborns. This suggests that BA is acquired late in gestation or in the perinatal period and is manifested a few weeks after birth. The majority of cases of BA (85%) have a complete obliteration of the extrahepatic biliary tree at or above the porta hepatitis (Hassan & Balistreri, 2020).

Many newborns with BA are full term and appear healthy at birth. Jaundice (hyperbilirubinemia), manifesting with yellow discoloration of the skin or sclerae, is the most common early symptom of BA. Jaundice, which indicates cholestasis (the accumulation of compounds that cannot be excreted because of occlusion or obstruction of the biliary tree), can be visible at a total serum bilirubin concentration as low as 85 mcmol/L. Conjugated (direct) hyperbilirubinemia often occurs after the resolution of physiological (neonatal) jaundice caused by an elevation in unconjugated (indirect) bilirubin. Eighty percent of newborns with this unconjugated hyperbilirubinemia will no longer appear jaundiced by 2 weeks of age. It is therefore advised that all children who have jaundice at 2 weeks of age have a serum fractionated bilirubin assessment, as an elevated conjugated bilirubin result is indicative of liver disease.

Jaundice is often associated with pale stool and dark urine. Histological study demonstrates bile duct remnants and a progressive inflammatory process. Hepatomegaly is present early in the course of the disease, and the liver is firm on palpation.

Diagnostic Evaluation. Early diagnosis is the key to survival of the child with BA. Often, infants with BA appear well and have only very mild jaundice during the first 2 to 8 weeks of life, but will soon begin failing to grow and thrive.

Several clinical signs may indicate the presence of BA (Box 46.14). Blood tests should include a CBC, electrolytes, fractionated bilirubin, and liver enzymes. Additional laboratory analyses, including α_1-antitrypsin level, TORCH titres (see discussion of maternal infections in Chapter 29), hepatitis serology, alpha-fetoprotein, urine cytomegalovirus, and a sweat chloride test, are indicated to rule out other conditions that cause persistent cholestasis and jaundice. Abdominal ultrasonography allows inspection of the liver and biliary system. Hepatobiliary scintigraphy (also known as a HIDA scan) demonstrates biliary patency but does not provide diagnostic certainty. Percutaneous liver biopsy is highly reliable when the biopsy contains specimens from a number of portal areas. Definitive diagnosis of BA is obtained during surgical laparotomy and an intraoperative cholangiogram that demonstrates complete obstruction at some level of the biliary tree.

BOX 46.14 Clinical Manifestations of Extrahepatic Biliary Atresia

Jaundice
- Earliest manifestation and most striking feature of disorder
- First observed in sclera
- May be present at birth, but usually not apparent until age 2 to 3 weeks

Urine dark and stains diaper

Stools lighter than expected or white or tan

Hepatomegaly and abdominal distension common

Splenomegaly occurs later

Poor fat metabolism results in:
- Poor weight gain
- General growth failure

Pruritus

Irritability; difficulty comforting infant

Therapeutic Management. The primary treatment of BA is *hepatic portoenterostomy (Kasai procedure)*, in which a segment of intestine is anastomosed to the resected porta hepatis to attempt bile drainage. The establishment of bile flow via surgical intervention is best done in very young infants. A Roux-en-Y jejunal limb is then anastomosed to the porta hepatis (a Y-shaped anastomosis) to provide bile drainage without reflux. This surgery has several variations, and successful bile drainage is achieved in approximately 80 to 90% of newborns who undergo surgery when younger than 8 weeks of age, although bile flow is not necessarily predictive of good long-term outcomes (Hassan & Balistreri, 2020). Kasai failure and progressive cirrhosis still occur in many children, necessitating eventual liver transplantation. Prophylactic antibiotics are given after the Kasai procedure to minimize the risk of ascending cholangitis.

Medical management is primarily supportive; it includes nutritional support with breast milk or infant formulas that contain medium-chain triglycerides and essential fatty acids. Supplementation is usually required with fat-soluble vitamins (A, D, E, K), a multivitamin, and minerals, including iron, zinc, and selenium. Aggressive nutritional support with continuous gastrostomy feedings or TPN is indicated for moderate-to-severe growth failure. The enteral solution should be low in sodium. Ursodeoxycholic acid is used to decrease cholestasis and treat intense pruritus and hypercholesterolemia. If the child has advanced liver damage, the management is the same as that for cirrhosis.

Prognosis. Untreated BA results in progressive cirrhosis and death in most children by 2 years of age. The Kasai procedure improves the prognosis but is not a cure and is consider a palliative procedure. The best rate of long-term survival without liver transplant occurs when children have Kasai portoenterostomy before 30 days of age, with 49% of children surviving with their native liver at 10 years of age. Children who undergo the Kasai procedure after 90 days of age only have a 15% survival rate at 10 years of age with their native liver (Butler et al., 2016).

Nursing Care. Nursing interventions for the child with BA include support of the family before, during, and after surgical procedures and education regarding the treatment plan. In the postoperative period of a portoenterostomy, nursing care is similar to that after major abdominal surgery. Family members need education from the nurse regarding proper administration of medications and nutritional therapy, including special formulas, vitamin and mineral supplements, tube feedings, or parenteral nutrition in the home. In these infants, growth failure is common, and increased metabolic needs, combined with ascites, pruritus, and nutritional anorexia, are major challenges for care. Pruritus can often be relieved by medication therapy or comfort measures such as colloidal oatmeal baths; trimming fingernails may help decrease the chance of secondary infection as a result of skin breakdown. The risks of BA, such as cholangitis, portal hypertension, GI bleeding, and ascites, need to be explained to the family.

Children and their families also need psychosocial support. The uncertain prognosis, discomfort, and waiting for transplantation produce stress, and hospitalizations, pharmacological therapy, and nutritional therapy impose financial burdens on the family. Families can receive help from the Canadian Liver Foundation, which provides educational materials, programs, and support systems (see Additional Resources at the end of this chapter).

STRUCTURAL DEFECTS

Cleft Lip or Cleft Palate

Cleft lip (CL) and cleft palate (CP) are facial malformations that occur during embryonic development and are the most common congenital malformations of the head and neck. They may appear separately or, more often, together. CL results from failure of the maxillary and median nasal processes to fuse; CP is a midline fissure of the palate that results from failure of the two sides to fuse.

CL may vary from a small notch to a complete cleft extending into the base of the nose (Figure 46.6). Clefts can be unilateral or bilateral. Deformed dental structures are associated with CL. CP alone occurs in the midline and may involve the soft and hard palates. The palate can be divided into primary and secondary palates. The primary one consists of the medial portion of the upper lip and the portion of the alveolar ridge that contains the central and lateral incisors. The secondary palate consists of the remaining portion of the hard palate and all of the soft palate. When associated with CL, the defect may involve the midline and extend into the soft palate on one or both sides (CL/P).

These malformations are two of the most common birth defects in Canada; the rate of CL/P is 9.4 per 10 000 and CP is 7.0 per 10 000; combined they affect 600 newborns every year. There is a higher incidence in certain ethnic groups, including the Indigenous population (Public Health Agency of Canada [PHAC], 2013). Approximately

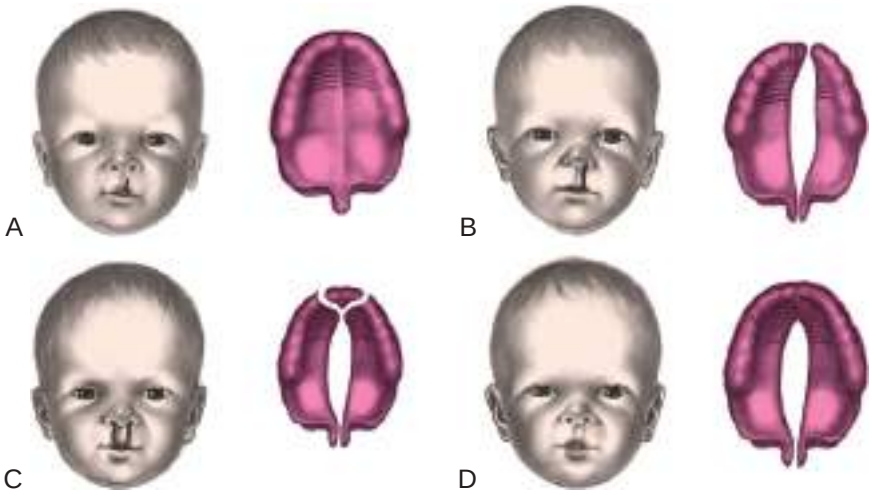

Fig. 46.6 Variations in clefts of lip and palate at birth. **A:** Notch in vermilion border. **B:** Unilateral cleft lip and cleft palate. **C:** Bilateral cleft lip and cleft palate. **D:** Cleft palate.

60 to 80% of children born with CL/P are male. Females have a higher frequency of isolated clefts of the secondary palate. Unilateral clefts are nine times more common than bilateral clefts and occur twice as frequently on the left side. Isolated bilateral CLs are uncommon; approximately 86% of those with bilateral CL also have palatal clefts (CL/P). See Figure 46.6 to see the variations in clefts of lip and palate at birth.

Etiology. Cleft deformities may be an isolated anomaly, or they may occur with a recognized syndrome. CL with or without CP is distinct from isolated CP. Clefts of the secondary palate alone are more likely to be associated with syndromes than is isolated CL or CL/P.

CL/P may be caused by exposure to teratogens such as alcohol, cigarette smoking, anticonvulsants, steroids, and retinoids and folic acid deficiency. Use of phenytoin during pregnancy is associated with a 10-fold increase in the incidence of CL. Canadian statistics suggest maternal obesity and smoking as possible risk factors for CL/P in infants (PHAC, 2013).

Pathophysiology. Cleft deformities represent a genetic defect in cell migration that results in a failure of the maxillary and premaxillary processes to come together between the third and twelfth week of embryonic development. Although often appearing together, CL and CP are distinct malformations embryologically, occurring at different times during the developmental process. Merging of the upper lip at the midline is completed between the seventh and eleventh weeks of gestation. Fusion of the secondary palate (hard and soft palate) takes place later, between the seventh and twelfth weeks of gestation. In the process of migrating to a horizontal position, the palates are separated by the tongue for a short time. If there is delay in this movement or if the tongue fails to descend soon enough, the remainder of development proceeds, but the palate never fuses.

Diagnostic Evaluation. CL and CL/P are apparent at birth. CP is less obvious than CL and may not be detected without a thorough assessment of the mouth. CP is identified when the examiner places a gloved finger directly on the palate. Clefts of the hard palate form a continuous opening between the mouth and the nasal cavity. The severity of the CP has an impact on feeding; the newborn is unable to generate negative pressure and create suction in the oral cavity. This impairs feeding, even though in most cases the newborn's ability to swallow is normal.

Prenatal diagnosis with fetal ultrasonography is not reliable until the soft tissues of the fetal face can be visualized at 13 to 14 weeks. The sensitivity of fetal ultrasound for facial clefting is almost 100% when CL/P is associated with other structural anomalies. In isolated CP, sensitivity may be 50%; an intact lip is the most difficult to diagnose prenatally (Robbins et al., 2010).

Therapeutic Management. Treatment of the child with isolated CL is surgical and involves no long-term interventions other than possible scar revision. The management of CP involves the collaborative efforts of an interprofessional health care team, including pediatrics, plastic surgery, orthodontics, otolaryngology, speech/language pathology, audiology, nursing, and social work. Management is directed toward closure of the cleft(s), prevention of complications, and facilitation of normal growth and development in the child.

Surgical correction of cleft lip. CL repair typically occurs at most centres between 2 and 3 months of age. The two most common procedures for repair of CL are the Fisher technique and the Millard rotational advancement technique. Improved surgical techniques have minimized scar retraction, and in the absence of infection or trauma healing occurs with little scar formation. Nasoalveolar moulding may also be used to bring the cleft segments closer together before definitive CL repair, reducing the need for CL revision. However, optimal cosmetic results may be difficult to obtain in severe defects. Additional revisions may be necessary at a later age.

Surgical correction of cleft palate. CP repair typically occurs before 12 months of age, to enhance normal speech development (Dhar, 2020). The most common techniques to repair CP include the Veau-Wardill-Kilner V-Y pushback procedure and the Furlow double-opposing Z-plasty. Approximately 20 to 30% of children with repaired CP need a secondary surgery to improve velopharyngeal closure for speech. Secondary procedures may include palatal lengthening, pharyngeal flap, sphincter pharyngoplasty, or posterior pharyngeal wall augmentation. If the child is not a candidate for surgical revision to improve velopharyngeal function, prosthetic management should be considered.

Prognosis. Children with CL may require multiple surgeries to achieve optimal aesthetic outcomes but are still at risk for increased speech challenges. Although some children with CP and CL/P do not require speech therapy, many have some degree of speech impairment that requires speech therapy at some point during childhood. Articulation errors result from a history of velopharyngeal dysfunction, incorrect articulatory placement, improper tooth alignment, and varying degrees of hearing impairment. Improper drainage of the middle ear as a result of inefficient function of the eustachian tube contributes to recurrent otitis media and otitis media with effusion, which can cause scarring of the tympanic membrane, leading to hearing impairment in many children with CP. Myringotomy tubes are often used to drain the middle ear and help to prevent hearing impairment (see Chapter 45). Upper respiratory tract infections require immediate and meticulous attention, and extensive orthodontics and prosthodontics may be needed to correct malposition of teeth and maxillary arches.

Long-term issues are related to the child's social adjustment. The better the physical care, the better is the chance for emotional and social adjustment, although the type of the defect and the degree of residual disability are not always directly related to a satisfactory adjustment. Physical defects can be a challenge to self-image, and abnormal speech quality can be an impediment to social expression. Academic achievement, social adjustment, and behaviour should be monitored, particularly in children with syndromic cleft conditions.

Nursing Care. The immediate nursing concerns in caring for a newborn with CL or CP deformities are related to feeding. Parents of newborns with clefts place high priority on learning how to feed their infants and identify when they are sick, but they also express interest in learning about the newborn's "normal" features. Whenever possible, they should be referred to a comprehensive CL/P team.

The nurse should encourage expression of any parental grief and fears; such expression may promote attachment in the preoperative period. It is especially important to emphasize the positive aspects of the newborn's physical appearance and to express optimism regarding surgical correction while acknowledging the parents' concern. The manner of handling the newborn should convey to the parents that the newborn is indeed a precious human being.

Feeding. Feeding the newborn with CL, CP, or CL/P can be difficult, and teaching the parent to successfully feed the child is perhaps one of the most significant and challenging nursing roles. Growth failure in infants with CL, CP, or both has been attributed to preoperative feeding difficulties. After surgical repair, most infants with isolated CL or CP and no associated syndrome gain weight successfully or achieve adequate weight and height for age.

CL may interfere with an infant's ability to achieve an adequate anterior lip seal. An infant with an isolated CL typically has no difficulty breastfeeding because the breast tissue is able to conform to the cleft.

Cheek support (squeezing the cheeks together to decrease the width of the cleft) may be useful in improving lip seal during feeding.

Infants with CP and CL/P are often unable to feed using conventional methods before surgical management. CP reduces the infant's ability to suck, which interferes with breastfeeding and traditional bottle-feeding. Modifications to positioning, bottle selection, and feeder supportive techniques can help infants with CP feed efficiently. The infant with CP is placed in an upright position with the head supported by the caregiver's hand or cradled in the arm; this position allows gravity to assist with the flow of the liquid so it is swallowed instead of resulting in a loss of liquid through the nose.

Breastfeeding the newborn with CL/P is a viable option and in some cases more successful than bottle-feeding. The nipple is positioned and stabilized well back in the oral cavity so that tongue action facilitates milk expression. However, the suction required to stimulate milk let-down may be absent initially; thus a breast pump may be useful before breastfeeding to stimulate the **let-down reflex**. The advantages of breastfeeding include those described in Chapter 27; in addition, there is evidence that breastfeeding infants with CL/P is protective for otitis media.

Suction is almost certainly impaired in infants with CL/P because the velum is unable to elevate and separate the oral nasal cavities while generating adequate negative intraoral pressure. A number of special feeding devices are available for feeding the infant with CL/P, and some are more successful than others, depending on a number of factors (Figure 46.7). One device is the Cleft Lip/Cleft Palate Nurser, which consists of a squeezable plastic bottle and a cross-cut nipple. The Special Needs Feeder may also be used successfully in infants with a poor or disorganized suck. The Special Needs Feeder has a specially designed valve and nipple to adjust the flow of milk to the infant and prevent choking or gagging. A Gravity Flow nipple attached to a squeezable plastic bottle allows formula to be deposited into the mouth of the infant with CL/P. The Pigeon bottle has a nipple with a Y-cut, and the nipple is slightly larger and more bulbous to fit naturally into the oral cavity. A one-way backflow valve prevents milk from flowing retrograde into the bottle to minimize the amount of air the infant swallows.

Infants with clefts tend to swallow excessive air during feedings; thus it is important to pause during feedings and burp the infant. Some CP specialists advocate the use of feeding obturators to help with feeding; these devices may increase compression surfaces within the oral cavity but do not improve feeding efficiency or growth within the first year of life (Jindal & Khan, 2013).

Fig. 46.7 **A:** Haberman feeder. **B:** Mead-Johnson bottle used to feed infant with cleft lip and palate. **C:** Pigeon bottle. (**A** and **B**, Courtesy Texas Children's Hospital. **C**, Courtesy Paul Vincent Kuntz.)

Regardless of the feeding method used, the parent should begin to feed the newborn as soon as possible. When parental feeding is initiated early, the parent can help to determine the method best suited to them and the newborn and can become adept in the technique before discharge from the hospital.

Preoperative care. In preparation for surgical repair, the parents can use the postoperative feeding techniques several days ahead of surgery. The infant must be positioned on the back or side postoperatively. Most infants tolerate these positions well because they are accustomed to being supine for sleeping. It is also helpful before admission to feed the infant with a rubber-tipped Asepto syringe or other device (e.g., soft Sipee cup) that will be used postoperatively.

Postoperative care. The major efforts in the postoperative period are directed toward protecting the operative site.

For children with CL who have undergone surgery, parents may be advised to apply petroleum jelly to the operative site for several days after surgery. For infants with CL, CP, or CL/P, elbow immobilizers may be used to prevent the infant from rubbing or disturbing the suture line; they are applied immediately after surgery and may be used for 7 to 10 days. Adequate analgesia is required to relieve postoperative pain and prevent restlessness. It is important to try and prevent the child from crying, which could cause tension on the suture line.

Feeding is resumed when tolerated. An upright or infant seat position is helpful in the immediate postoperative period (especially for infants who have difficulty handling secretions). Some children are able to be breastfed immediately after surgery with good lactation support. Some centres advocate using a syringe for feeding for 7 to 10 days after CL or CP repair and no sucking for the first 7 days.

The older infant or child may be discharged on a blenderized or soft diet, and parents are instructed to continue the diet until the surgeon directs them otherwise. Parents should be cautioned against allowing the child to eat hard items (e.g., toast, hard cookies, and potato chips) that can damage the repaired palate. The expected outcomes are described in the Nursing Process: The Child With a Cleft Lip or Palate available on Evolve.

! NURSING ALERT

Avoid the use of suction or other objects in the mouth, such as tongue depressors, thermometers, pacifiers, spoons, or straws, following a palatoplasty to maintain the integrity of the surgically repaired palate.

Long-Term Care. Children with any cleft often require a variety of services during recovery. Family members need support and encouragement from health care providers and guidance in activities that facilitate a healthy outcome for their child. With the combined efforts of the family and the health team, most children achieve a satisfactory outcome. Many children with CL or CL/P have surgical correction that creates a near normal–appearing lip and permits good function. Parents need to understand the function of therapy, the purpose and care of all appliances, and the importance of establishing good mouth care and proper toothbrushing habits.

Throughout the child's development, an important goal is the development of a healthy personality and self-esteem. Many communities have CL/P parents' groups that offer help and support to families (see Additional Resources at the end of this chapter).

Esophageal Atresia and Tracheoesophageal Fistula

Congenital atresia of the esophagus (EA) and tracheoesophageal fistula (TEF) are rare malformations that result from failed separation of the esophagus and trachea by the fourth week of gestation and failure of the

trachea and esophagus to separate into distinct structures. These defects may occur as separate entities or in combination, and without early diagnosis and treatment they pose a serious threat to the infant's well-being.

Etiology. EA is the most common esophageal malformation, occurring in approximately 1.7 per 10 000 live births with greater than 90% associated with tracheoesophageal fistula (TEF) (Khan et al., 2020). A history of maternal polyhydramnios is present in approximately 50% of infants with the defects.

EA/TEF is often present with the VATER or VACTERL syndromes, acronyms for syndromes involving a combination of **V**ertebral, **A**norectal, **C**ardiovascular, **T**racheo**E**sophageal, **R**enal, and **L**imb abnormalities. The cardiac and renal anomalies occur most frequently with EA/TEF. Other associated conditions include DiGeorge syndrome, Down syndrome, Pierre-Robin sequence, Fanconi syndrome, and CHARGE syndrome (**C**oloboma, **H**eart defects, choanal **A**tresia, developmental **R**estriction, **G**enital hypoplasia, and **E**ar deformities) (Khan et al., 2020).

Pathophysiology. Anomalies involving the trachea and esophagus are caused by defective separation, incomplete fusion of the tracheal folds after this separation, or altered cellular growth during embryonic development. In the most frequently encountered form of EA and TEF (80 to 95% of cases), the proximal esophageal segment terminates in a blind pouch, and the distal segment is connected to the trachea or primary bronchus by a short fistula at or near the bifurcation (Figure 46.8, *C*). The second most common variety (5 to 8%) consists of a blind pouch at each end, widely separated and with no communication to the trachea (see Figure 46.8, *A*). Less frequently, in H-type EA (4 to 5%), an otherwise normal trachea and esophagus are connected by a common fistula (see Figure 46.8, *E*). Extremely rare anomalies involve a fistula from the trachea to the upper esophageal segment (0.8%) (see Figure 46.8, *B*) or to both the upper and lower segments (0.7 to 6%) (see Figure 46.8, *D*).

Diagnostic Evaluation. TEF is suspected on the basis of clinical manifestations (Box 46.15). EA should also be suspected in cases of maternal polyhydramnios. Although the diagnosis is established on the basis of clinical signs and symptoms, the exact type of anomaly is determined by radiographic studies. A radiopaque catheter is inserted into the hypopharynx and advanced until it encounters an obstruction. Chest films are taken to ascertain esophageal patency or the presence and level of a blind pouch. Sometimes fistulas are not patent, which makes them more difficult to diagnose. The presence of gas in the stomach or small bowel is indicative of a coexisting TEF.

BOX 46.15 Clinical Manifestations of Tracheoesophageal Fistula

Excessive salivation and drooling
Three C's of tracheoesophageal fistula:
- Coughing
- Choking
- Cyanosis

Apnea
Increased respiratory distress during and after feeding
Abdominal distension

The presence of polyhydramnios (accumulation of 2 000 mL of amniotic fluid) prenatally is a clue to the possibility of EA in the fetus, especially with defect type A, B, or C. With these types of EA/TEF, amniotic fluid normally swallowed by the fetus is unable to reach the GI tract to be absorbed and excreted by the kidneys. The result is an abnormal accumulation of amniotic fluid, or polyhydramnios.

Therapeutic Management. The treatment of newborns with EA and TEF includes maintenance of a patent airway, prevention of pneumonia, gastric or blind pouch decompression, supportive therapy, and surgical repair of anomaly. When EA/TEF is suspected, the newborn is immediately taken off oral intake, started on IV fluids, and placed in the position least likely to cause aspiration of either mouth or stomach secretions (usual elevation of the head 30 to 45 degrees, as the newborn's condition allows or prone). Removal of secretions from the mouth and upper pouch requires frequent or continuous suction. A double-lumen catheter should be positioned into the upper esophageal pouch and attached to intermittent or continuous low suction. The newborn's head is kept upright to facilitate removal of fluid collected in the pouch and prevent aspiration of gastric contents. Broad-spectrum antibiotic therapy is often instituted if there is a concern about aspiration of gastric contents.

Most malformations can be corrected surgically in one operation or in two or more staged procedures. The success depends on early diagnosis before complications occur and on the presence and severity of associated anomalies and illness factors, including preterm birth. With measures instituted to prevent aspiration pneumonia and ensure adequate hydration and nutrition, surgery may be postponed to allow for more effective treatment of pneumonia and physiological stabilization

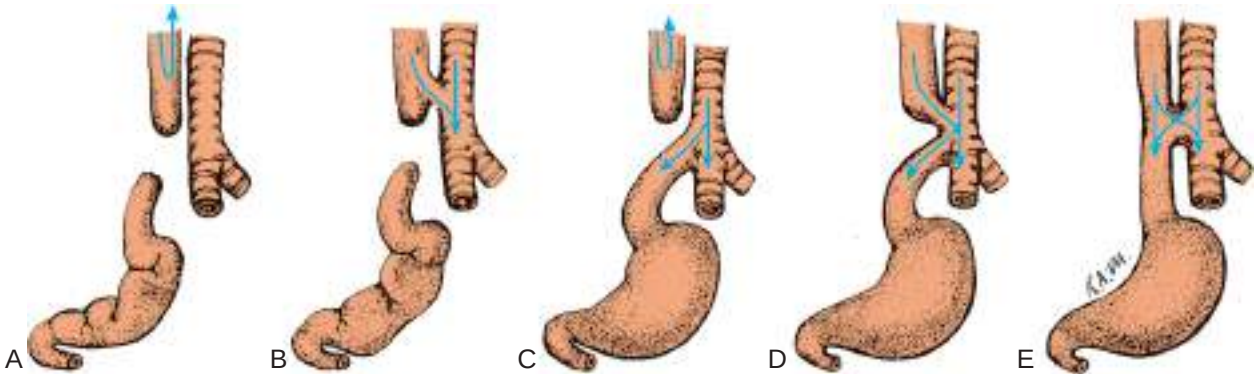

Fig. 46.8 The five most common types of esophageal atresia and tracheosesophageal fistula. **A**: Esophageal atresia (blind pouch at each end). **B**: Fistula from upper esophageal segment to trachea. **C**: Esophageal pouch and distal segment is connected to the trachea. **D**: Fistula to upper and lower segment of esophagus from trachea. **E**: Normal esophagus and trachea connected by a fistula.

so the infant can better withstand the complex surgery. The delay also offers an opportunity for further evaluation and assessment to rule out any associated anomalies and optimize respiratory support.

Primary surgical correction consists of a thoracotomy with division and ligation of the TEF and an end-to-side or end-to-end anastomosis of the esophagus. A chest tube may be inserted to drain intraplural fluid and air. This may consist of one operation or be staged with two or more procedures. For infants who are preterm, have multiple anomalies, or are in poor condition, a staged procedure is preferred that involves palliative measures, including gastrostomy, ligation of the TEF, and provision of constant drainage of the esophageal pouch. A delayed esophageal anastomosis is usually attempted after several weeks to months when the upper pouch elongates. Further surgical techniques may be performed later to facilitate esophageal lengthening. In some centres, thoracoscopic repair of EA/TEF has been successful, negating the need for a thoracotomy and thus minimizing associated operative complications and morbidities (Guidry & McGahren, 2012).

If an esophageal anastomosis cannot be accomplished, a gastrostomy is recommended. A cervical esophagostomy (to allow drainage of saliva through a stoma in the neck) used to be performed in cases of a long-gap atresia, but this is no longer recommended because it makes subsequent surgical repair more difficult (Kunisaki & Foker, 2012).

A primary anastomosis may be impossible because of insufficient length of the two segments of the esophagus. If the gap is 3 to 4 cm, it is called a *long-gap EA*, and in these cases an esophageal replacement procedure using a part of the colon or gastric tube interposition may be necessary to bridge the missing esophageal segment. An esophageal growth induction procedure may also be used (Kunisaki & Foker, 2012).

Up to 75% of infants with EA have *tracheomalacia*, but only 10 to 20% have significant tracheomalacia, which is a weakness in the tracheal wall that occurs when a dilated proximal pouch compresses the trachea in early fetal life or when the trachea does not develop normally because of a loss of intratracheal pressure. Signs of tracheomalacia include barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and possibly apnea. If severe, surgical intervention may be required.

Prognosis. The prognosis is related to the birth weight, associated congenital anomalies, and time of diagnosis. The survival rate is nearly 100% in full-term newborns without severe respiratory distress or other anomalies. Most deaths are the result of extreme prematurity or other lethal anomalies. In preterm low–birth-weight infants with associated anomalies, the incidence of complications is high. Complications of a primary repair include an anastomotic leak, strictures resulting from tension or ischemia, esophageal motility disorders causing dysphagia, and GER. Strictures resulting from tension or ischemia can cause dysphagia, choking, and respiratory distress and are often treated with routine esophageal dilation. Feeding difficulties are common for months or years later and growth must be monitored. In some instances, fundoplication may be required. Sometime the infant must be fed by gastrostomy or jejunostomy to ensure weight gain.

Nursing Care. Nursing responsibility for detection of this malformation begins *immediately* after birth. Ideally, the diagnosis should be made before the initial feeding, but often it is not. If fed, the newborn swallows normally but will suddenly cough and struggle, and the fluid is aspirated or returns through the nose and mouth. Early breastfeeding should not be prevented unless there is a strong suspicion of EA. If EA signs are present, the newborn must have a patent airway established to prevent further respiratory compromise.

! NURSING ALERT

Any newborn who has an excessive amount of frothy saliva in the mouth or difficulty with secretions and unexplained episodes of cyanosis should be suspected of having an EA/TEF and referred immediately for medical evaluation.

Cyanosis is usually a result of laryngeal spasm caused by overflow of saliva into the larynx from the proximal esophageal pouch or aspiration; it normally resolves after removal of the secretions from the oropharynx by suctioning. The passage of a small-gauge orogastric feeding tube via the mouth into the stomach during the initial nursing physical assessment is helpful to rule out EA or other obstructive defects.

Preoperative care. The nurse carefully suctions the mouth and nasopharynx and places the newborn in an optimum position to facilitate drainage and avoid aspiration. The most desirable position for a newborn who is suspected of having the typical EA with a TEF (e.g., type C) is supine (or sometimes prone) with the head elevated on an inclined plane of at least 30 degrees. This positioning minimizes the reflux of gastric secretions at the distal esophagus into the trachea and bronchi, especially when intra-abdominal pressure is elevated.

It is imperative that the source of aspiration be removed at once. Oral fluids need to be withheld and the newborn's fluid needs met parenterally. Until surgery, the blind pouch is kept empty by intermittent or continuous suction through an in-dwelling double-lumen nasal catheter that extends to the end of the pouch. The catheter needs attention because it has a tendency to become clogged with mucus. It is usually replaced daily. In the event that a staged repair is performed, a gastrostomy tube is inserted and left open so that air entering the stomach through the fistula can escape, thus minimizing the danger that gastric contents will be regurgitated into the trachea. The tube empties by gravity drainage. Feedings through the gastrostomy tube and irrigations with fluid are contraindicated before surgery in the infant with a distal TEF. Nursing interventions include respiratory assessment, airway management, thermoregulation, fluid and electrolyte management, and often parenteral nutrition.

Postoperative care. Postoperative care is essentially the same as that for any high-risk newborn. Adequate thermoregulation is provided, the double-lumen NG catheter is attached to low-suction or gravity drainage, parenteral nutrition is provided, and the gastrostomy tube (if applicable) is returned to gravity drainage until feedings are tolerated. If a thoracotomy is performed and a chest tube is inserted, attention to the appropriate function of the closed drainage system is imperative. Pain management in the postoperative period is important even if only a thoracoscopic approach is used. In the first 24 to 36 hours, the nurse should provide pain management for the newborn. Tracheal suction should only be done using a premeasured catheter and with extreme caution to avoid injury to the suture line.

If tolerated, gastrostomy feedings may be initiated and continued until the esophageal anastomosis is healed. Before oral feedings are initiated and the chest tube (if applicable) is removed, a contrast study or esophagram will verify the integrity of the esophageal anastomosis.

The nurse must carefully observe the initial attempt at oral feeding carefully to make certain the infant is able to swallow without choking. Until the infant is able to take a sufficient amount by mouth, oral intake may need to be supplemented by bolus or continuous gastrostomy feedings. Ordinarily infants are not discharged until they can take oral fluids well. The gastrostomy tube may be removed before discharge or maintained for supplemental feedings at home.

Special concerns. Upper respiratory tract complications are a threat to life in both the preoperative and postoperative periods. In addition to pneumonia, there is a constant danger of respiratory

distress resulting from atelectasis, pneumothorax, and laryngeal edema. Any persistent respiratory difficulty after removal of secretions must be reported to the surgeon immediately. The infant is monitored for anastomotic leaks, as evidenced by purulent chest tube drainage, increased WBC count, and temperature instability.

Some infants with EA/TEF may require periodic esophageal dilations on an outpatient basis. Discharge education should include instructions about feeding techniques in the infant with a repaired esophagus, including a semi-upright feeding position, small feedings, and observation for adequacy of swallowing (regurgitation, cyanosis, choking). Tracheomalacia is often a complication; parents need to be educated in the signs and symptoms of this condition. GER may also occur when feedings resume and may contribute to reactive airway disease with wheezing and laboured respirations as the prominent clinical manifestations. Difficulties with thriving and gaining weight may occur in the first 5 years of life in the child with EA/TEF, especially if the child is born preterm, and the nurse should be alert to the achievement of developmental milestones that indicate a need for early intervention and interprofessional referral.

For the infant who requires esophageal replacement, non-nutritive sucking is provided by a pacifier. Sometimes small amounts of water or formula are given orally; although the liquid drains from the esophagostomy, this process allows the infant to develop mature sucking patterns. Infants who remain NPO for an extended period or who have not received oral stimulation have difficulty eating by mouth after corrective surgery and may develop oral hypersensitivity and food aversion, so oral stimulation is important. They require patient, firm guidance to learn how to take food into the mouth and swallow after repair. A referral to an interprofessional feeding behaviour program is often necessary.

As with any congenital anomaly, parents need support in adjusting to the child's condition. One difficulty is the immediate transfer of the sick newborn to the critical care unit and the length of hospitalization. Encouraging parents to visit the newborn, participate in care when appropriate, and express their feelings regarding the child's condition facilitates the attachment process. The nurse in the critical care unit should assume responsibility for ensuring that the parents are kept fully informed of the newborn's progress.

Preparing parents for discharge involves teaching them skills they will need at home. They should be taught to observe for behaviours that indicate the need for suctioning and for signs of respiratory distress and constriction of the esophagus (e.g., poor feeding, dysphagia, drooling, regurgitation of undigested food). Discharge planning also includes obtaining the necessary equipment and home nursing services to provide home care.

Hernias

A *hernia* is a protrusion of a portion of an organ or organs through an abnormal opening. The danger from herniation arises when the organ protruding through the opening is constricted to the extent that circulation is impaired or when the protruding organs encroach on and impair the function of other structures.

The umbilical hernia is a common hernia observed in infants. An umbilical hernia usually is an isolated defect, but it may be associated with other congenital anomalies, such as Down syndrome (trisomy 21) and trisomies 13 and 18. Inguinal hernias account for approximately 80% of all childhood hernias and occur more frequently in boys than in girls. An inguinal hernia that cannot be reduced easily is called an *incarcerated hernia.* A *strangulated hernia* is one in which the blood supply to the herniated organ is impaired. The herniations of concern are those that protrude through the diaphragm, the abdominal wall, or the inguinal canal. The other hernias of significance to pediatric age groups are outlined in Table 46.9.

Omphalocele and Gastroschisis. Omphalocele and gastroschisis are two congenital defects that occur in the abdominal wall. They are rare, however, with omphalocele occurring in approximately 1 in 3 000 to 10 000 live births, whereas the incidence of gastroschisis is 1 in 6 000 live births (Blackburn, 2018). In Canada, the prevalence rate of gastroschisis between 2002 and 2009 was 3.7 per 10 000 total births. Interestingly, during this period a gradual increase in the prevalence was noted (PHAC, 2013).

Pathophysiology. An *omphalocele* is a covered defect of the umbilical ring into which varying amounts of the abdominal organs may herniate (Figure 46.9). Although it is covered with a thin, often translucent peritoneal sac, the sac may rupture during or after birth. Many infants

TABLE 46.9 Summary Outline of Hernias

Type	Manifestations/Diagnostic Evaluation	Management
Diaphragmatic (Congenital) Protrusion of abdominal organs through opening in diaphragm, commonly on left side, causing severe respiratory compromise and inability to adequately expand affected lung, which may be hypoplastic (see complete discussion in Chapter 45, Congenital Diaphragmatic Hernia)		
Hiatal **Sliding:** Protrusion of an abdominal structure (usually stomach) through esophageal hiatus	**Symptoms:** Dysphagia, growth failure, vomiting, neck contortions, frequent unexplained respiratory difficulties, bleeding; usually associated with GER; may cause gastric volvulus and obstruction **Diagnosis:** Made by fluoroscopy	**Therapeutic:** Management of GER symptoms; positioning; pharmacological treatment; and dietary management Surgical treatment when complications are related to GER despite medical management **Nursing:** Be alert to significant signs and carry out routine postoperative care.

TABLE 46.9 Summary Outline of Hernias—cont'd

Type	Manifestations/Diagnostic Evaluation	Management
Abdominal		
Umbilical: Weakness in abdominal wall around umbilicus; incomplete closure of abdominal wall, allowing intestinal contents to protrude through opening	**Symptoms:** Noted by inspection and palpation of the abdomen High incidence in preterm and Black infants Usually closes spontaneously by 1–2 yr of age	**Therapeutic:** No treatment of small defects Operative repair if persists to age 4–6 yr or if defect is >1.5–2.0 cm by age 2 yr **Nursing:** Discourage use of home remedies (e.g., belly bands, coins). Reassure parents.
Omphalocele: Protrusion of intra-abdominal viscera into base of umbilical cord; sac is covered with peritoneum without skin	**Symptoms:** Usually obvious on inspection; however, small omphalocele may appear to be a hematoma in umbilical cord Observe for other malformations such as bladder exstrophy and hypospadias	**Therapeutic:** Surgical repair of defect *Preoperative:* Protect defect from trauma or drying. Keep sac or viscera moist with saline-soaked dressings. Maintain thermoregulation. Carry out routine care of IV fluids and line. Administer prophylactic antibiotics as prescribed. Provide nasogastric suction for gastric decompression. Keep patient NPO. Assess for associated birth defects such as CL or CP. *Postoperative:* Monitor vital signs and BP. Assess for and manage pain. Bowel decompression–NG tube IV fluid intake Monitor return of bowel function.
Gastroschisis: Protrusion of intra-abdominal contents through defect in abdominal wall lateral to umbilical ring; there is never a peritoneal sac covering the intestinal contents	Defect obvious at birth if not detected prenatally by ultrasonography	**Therapeutic:** Surgical repair of defect For large lesions provide gradual reduction of abdominal contents via Siloh pouch before surgical closure. **Nursing:** *Preoperative:* Keep sac covered with a bowel bag to prevent trauma, drying of viscera. NG decompression Maintain thermoregulation. Administer IV fluids. Administer antibiotics. Observe exposed bowel for signs of necrosis or constriction at exit site. *Postoperative:* Monitor vital signs and BP. Bowel decompression with NG tube Administer IV fluids. Assess for and manage pain. Monitor surgical closure site for infection. Monitor lower extremities for pulses and circulation (in case of vena cava compression by large bowel in small abdominal cavity). Monitor for return of bowel function and peristalsis. In event of Siloh pouch, nursing care should also include monitoring vital signs, keeping pouch clean, and aseptic technique with dressing changes (if not done by surgeon). Monitor lower extremities for circulation (as noted previously). Provide emotional support for parents. Long-term issues are associated with feeding and weight gain for gastroschisis and large omphalocele.

BP, Blood pressure; *CDH,* congenital diaphragmatic hernia; *CL,* cleft lip; *CP*, cleft palate; *ECMO,* extracorporeal membrane oxygenation; *GER,* gastroesophageal reflux; *GI,* gastrointestinal; *IV,* intravenous; *NG*, nasogastric; *NPO,* nothing by mouth.

Fig. 46.9 Omphalocele. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn.* Hoffmann–La Roche. Used with permission of F. Hoffmann-La Roche Ltd.)

born with an omphalocele are preterm, and more than half have other defects involving the GI, cardiac, genitourinary, musculoskeletal, and nervous systems.

Gastroschisis is the herniation of the bowel through a defect in the abdominal wall to the right of the umbilical cord. Unlike an omphalocele, there is no membrane covering the organs. In contrast to infants with omphalocele, there is less than 10 to 15% likelihood of associated anomalies, including intestinal atresia and cardiac anomalies.

Therapeutic management and nursing care. The preoperative nursing care is similar for newborns with either defect. Exposure of the viscera causes difficulties with thermoregulation and fluid and electrolyte balance. Before closure is performed, the exposed viscera are covered with moistened saline gauze and plastic wrap. Antibiotics, fluid and electrolyte replacement, gastric decompression, and thermoregulation are needed for physiological support. If complete closure is impossible because of the small size of the abdominal cavity and the large amount of viscera to be replaced, a Silastic Siloh pouch is created and sewn to the fascia of the abdominal defect. The defect is closed surgically after the reduction of contents is complete, which usually takes 7 to 10 days. With surgical treatment, nutritional support, and medical management, the prognosis has improved for infants born with an abdominal wall defect. It is estimated that more than 80% of newborns with omphalocele survive, as do more than 90% of newborns with gastroschisis, although residual feeding difficulties such as GER are not uncommon.

OBSTRUCTIVE DISORDERS

Obstruction in the GI tract occurs when the passage of nutrients and secretions is impeded by a constricted or occluded lumen or when there is impaired motility (*paralytic ileus*). Obstructions may be congenital or acquired. Many congenital obstructions such as atresia, imperforate anus, meconium plug, and meconium ileus usually appear in the newborn period. Other obstructions of congenital etiology such as malrotation, HD, volvulus, incarcerated hernia, and Meckel diverticulum appear after the first few weeks of life. Intestinal obstruction from acquired causes such as intussusception, pyloric stenosis, and tumours may occur in infancy or childhood. Intestinal obstructions from any cause are characterized by similar signs and symptoms (Box 46.16).

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis (HPS) occurs when the circumferential muscle of the pyloric sphincter becomes thickened, resulting in elongation and narrowing of the pyloric channel. This produces an outlet obstruction and compensatory dilation, hypertrophy, and hyperperistalsis of the stomach. This condition usually develops in the first 2 to 5 weeks of life, causing projectile nonbilious vomiting, dehydration, metabolic alkalosis, and eventually, growth failure. The precise etiology is unknown. Boys are affected four to six times more frequently than girls. It is more common in Whites of northern European ancestry, less common in Blacks, and rare in Asians. The offspring of a mother and, to a lesser extent, the father who had pyloric stenosis are at higher risk for pyloric stenosis (Maqbool & Liacouras, 2020b).

Pathophysiology. The circular muscle of the pylorus thickens as a result of hypertrophy (increased size) and hyperplasia (increased mass). This produces severe narrowing of the pyloric canal between the stomach and the duodenum, causing partial obstruction of the lumen (Figure 46.10, *A*). Over time, inflammation and edema further reduce the size of the opening, resulting in complete obstruction. The hypertrophied pylorus may be palpable as an olivelike mass in the upper abdomen.

Pyloric stenosis is not a congenital disorder. It is believed that local innervation may be involved in the pathogenesis. In most cases HPS is an isolated lesion; however, it may be associated with intestinal malrotation, esophageal and duodenal atresia, and anorectal anomalies.

Diagnostic Evaluation. The diagnosis of HPS is often made after the history and physical examination. The olivelike mass is easily palpated when the stomach is empty, the infant is quiet, and the abdominal muscles are relaxed. Vomiting usually occurs 30 to 60 minutes after feeding and becomes projectile as the obstruction progresses. Emesis is nonbilious, usually consisting of stale milk. Often these infants become

BOX 46.16 Clinical Manifestations of Mechanical or Paralytic Intestinal Obstruction

Colicky abdominal pain—From peristalsis attempting to overcome the obstruction
Abdominal distension—As a result of accumulation of gas and fluid above the level of the obstruction
Vomiting—Often the earliest sign of a high obstruction; a later sign of lower obstruction (may be bilious or feculent)
Constipation and obstipation—Early signs of low obstructions; later signs of higher obstructions
Dehydration—From losses of large quantities of fluid and electrolytes into the intestine
Rigid and boardlike abdomen—From increased distension
Bowel sounds—Initially increased when peristalsis is trying to clear the obstruction; gradually diminish and cease
Respiratory distress—Occurs as the diaphragm is pushed up into the pleural cavity
Shock—Plasma volume diminishes as fluids and electrolytes are lost from the bloodstream into the intestinal lumen (third spacing)
Sepsis—Caused by bacterial proliferation with invasion into the circulation

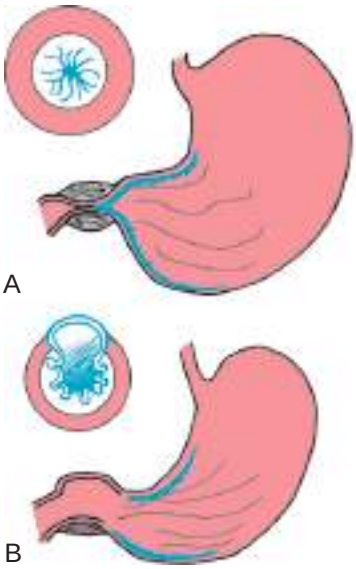

Fig. 46.10 Hypertrophic pyloric stenosis. **A:** Enlarged muscular area nearly obliterates pyloric channel. **B:** Longitudinal surgical division of muscle down to submucosa establishes adequate passageway.

dehydrated and lethargic and eventually may appear significantly malnourished if an early diagnosis is not established.

If the diagnosis is inconclusive from the history and physical signs (Box 46.17), ultrasonography will demonstrate an elongated, sausage-shaped mass with an elongated pyloric channel. The widespread availability of diagnostic ultrasonography has made the diagnosis and treatment more expedient. If ultrasound scanning fails to demonstrate a hypertrophied pylorus, upper GI radiography should be done to rule out other causes of vomiting. Laboratory findings reflect the metabolic alterations created by severe depletion of both fluid and electrolytes in the event that vomiting is prolonged and the condition remains undiagnosed. There are decreased serum levels of both sodium and potassium, although these may be masked by the hemoconcentration from ECF depletion. Of greater diagnostic value is a decrease in serum chloride levels and increases in pH and bicarbonate (carbon dioxide content) characteristic of metabolic alkalosis. The BUN level is elevated as evidence of dehydration. Hyperbilirubinemia (unconjugated) may also be present and often resolves after surgical correction of the obstruction (Maqbool & Liacouras, 2020b).

BOX 46.17 Clinical Manifestations of Hypertrophic Pyloric Stenosis

Projectile vomiting
- May be ejected 1 metre from the child when in a side-lying position, 30 cm or more when in a back-lying position
- Occurs shortly after a feeding (may not occur for several hours)
- May follow each feeding or appear intermittently
- Nonbilious vomitus; may be blood tinged

Infant is hungry, avid nurser; eagerly accepts a second feeding after vomiting episode

No evidence of pain or discomfort except that of chronic hunger

Weight loss

Signs of dehydration

Distended upper abdomen

Readily palpable olive-shaped tumour in the epigastrium just to the right of the umbilicus

Visible gastric peristaltic waves that move from left to right across the epigastrium

Therapeutic Management. Surgical relief of the pyloric obstruction by **pyloromyotomy** (*Fredet-Ramstedt procedure*) is the standard treatment for this disorder. Before surgery, the infant must be rehydrated and the metabolic alkalosis must be corrected. Replacement fluid therapy may necessitate delay of surgery for 24 to 48 hours. The stomach may be decompressed by an NG tube. In infants with no evidence of fluid and electrolyte imbalance, surgery is performed without delay.

The surgical procedure is often performed by laparoscope and consists of a longitudinal incision through the circular muscle fibres of the pylorus down to, but not including, the submucosa (pyloromyotomy, or the Fredet-Ramstedt procedure) (see Figure 46.10, *B*). The procedure has a high success rate. Laparoscopic surgery through a single small incision often results in a shorter surgical time, more rapid postoperative feeding, and shorter hospital stay (Maqbool & Liacouras, 2020b).

Prognosis. The prognosis for infants and small children with HPS is excellent when the diagnosis is confirmed early. Most infants recover completely and rapidly after pyloromyotomy. Postoperative complications include persistent pyloric obstruction and, rarely, wound dehiscence.

Nursing Care. The diagnosis of HPS is considered in the infant less than 6 to 8 weeks of age who appears alert but often fails to gain weight and has a history of vomiting after milk consumption. Assessment is based on observation of eating behaviours and evidence of other characteristic clinical manifestations.

Preoperative care. Preoperatively, emphasis is placed on restoring hydration and electrolyte balance; however, often the condition is brought to the health care provider's attention and readily diagnosed before fluid and electrolyte issues occur. Infants are usually given no oral feedings and receive IV fluids with glucose and electrolyte replacement based on laboratory serum electrolyte values. Careful monitoring of the IV infusion and diligent attention to intake, output, and urine specific gravity measurements are important. Vomiting and the number and character of stools need to be observed and recorded accurately.

Observations also include assessment of vital signs, particularly those that might indicate fluid or electrolyte imbalances. These infants may have metabolic alkalosis from loss of hydrogen ions and from potassium, sodium, and chloride depletion if vomiting is prolonged. The skin, mucous membranes, and daily weight are assessed for alterations in hydration status and water gain or loss.

If stomach decompression and gastric lavage are used preoperatively, the nurse is responsible for ensuring that the tube is patent and functioning properly and for measuring and recording the type and amount of drainage. Infants who are receiving IV fluids or have an NG tube for continuous drainage must be observed to prevent the infusion device or tube from becoming dislodged.

General hygienic care, with attention to the skin and mouth in dehydrated infants, is essential. Protection from bacteria and viruses is also important because infants with impaired nutritional status tend to be more susceptible to infections. Parental involvement should be encouraged and promoted.

Postoperative care. Postoperative vomiting may occur, and most infants, even with successful surgery, exhibit some vomiting during the first 24 to 48 hours because of edema resulting from the surgery. IV fluids are administered until the infant can retain adequate amounts by mouth. Observation of physical signs, monitoring of IV fluids, and careful recording of intake and output are maintained. The infant is also observed for evidence of pain, and appropriate analgesics are given.

Feedings are usually instituted soon after surgery, beginning with clear liquids or breast milk and advancing to formula as tolerated. They are offered slowly, in small amounts, and at frequent intervals as ordered by the health care provider. Observation and recording of feedings and the infant's responses to feedings are a vital part of postoperative care. Care of the operative site consists of observation for any drainage or signs of inflammation and care of the incision as directed by the surgeon.

Parents should be encouraged to remain with their child and become involved in the child's care as much as possible. Vomiting of a projectile nature can be frightening to parents, and they often believe that they may have done something wrong or that surgery was not successful. Most parents need support and reassurance that the condition has a structural cause and is in no way a reflection on their parenting skills and capacities.

Intussusception

Intussusception is the most common cause of intestinal obstruction in children between the ages of 5 months and 3 years (Maqbool & Liacouras, 2020c). Intussusception is more common in boys than in girls. Although specific intestinal lesions occur in a small percentage of these children, generally the cause is not known. More than 90% of intussusceptions do not have a pathological lead point such as a polyp, lymphoma, or Meckel's diverticulum. Idiopathic cases may be caused by hypertrophy of intestinal lymphoid tissue secondary to viral infection.

Pathophysiology. Intussusception occurs when one portion of bowel invaginates into a more distant portion of the bowel, pulling the mesentery with it. The mesentery is compressed and angled, resulting in lymphatic and venous obstruction. As the edema from the obstruction increases, pressure within the area of intussusception increases. When the pressure equals the arterial pressure, arterial blood flow stops, resulting in ischemia and the pouring of mucus into the intestine. Venous engorgement also leads to leaking of blood and mucus into the intestinal lumen, forming the classic currant jelly stools. The most common site is the ileocecal valve (ileocolic), where the ileum invaginates into the cecum and colon (Figure 46.11). Other forms include ileoileal (one part of the ileum invaginates into another section of the ileum) and colocolic (one part of the colon invaginates into another area of the colon, usually in the area of the hepatic or splenic flexure or at some point along the transverse colon).

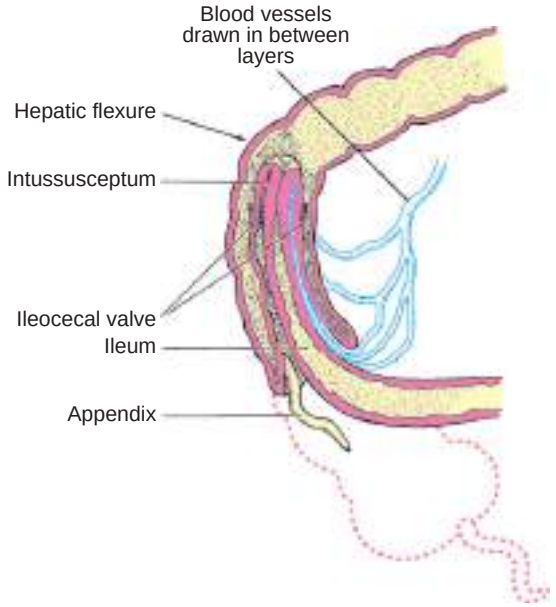

Fig. 46.11 Ileocecal (ileocolic) intussusception.

> **! NURSING ALERT**
>
> The classic triad of intussusception symptoms (abdominal pain, abdominal mass, bloody stools) is present in less than 30% of children (Maqbool & Liacouras, 2020c). Initially children might also respond with screaming, irritability, lethargy, vomiting, diarrhea or constipation, fever, dehydration, and shock. Intussusception is potentially life-threatening; the nurse should be aware of alternative presentations; observe these children closely, and refer them for further evaluation.

Diagnostic Evaluation. Frequently subjective findings lead to the diagnosis (Box 46.18), which can be confirmed by ultrasound. A rectal examination reveals mucus, blood, and occasionally a low intussusception itself.

Therapeutic Management. Conservative treatment consists of radiologist-guided pneumoenema (air enema) with or without water-soluble contrast, or ultrasound-guided hydrostatic (saline) enema to reduce the defect; the advantage of the latter is that no ionizing radiation is needed (Maqbool & Liacouras, 2020c).

Recurrence of intussusception after conservative treatment is rare; however, this procedure should not be attempted with prolonged intussusception, signs of shock, peritoneal irritation, or intestinal perforation (Maqbool & Liacouras, 2020c).

IV fluids, NG decompression, and antibiotic therapy may be used before hydrostatic reduction is attempted. If these procedures are not successful, the child may require surgical intervention. Surgery involves manually reducing the invagination and, when indicated, resecting any nonviable intestine.

Prognosis. Nonoperative reduction is successful in approximately 80 to 95% of cases (Maqbool & Liacouris, 2020c). Surgery is required for patients in whom the contrast enema is unsuccessful. With early diagnosis and treatment, serious complications and death are uncommon.

Nursing Care. The nurse can help establish a diagnosis by listening to the parent's description of the child's physical and behavioural symptoms. It is not unusual for parents to state that they thought something was seriously wrong before others shared their concerns. The description of the child's severe colicky abdominal pain combined with vomiting is a significant sign of intussusception.

BOX 46.18 Clinical Manifestations of Intussusception

- Sudden acute abdominal pain
- Child screaming and drawing the knees toward the chest
- Child appearing normal and comfortable during intervals between episodes of pain
- Vomiting
- Lethargy
- Passage of red, currant jelly–like stools (stool mixed with blood and mucus)
- Tender, distended abdomen
- Palpable sausage-shaped mass in upper right quadrant
- Empty lower right quadrant (Dance sign)
- Eventual fever, prostration, and other signs of peritonitis

As soon as a possible diagnosis of intussusception is made, the nurse should prepare the parents for the immediate need for hospitalization, the nonsurgical technique of hydrostatic reduction, and the possibility of surgery. It is important to explain the basic defect of intussusception. A model of the defect is easily demonstrated by pushing the end of a finger on a rubber glove back into itself or using the example of a telescoping rod. The principle of reduction by hydrostatic pressure can be simulated by filling the glove with water, which pushes the "finger" into a fully extended position.

Physical care of the child does not differ from that for any child undergoing abdominal surgery. Even though nonsurgical intervention may be successful, the usual preoperative procedures, such as maintenance of NPO status, routine laboratory testing (CBC and urinalysis), signed parental consent, and preanaesthetic sedation, are performed. For the child with signs of electrolyte imbalance, hemorrhage, or peritonitis, additional preparation, such as replacement fluids, whole blood or plasma, and NG suctioning, may be needed. Before surgery the nurse should monitor all stools.

! NURSING ALERT

Passage of a normal brown stool usually indicates that the intussusception has reduced itself. This should be immediately reported to the primary health care provider, who may choose to alter the diagnostic and therapeutic care plan.

Postprocedural care includes observations of vital signs, blood pressure, intact sutures and dressing, and the return of bowel sounds. After spontaneous or hydrostatic reduction, the nurse should observe for passage of water-soluble contrast material (if used) and the stool patterns, since the intussusception may recur. Children may be admitted to the hospital or monitored on an outpatient basis. A recurrence is treated with the conservative reduction techniques described previously, but a laparotomy is considered for multiple recurrences.

Malrotation and Volvulus

Pathophysiology. Malrotation of the intestine is caused by the abnormal rotation of the intestine around the superior mesenteric artery during embryological development. Malrotation may manifest in utero or may be asymptomatic throughout life. Infants with malrotation may have intermittent bilious vomiting, recurrent abdominal pain, distension, or lower GI bleeding. Malrotation is the most serious type of intestinal obstruction because, if the intestine undergoes complete volvulus (the intestine twisting around itself), compromise of the blood supply will result in intestinal necrosis, peritonitis, perforation, and death.

Diagnostic Evaluation. It is imperative that malrotation and volvulus be diagnosed promptly and surgical treatment instituted quickly. An upper GI series is the definitive procedure to diagnose this condition.

Therapeutic Management. Surgery is indicated to remove the affected area. Because of the extensive nature of some lesions, short-bowel syndrome is a postoperative complication.

Nursing Care. Preoperatively, the nursing care is the same as that provided to an infant or child with intestinal obstruction. Postoperatively, the nursing care is similar to that provided to the infant or child who has undergone abdominal surgery.

Nursing care is aimed at supporting the infant until surgical intervention can be carried out to eliminate the obstruction. Oral feedings are held, an NG tube is inserted for decompression, and IV therapy is initiated to provide needed fluids and electrolytes. In infants with an intestinal obstruction, surgery consists of resecting the obstructed area of bowel and anastomosing the unaffected bowel. In recent years, the survival rate for these infants has risen to 90 to 95% as a result of better treatments, improved neonatal intensive care, and an increased understanding of the condition.

Anorectal Malformations

Anorectal malformations are among the more common congenital malformations caused by abnormal development, with an incidence of approximately 1 in 5 000 births and occur more often in male than female infants (Blackburn, 2018). These malformations may range from simple imperforate anus to other associated complex anomalies of genitourinary and pelvic organs, which may require extensive treatment for fecal, urinary, and sexual function. Anorectal malformations may occur in isolation or as a part of the VACTERL association (see earlier in this chapter). These anomalies are classified according to the newborn's gender and abnormal anatomical features, including genitourinary defects (Box 46.19).

The anus and rectum originate from an embryological structure called the *cloaca*. Lateral growth of the cloaca forms the urorectal septum that separates the rectum dorsally from the urinary tract ventrally. The rectum and urinary tract separate completely by the seventh week of gestation. Anomalies that occur reflect the stage of development of these processes.

Rectal atresia and stenosis occur when the anal opening appears normal, there is a midline intergluteal groove, and usually no fistula exists between the rectum and urinary tract. *Rectal atresia* is a complete obstruction (inability to pass stool) and requires immediate surgical intervention. *Rectal stenosis* may not become apparent until later in infancy when the infant has a history of difficult stooling, abdominal distension, and ribbonlike stools.

A *persistent cloaca* is a complex anorectal malformation in which the rectum, vagina, and urethra drain into a common channel that opens onto the perineum via the usual urethral site. *Cloacal exstrophy* is a rare, severe defect in which there is externalization of the bladder and bowel through the abdominal wall. Often the genitalia are indefinite, and chromosome studies are necessary to determine the child's gender, which is almost always female. The exstrophic bladder is separated into two halves by the cecum; other features may include an omphalocele, imperforate anus, and, at times, a neural tube defect.

BOX 46.19 Classification of Anorectal Malformations

Male Defects
Perineal fistula
Rectourethral bulbar fistula
Rectourethral prostatic fistula
Rectovesicular (bladder neck) fistula
Imperforate anus without fistula
Rectal atresia and stenosis

Female Defects
Perineal fistula
Vestibular fistula
Imperforate anus without fistula
Rectal atresia and stenosis
Cloaca

Fig. 46.12 Anorectal malformation (imperforate anus). (From Chessell, G., Jamieson, M. J., & Morton, M. [1984]. *Diagnostic picture tests in clinical medicine: Vol. 2.* Mosby-Wolfe.)

Imperforate anus includes several forms of malformation without an obvious anal opening (Figure 46.12). Frequently a *fistula* (an abnormal communication) leads from the distal rectum to the perineum or genitourinary system. The fistula may be evidenced when meconium is evacuated through the vaginal opening, the perineum below the vagina, the male urethra, or the perineum under the scrotum. A fistula may not be apparent at birth, but as peristalsis increases, meconium is forced through the fistula into the urethra or onto the newborn's perineum.

The level of rectal descent is determined by the relationship of the termination of the bowel to the puborectalis sling of the levator ani musculature. About 50% of children with anorectal anomalies have urological complications.

Diagnostic Evaluation. Checking for patency of the anus and rectum is a routine part of the newborn assessment and should include observations regarding the passage of meconium. Inspection of the perineal area reveals absence of the normal anal opening; however, the appearance of the perineum alone does not accurately predict the level of the lesion. Genitourinary and pelvic anomalies associated with anorectal malformations should be considered.

In the newborn, the presence of meconium on the perineum does not always indicate anal patency (particularly in girls) because a fistula may be present and allow evacuation of meconium through the vagina. Rectourinary fistulas should be suspected if there is meconium in the urine. Anal stenosis may not be identified until the child is older and comes to the health care provider with a history of difficult defecation, abdominal distension, and ribbonlike stools.

Abdominal ultrasonography is performed to determine the existence of other malformations. An IV pyelogram and voiding cystourethrogram are recommended for an infant with a high malformation to identify anomalies of the urinary tract. Further examination is also indicated when there is evidence of urinary tract infection or other symptoms. If a syndrome is suspected, cardiac evaluation and spinal films should be obtained.

Therapeutic Management. Successful treatment for anal stenosis is generally accomplished by manual dilations. The procedure is initiated by a health care provider and repeated on a regular basis by nurses in the hospital. Parents should be taught to continue the dilations at home. Perineal fistulas are treated by anoplasty during the newborn period. The opening is moved to the centre of the external sphincter and dilations are begun. More extensive defects are usually managed with a colostomy, and corrective surgical repair is performed later in the first year.

The type of defect, the sacral anatomy, and the quality of muscles influence the long-term prognosis. In general, if the newborn has a deep midline groove, two well-formed buttocks, and an anal dimple, the prognosis for bowel control is better than if the infant has a flat or "rocker" bottom and no midline groove because of associated neurological issues. A functioning interior anal sphincter is important to achieve continence. In its absence, the child may need a bowel program to achieve socially acceptable bowel continence. Other potential complications after surgical treatment include strictures, recurrent rectourinary fistula, mucosal prolapse, and constipation.

The surgical treatment of anorectal malformations varies according to the defect but usually involves one or a combination of several of the following procedures: anoplasty, colostomy, posterior sagittal anorectoplasty (PSARP), or other pull-through with colostomy and colostomy (take-down) closure. The PSARP is a common surgical procedure for the repair of anorectal malformations in infants approximately 1 to 2 months after the initial colostomy. In the PSARP procedure the repair is made via a posterior midline sacral approach to dissect the different muscle groups involved without damaging strategic innervation of pelvic structures so optimum postoperative bowel continence is achieved. A laparotomy may be required if the rectum is unidentifiable by the posterior approach. Additional management after successful repair involves a program of anal dilations, colostomy closure, and a bowel management program.

A primary laparoscopic repair (without colostomy) of anorectal malformation is being performed successfully in some centres. This minimizes surgical risks, associated mortality, and postoperative pain.

Nursing Care. The first nursing responsibility is identification of undetected anorectal malformations. A newborn who does not pass a stool within 24 hours of birth requires further assessment. In addition, meconium that appears at an inappropriate orifice should be reported. Preoperative care includes diagnostic evaluation, GI decompression, and IV fluids.

For the newborn with a perineal fistula an *anoplasty* is performed, which involves moving the fistula opening to the centre of the sphincter and enlarging the rectal opening. Postoperative nursing care after anoplasty is primarily directed toward healing the surgical site without other complications. A program of anal dilations is usually initiated when the child returns for the 2-week checkup. Feedings are started soon after surgical repair, and breastfeeding is encouraged because it causes less constipation.

In newborns with anomalies such as cloaca (girls), rectourethral prostatic fistula (boys), and vestibular fistula (girls), a descending colostomy may be performed to allow fecal elimination and avoid fecal contamination of the distal imperforate section and subsequent urinary tract infection in infants with urorectal fistulas. With a colostomy, postoperative nursing care is directed toward maintaining appropriate skin care at the stoma sites (both distal and proximal), managing postoperative pain, and administering IV fluids and antibiotics. Postoperative NG decompression may be required with laparotomy, and nursing care focuses on maintenance of appropriate drainage (see Chapter 44, Ostomies for Colostomy Care).

Parents are instructed in perineal and wound care or care of the colostomy as needed. Anal dilations may be necessary for some infants. Parents should observe stooling patterns and for signs of anal stricture or complications. Information about dietary modifications and administration of medications is included in counselling.

Preoperative PSARP care often involves irrigation of the distal stoma to prevent fecal contamination of the operative site. During this

time, parents must be given accurate yet simple information regarding the infant's appearance postoperatively and expectations for postoperative care.

Nurses have a vital role in helping families of a child with anorectal malformations provide optimum care so that bowel management is successful and quality of life enhanced for the child and family.

Family support, discharge planning, and home care. Long-term follow-up is important for children with complex malformations. After the definitive pull-through procedure, toilet learning is delayed, and complete continence is seldom achieved at the usual age of 2 to 3 years. Prevention of constipation is important, and breastfeeding is encouraged postoperatively. If a cow's milk–based formula is used, a mild laxative may be prescribed. Bowel habit training, diet modification, and administration of stool softeners or fibre are important aspects of bowel management. Optimum bowel function may not be achieved until late childhood or adolescence. Support and reassurance are important during the slow progression to normal function. Some children never achieve bowel continence and must rely on daily bowel irrigations.

MALABSORPTION SYNDROMES

Chronic diarrhea and malabsorption of nutrients characterize malabsorption syndromes. An important complication of malabsorption syndromes in children is growth failure (failure to thrive). Most cases are classified according to the location of the supposed anatomical or biochemical defect.

Digestive defects are conditions in which the enzymes necessary for digestion are diminished or absent, such as (1) cystic fibrosis, in which pancreatic enzymes are absent, (2) biliary or liver disease, in which bile flow is affected, or (3) lactase deficiency, in which there is congenital or secondary lactose intolerance.

Absorptive defects are conditions in which the intestinal mucosal transport system is impaired. This may occur because of a primary defect (e.g., celiac disease) or as secondary to IBD, resulting in impaired absorption because bowel motility is accelerated (e.g., UC). Obstructive disorders (e.g., HD) also cause secondary malabsorption from enterocolitis.

Anatomical defects, such as extensive resection of the bowel or short-bowel syndrome (SBS), affect digestion by decreasing the transit time of substances and affect absorption by severely compromising the absorptive surface.

Celiac Disease (Gluten-Sensitive Enteropathy)

The term *celiac disease* is often used to describe a symptom complex with four characteristics: (1) steatorrhea (fatty, foul, frothy, bulky stools), (2) general malnutrition, (3) abdominal distension, and (4) secondary vitamin deficiencies. *Celiac disease*, also known as *gluten-induced enteropathy, gluten-sensitive enteropathy,* and *celiac sprue*, is a permanent intestinal intolerance to dietary gluten, a protein present in wheat, barley, and rye that causes damage to the villi in the small intestine. Celiac sprue used to be considered a disease of childhood, but adult presentation is becoming more common. The incidence varies and has been reported in 1 in 3 000 to 1 in 4 000 people. More recently the incidence has been shown to be closer to 1 in 266, as a result of improved screening tests (McCabe et al., 2012). It is seen more frequently in Europe than in North America and is rarely reported in Asians or Blacks. It is more prevalent in women than men. Although the exact cause is unknown, it is now generally accepted that celiac disease is a T-cell–mediated autoimmune and genetic small intestine enteropathy (McCabe et al., 2012). The mucosal lesions contain features that suggest both humoral and cell-mediated immunological overstimulation.

Gradual introduction of gluten in the infant's diet between 4 and 12 months may play a role in the prevention of celiac disease (Troncone & Shamir, 2020). The exact cause of celiac disease is unknown, but there appears to be an inherited predisposition with an influence by environmental factors.

Pathophysiology. Celiac disease is characterized by villous atrophy in the small bowel in response to the protein, gluten. Gluten is found in wheat, barley, rye, and oat grains, although pure oats that are uncontaminated during processing are gluten free. When individuals are unable to digest the gliadin component of gluten, an accumulation of a toxic substance that is damaging to the mucosal cells of the small bowel occurs. This damage leads to villous atrophy, hyperplasia of the crypts, and infiltration of the epithelial cells with lymphocytes. The atrophy leads to malabsorption caused by the reduced absorptive surface.

Membrane receptors involved in preferential antigen presentation to CD4+ T cells play a crucial role in the immune response characteristic of celiac disease. Genes located on the HLA region of chromosome 6 (i.e., HLA-DQ2 or HLA-DQ8) are found in almost 90% of those affected with celiac disease (Troncone & Shamir, 2020). Once the inflammatory reaction is activated by gluten, CD4+ T cells produce cytokines, which are likely to contribute to the intestinal damage. The damage consists of infiltration of the lamina propria, crypt hyperplasia, and villous atrophy and flattening. When there is sufficient villous atrophy, malabsorption occurs.

Classic symptoms of celiac disease are GI manifestations usually noted several months after the introduction of gluten-containing grains into the diet, usually between the ages of 6 months and 2 years (Box 46.20). Typically, children are seen with impaired growth, chronic diarrhea, abdominal distension, muscle wasting with hypotonia, poor

BOX 46.20 Clinical Manifestations of Celiac Disease

Classic Celiac Disease
- Diarrhea
- Abdominal distension
- Failure to thrive, or weight loss
- Positive serology, HLA, and villous atrophy

Atypical Celiac Disease
- Iron-deficiency anemia
- Osteoporosis
- Short stature
- Arthritis
- Infertility
- Peripheral neuropathy
- Abnormal LFTs, positive serology, HLA, and varying degrees of villous atrophy

Silent Celiac Disease
- Asymptomatic but with positive serology, HLA, and villous atrophy

Latent Celiac Disease
- Variation in expression between atypical and asymptomatic
- Positive or negative serology, HLA, and no villous atrophy

HLA, Human leukocyte antigen; *LFT,* liver function test.
Modified from Scanlon, S. A., & Murray, J. A. (2011). Update on celiac disease—Etiology, differential diagnosis, drug tests, and management advances. *Clinical & Experimental Gastroenterology, 4*, 297–311.

appetite, and lack of energy. The clinical manifestations are usually insidious and chronic. The first evidence may be growth failure and diarrhea. Less typical presentation has been observed in children ages 5 to 7 years who have abdominal pain, nausea, vomiting, bloating, and constipation, or extraintestinal manifestations, including short stature, pubertal delay, iron deficiency, dental enamel defects, and abnormal LFTs. Older children have been found to have osteoporosis. Untreated celiac disease can evolve into celiac crisis, characterized by abdominal distension, explosive watery diarrhea, and dehydration with electrolyte imbalance, leading to hypotensive shock and lethargy.

Diagnostic Evaluation. The diagnosis of celiac disease is based on a biopsy of the small intestine demonstrating the characteristic changes of mucosal inflammation, crypt hyperplasia, and villous atrophy with hyperplasia of the crypts and abnormal surface epithelium while the individual is eating adequate amounts of gluten and a full clinical remission after gluten is withdrawn (Troncone & Shamir, 2020). Within a day or two of instituting the gluten-free diet, most children with celiac disease demonstrate a favourable response, including weight gain and improved appetite. Within a few weeks, diarrhea and steatorrhea resolve.

There is no diagnostic genetic testing for celiac disease readily available in Canada. Tests are available for HLA genes, but these genes are found in up to 40% of North Americans while the prevalence of celiac disease is 0.5 to 1.0 in the same population, so this testing is not considered helpful (Canadian Celiac Association, 2008). Commercially available serological tests for celiac disease include antigliadin antibodies of both the immune globulin A and G classes (IgA and IgG); antiendomysium IgA; and antitissue transglutaminase IgA and IgG antibodies for screening first-degree relatives of known celiac disease patients and those with known celiac disease–associated disorders such as type 1 diabetes, thyroiditis, arthritis, primary biliary cirrhosis, Down syndrome, Turner syndrome, Williams syndrome, and osteopenia or osteoporosis.

Therapeutic Management. Treatment of chronic celiac disease is primarily dietary. Although the diet is called *gluten free*, it is actually low in gluten, since it is impossible to remove every source of this protein. Because gluten is found primarily in wheat and rye, but also in smaller quantities in barley, these foods are eliminated from the diet. Pure oats that are processed in a way that ensures no contamination can be certified as gluten free. Corn and rice become substitute grain foods.

Children with untreated celiac disease may have associated lactose intolerance related to intestinal mucosal lesions, which usually improves with gluten withdrawal and intestinal healing. Specific nutritional deficiencies such as iron, folic acid, and fat-soluble vitamin deficiencies are treated with appropriate supplements.

Prognosis. Celiac disease is regarded as a chronic disease. The most severe symptoms usually occur in early childhood and again in adult life. Strict dietary avoidance of gluten prevents symptoms and may minimize the risk of developing lymphoma, the most serious complication of the disease.

Nursing Care. The main nursing consideration is helping the child adhere to the dietary regimen of eating no wheat, barley, or rye. Oats may be safe for most patients, but contamination with other gluten products may occur in harvesting; therefore, caution should be exercised with including oats. Children who have silent celiac disease without clinical manifestations should also adhere to a strict gluten-free diet (Troncone & Shamir, 2020). Considerable time is involved in explaining the disease process to the child and parents, the specific role of gluten in aggravating the disorder, and the foods that must be restricted. It is especially difficult to maintain a diet indefinitely when the child has no symptoms and temporary transgressions result in no difficulties. However, evidence indicates that most individuals who relax their diet experience a relapse of their disease.

Although the chief source of gluten is cereal and baked goods, grains are frequently added to processed foods as thickeners or fillers. To compound the issue, gluten is added to many foods as hydrolyzed vegetable protein, which is derived from cereal grains. The nurse must advise parents to read carefully all ingredients on labels in order to avoid hidden sources of gluten.

Many of children's favourite foods contain gluten, including bread, cake, cookies, crackers, doughnuts, pies, spaghetti, pizza, prepared soups, some processed ice cream, many types of chocolate candy, hot dogs, luncheon meats, meat gravy, and some prepared hamburgers. Many of these products can be eliminated from an infant's or young child's diet fairly easily, but monitoring the diet of a school-age child or adolescent is more difficult. Luncheon preparation away from home is particularly difficult because bread, luncheon meats, and instant soups are not allowed in the child's diet. For families on restricted food budgets, the diet adds an additional financial burden because many inexpensive and convenient foods, which often contain gluten, cannot be used.

In addition to restricting gluten, other dietary alterations may be necessary. For example, in some children who have more severe mucosal damage, the digestion of disaccharides is impaired, especially in relation to lactose. Therefore, these children often need a temporarily lactose-free diet, which requires eliminating all milk products. In general, dietary management includes a diet high in calories and proteins with simple carbohydrates such as fruits and vegetables but low in fats. Because the bowel is inflamed as a result of the pathological processes in absorption, the child must avoid high-fibre foods such as nuts, raisins, raw vegetables, and raw fruits with skin until inflammation has subsided.

It is important to stress long-range complications and remind parents of the child's physical status before dietary treatment and the dramatic improvement after treatment. The nurse can be instrumental in allowing the child to express concerns and frustration while focusing on ways in which they can still feel like everyone else. A clinical dietitian can be consulted to provide children and their families with detailed dietary instructions and education.

Several organizations and resources are available to help families cope with this condition. The Canadian Celiac Association provides support, guidance, and educational materials including information on a gluten-free diet, food sources, recipes, and travel information. Several published cookbooks contain gluten-free recipes. See Additional Resources at the end of this chapter.

Lactose Intolerance

Lactose intolerance refers to the inability to digest lactose, a sugar found in milk and dairy products. It involves a deficiency of the enzyme *lactase*, which is needed for the hydrolysis or digestion of lactose in the small intestine; lactose is hydrolyzed into glucose and galactose. There are at least four types of lactase deficiency that leads to lactose intolerance. *Congenital lactase deficiency* occurs soon after birth, after the newborn has consumed lactose-containing milk (human milk or commercial formula). This inborn error of metabolism involves the complete absence or severely reduced presence of lactase and requires a lifelong lactose-free diet or one extremely reduced in lactose. *Developmental lactase deficiency* refers to the relative lactase deficiency observed in preterm infants of less than 34 weeks of gestation and is

usually reversible with time. *Primary lactase deficiency* is the most common type of lactose intolerance and is manifested usually by 2 years of age, although the time of onset varies. Ethnic groups with a high incidence of lactase deficiency include Indigenous peoples, Asians, southern Europeans, Arabs, Israelis, and people of African descent; Scandinavians tend to have the lowest incidence. In Canada, researchers discovered during an Inuit health study in children under 6 years of age that 5% of Inuit children had lactose intolerance (Findlay & Janz, 2012). *Secondary lactase deficiency* may occur secondary to damage of the intestinal lumen, which decreases or destroys the enzyme lactase. Cystic fibrosis, sprue, celiac disease, kwashiorkor, or infections such as giardiasis, HIV, or rotavirus may cause temporary or permanent lactose intolerance.

The primary symptoms of lactose intolerance include abdominal pain, bloating, flatulence, and diarrhea after the ingestion of lactose. The onset of symptoms occurs within 30 minutes to several hours after lactose consumption. Lactose intolerance is often perceived as an allergy or IBS; however, a dairy allergy is often immediate and accompanied by a skin rash or hives, and IBS is triggered by ingestion of fat, caffeine, sorbitol, and fructose in addition to lactose (Carter & Attel, 2013).

Lactose intolerance may be diagnosed on the basis of the history and improvement with a lactose-reduced diet. The breath hydrogen test is used to positively diagnose the condition. After ingesting 50 grams of a lactose solution, breath samples in lactose-deficient individuals will yield a higher percentage of hydrogen ($\geq$20 ppm [parts per million] above baseline). In infants, lactose malabsorption may be diagnosed by evaluating fecal pH and reducing substances after ingesting a lactose load; however, fructose, gastric motility, and water excretion can alter the sensitivity of the test (Carter & Attel, 2013).

Treatment of lactose intolerance is elimination of offending dairy products; however, some advocate decreasing amounts of dairy products rather than total elimination. Most individuals with lactose intolerance can tolerate a single serving of lactose (12 grams) per day, especially when consumed with food (Carter & Attel, 2013). The enzyme, lactase, can be added to foods or beverages to promote the breakdown of lactose. One concern is that dairy avoidance in children and adolescents with lactose intolerance contributes to reduced bone mineral density and osteoporosis (AAP, 2014). It has been suggested that individuals with lactose maldigestion who do not experience lactose intolerance symptoms continue to consume small amounts of dairy products with meals to prevent reduced bone mass density and subsequent osteoporosis (AAP, 2014). While there is some evidence that *probiotics* (food preparations containing microorganisms such as *Lactobacillus*, which alter the GI microflora and thus are beneficial to the host) improve lactose intolerance, the widespread use of probiotics in infants for this indication requires further study (Marchand & CPS, 2012/2019).

Because dairy products are a major source of calcium and vitamin D, supplementation of these nutrients is needed to prevent deficiency. Yogurt contains inactive lactase enzyme, which is activated by the temperature and pH of the duodenum; this lactase activity substitutes for the lack of endogenous lactase. Fresh, plain yogurt may be tolerated better than frozen or flavoured yogurt. Hard cheeses, lactase-treated dairy products, and lactase tablets taken with dairy products are also viable options. An important distinction between lactose intolerance and food hypersensitivity is that lactose intolerance does not manifest as an anaphylactic-type reaction.

Nursing Care. Nursing care is similar to the interventions discussed for CMA in this chapter and includes explaining the dietary restrictions to the family; identifying alternative sources of calcium, such as yogurt and calcium supplementation; explaining the importance of supplementation; and discussing sources of lactose, especially hidden sources, such as its use as a bulk agent in certain medications, and ways of controlling the symptoms. Parents should be advised to check with the pharmacist regarding potential lactose bulking agents when obtaining medication.

Short-Bowel Syndrome

Short-bowel syndrome (SBS) is a malabsorptive disorder that occurs when there is decreased mucosal surface area, usually as a result of extensive resection of the small intestine. Malabsorption may be exacerbated by other factors such as bacterial overgrowth and dysmotility. The most common causes of SBS in children are necrotizing enterocolitis (see Chapter 28), volvulus, jejunal atresias, and gastroschisis. Other causes include midgut volvulus and diffuse small-bowel CD in older children. Less frequent causes include trauma to the GI tract and HD with extension into the small bowel.

SBS includes two important findings: (1) decreased intestinal surface area for absorption of fluid, electrolytes, and nutrients; and (2) a need for parenteral nutrition. The prognosis for infants with SBS has improved dramatically in the past 20 to 30 years as a result of advances in parenteral nutrition and enteral feeding.

Therapeutic Management. The goals of treatment are to (1) preserve as much length of bowel as possible during surgery, (2) maintain the child's optimal nutritional status, growth, and development while intestinal adaptation occurs, (3) stimulate intestinal adaptation with enteral feeding, and (4) minimize complications related to the disease process and therapy (Shamir, 2020).

Nutritional support is the long-term focus of care. The initial phase of therapy includes parenteral nutrition as the primary source of nutrition. The second phase is the introduction of enteral feeding, which usually begins as soon as possible after surgery. Elemental formulas containing glucose, sucrose and glucose polymers, hydrolyzed proteins, and medium-chain triglycerides facilitate absorption. Usually these formulas are given by continuous infusion through an NG or gastrostomy tube. As the enteral feedings are advanced, the parenteral nutrition solution is decreased in terms of calories, amount of fluid, and total hours of infusion per day.

The final phase of nutritional support occurs when growth and development are sustained exclusively by enteral feedings. When parenteral nutrition is discontinued, there is a risk of nutritional deficiency secondary to malabsorption of fat-soluble vitamins (A, D, E, K) and trace minerals (iron, selenium, zinc). Serum vitamin and mineral levels should be obtained, and enteral supplementation of vitamins and minerals may be required. Pharmacological agents have been used to reduce secretory losses. H_2 blockers, PPIs, and octreotide inhibit gastric or pancreatic secretion. Cholestyramine is often prescribed to improve diarrhea that is associated with bile salt malabsorption. Growth factors have also been used to hasten adaptation and enhance mucosal growth, but these uses are still experimental.

Numerous complications are associated with SBS and long-term parenteral nutrition (see Chapter 44). Infectious, metabolic, and technical complications can occur. Catheter sepsis can occur after improper care of the catheter. The GI tract can also be a source of microbial seeding of the catheter. Bowel atrophy may foster increased intestinal permeability of bacteria. A lack of adequate sites for central lines may become a significant challenge for the child in need of long-term parenteral nutrition. Hepatic dysfunction, hepatomegaly with abnormal LFTs, and cholestasis may also occur (Shamir, 2020).

Bacterial overgrowth is likely to occur when the ileocecal valve is absent or when stasis exists as a result of a partial obstruction or a dilated segment of bowel with poor motility. Alternating cycles of

broad-spectrum antibiotics are used to reduce bacterial overgrowth. This treatment may also decrease the risk of bacterial translocation and subsequent central venous catheter infections. Other complications of bacterial overgrowth and malabsorption include metabolic acidosis and gastric hypersecretion.

Many surgical interventions, such as constructing intestinal valves, tapering enteroplasty or stricturoplasty, intestinal lengthening, and interposed segments, have been used to slow intestinal transit, reduce bacterial overgrowth, or increase mucosal surface area. Intestinal transplantation has been performed successfully in children. Only children with a permanent dependence on parenteral nutrition or severe complications of long-term parenteral nutrition are candidates for transplantation.

Prognosis. The prognosis for infants with SBS has improved with advances in parenteral nutrition and with the understanding of the importance of intraluminal nutrition. Improved surgical techniques for the management of therapy-related issues and the development of more specific immunosuppressive medications for transplantation have all contributed to improved management. The prognosis depends in part on the length of the residual small intestine. An intact ileocecal valve also improves the prognosis. Mortality in infants and children with SBS is usually associated with parenteral nutrition–related conditions, such as fulminant sepsis or severe parenteral nutrition cholestasis.

Nursing Care. The most important components of nursing care are administration and monitoring of nutritional therapy. During parenteral nutrition therapy, care must be taken to minimize the risk of complications related to the **central venous access device (CVAD)** (i.e., catheter infections, occlusions, dislodgment, or accidental removal). Care of the enteral feeding tubes and monitoring of enteral feeding tolerance are also important nursing responsibilities.

When long-term parenteral nutrition is required, preparing the family for home care is a major nursing responsibility that should be initiated early to help prevent a lengthy hospitalization with subsequent delays. Many infants and children can be successfully cared for at home with enteral and parenteral nutrition when the family is prepared and provided with adequate support services. Follow-up by an interprofessional nutritional support service is essential. The nurse plays an active and important role in the success of a home nutrition program. Home infusion companies provide portable equipment, which enables the child and family to maintain a more normal lifestyle.

Many infants with SBS have an intestinal ostomy when the bowel was resected. Routine ostomy care is another important nursing responsibility. Maintaining skin integrity and preventing skin breakdown is accomplished by cleansing frequently and applying skin barrier creams to protect skin from the chronic diarrhea that the child with SBS experiences.

When hospitalization is prolonged, the child's developmental and emotional needs must be met. This often requires special planning to promote normal family adjustment and adaptation of the hospital routines. Care of the hospitalized child is discussed in Chapter 43.

INGESTION OF INJURIOUS AGENTS

In Canada there is no national poison centre that monitors and tracks the occurrence of ingestion of injurious agents in the population. Each province and territory has its own regional centre that is responsible for both education and emergency management of these exposures. There are a total of 160 000 phone calls to the Canadian regional poison centres on a yearly basis. Unintentional poisoning is the fifth leading cause of injury, deaths, hospitalization, and emergency visits for all Canadian age groups. Researchers estimate that 50% of all poison exposures occur among children less than 6 years old. Among Ontario children under 6 years of age the top 10 leading injurious agents causing unintentional injury and death from their ingestion include the following (Ontario Poison Centre, 2020):

1. Household cleaners (bleach, all-purpose cleaners, laundry pods and detergents, and disinfectants)
2. Personal care products (toothpaste, creams, perfumes, and other personal care products)
3. Pain relievers (e.g., ibuprofen or acetaminophen)
4. Foreign bodies (e.g., plastic toys, soil, and coins)
5. Vitamins
6. Plants
7. Herbal and homeopathic remedies, dietary supplements
8. Skin creams
9. Pesticides
10. Stomach remedies

Single-use laundry detergent capsules (LCDs) have become a common household cleaning product ingested by children. The bright colours make them appealing to children and are easy to mistake for candy or toys. Ingestion of these products produces more symptoms than powdered laundry detergent, although the exact reason for this is unclear (Bonney et al., 2013).

Disk or button battery ingestion has recently emerged as the primary cause of fatal ingestions in children younger than 5 years of age; lithium batteries are reported to cause the most harm. Acute tissue injury can occur within 2 hours of any battery ingestion resulting in serious harm, and emergent removal is recommended (Glenn, 2015).

Many poisonings reflect the accessibility of the product in the home, where more than 90% of poisonings occur. Improper storage is a common reason for access to poisonous agents.

The developmental characteristics of young children predispose them to poisoning by ingestion; infants and toddlers explore their environment through oral experimentation. Because the sense of taste is not discriminating at this age, many unpalatable substances are ingested. In addition, toddlers and preschoolers are developing autonomy and initiative, traits that increase their curiosity and misbehaving. Imitation is also a powerful motivator, especially when combined with lack of awareness of danger.

This section is primarily concerned with the immediate emergency treatment of the ingestion of injurious agents. Specific management of corrosive, hydrocarbon, acetaminophen, salicylate, iron, and plant poisoning is summarized in Box 46.21. Because of the importance of lead poisoning among young children, the ingestion of lead is discussed separately.

Principles of Emergency Treatment

A poisoning may or may not require emergency intervention, but in every instance medical evaluation is necessary to initiate appropriate action. The first action for a caregiver of a child who may have ingested a toxic substance is to consult the local poison control centre (PCC). If the PCC cannot be reached, the child should be taken to the nearest emergency department. Parents are advised to call the PCC before initiating any intervention. The local PCC telephone number should be posted near each phone in the house and be included in the parent's cell phone contacts (see Emergency box: Poisoning).

BOX 46.21 Selected Poisonings in Children

Corrosives (Strong Acids or Alkali)

Drain, toilet, or oven cleaners
Electric dishwasher detergent (liquid, because of higher pH, is more hazardous than granular)
Mildew remover
Batteries
Clinitest tablets
Denture cleaners
Bleach

Clinical Manifestations

Severe burning pain in mouth, throat, and stomach
White, swollen mucous membranes; edema of lips, tongue, and pharynx (respiratory obstruction)
Violent vomiting (hemoptysis)
Drooling and inability to clear secretions
Signs of shock
Anxiety and agitation

Comments

Household bleach is a frequently ingested corrosive but rarely causes serious damage.
Liquid corrosives cause more damage than granular preparations.

Treatment

Assess child's breathing and level of consciousness.
Contact regional poison control centre for advice.
Inducing emesis is contraindicated (vomiting redamages the mucosa).
Dilute corrosive with water or milk (usually no more than 120 mL).
Do not neutralize. Neutralization can cause an exothermic reaction (which produces heat and causes increased symptoms or produces a thermal burn in addition to a chemical burn).
Maintain patent airway if needed.
Administer analgesics.
Do not allow oral intake.
Esophageal stricture may require repeated dilations or surgery.

Hydrocarbons

Gasoline
Kerosene
Lamp oil
Mineral seal oil (found in furniture polish)
Lighter fluid
Turpentine
Paint thinner and remover (some types)

Clinical Manifestations

Gagging, choking, and coughing
Nausea
Vomiting
Alterations in sensorium, such as lethargy
Weakness
Respiratory symptoms of pulmonary involvement
- Tachypnea
- Cyanosis
- Retractions
- Grunting

Comments

Immediate danger is aspiration (even small amounts can cause bronchitis and chemical pneumonia).
Gasoline, kerosene, lighter fluid, mineral seal oil, and turpentine cause severe pneumonia.

Treatment

Contact regional poison control centre.
Inducing emesis is generally contraindicated.
Gastric decontamination and emptying are questionable, even when the hydrocarbon contains a heavy metal or pesticide; if gastric lavage must be performed, a cuffed endotracheal tube should be in place before lavage because of a high risk of aspiration.
Symptomatic treatment of chemical pneumonia includes high humidity, oxygen, hydration, and antibiotics for secondary infection.

Acetaminophen

Clinical Manifestations

Occurs in four stages:
1. Initial period (2 to 4 hours after ingestion)
   - Nausea
   - Vomiting
   - Sweating
   - Pallor
2. Latent period (24 to 36 hours)
   - Patient improves
3. Hepatic involvement (may last up to 7 days and be permanent)
   - Pain in right upper quadrant
   - Jaundice
   - Confusion
   - Stupor
   - Coagulation abnormalities
4. Patients who do not die in hepatic stage gradually recover.

Comments

It occurs from acute ingestion.
Toxic dose is 150 mg/kg or greater in children.
Because of multiple formulations and concentrations, chronic acetaminophen toxicity is a significant concern.
Parents should be counselled to read product packaging carefully and to consult a health care provider to avoid inappropriate dosing.

Treatment

Antidote N-acetylcysteine (Mucomyst) can usually be given orally but is first diluted in fruit juice or a soft drink because of the antidote's offensive odour.
It is given as 1 loading dose and usually 17 maintenance doses in different dosages.
It may be given intravenously, but use is investigational.

Aspirin (Acetylsalicylic Acid [ASA])

Clinical Manifestations

Acute poisoning
- Nausea
- Disorientation
- Vomiting
- Dehydration
- Diaphoresis

Continued

BOX 46.21 Selected Poisonings in Children—cont'd

- Hyperpnea
- Hyperpyrexia
- Oliguria
- Tinnitus
- Coma
- Convulsions

Chronic poisoning

- Same as for acute poisoning but subtle onset (often mistaken for viral illness)
- Dehydration, coma, and seizures may be more severe.
- Bleeding tendencies

Comments

It may be caused by acute ingestion (severe toxicity occurs with 300 to 500 mg/kg).

It may be caused by chronic ingestion (i.e., more than 100 mg/kg/day for 2 or more days) and can be more serious than acute ingestion.

Time to peak serum salicylate level can vary with enteric Aspirin or the presence of concretions (bezoars).

Treatment

Hospitalization is required for severe toxicity.

Emesis, lavage, activated charcoal, or cathartic measures may be used.

Lavage will not remove concretions of ASA.

Activated charcoal is important early in ASA toxicity.

Sodium bicarbonate (intravenous) to correct metabolic acidosis and urinary alkalinization may be effective in enhancing elimination; urinary alkalinization is very difficult to achieve.

Be aware of the risk for fluid overload and pulmonary edema.

Prescribe:

- External cooling for hyperpyrexia
- Anticonvulsants
- Oxygen and ventilation for respiratory depression
- Vitamin K for bleeding

In severe cases, hemodialysis (not peritoneal dialysis) may be used.

Iron

Mineral supplement or vitamin containing iron

Clinical Manifestations

Occurs in five stages:

1. Initial period (0.5 to 6 hours after ingestion) (if child does not develop gastrointestinal symptoms in 6 hours, toxicity is unlikely)
   - Vomiting
   - Hematemesis
   - Diarrhea
   - Hematochezia (bloody stools)
   - Gastric pain
2. Latency (2 to 12 hours)
   - Patient improves
3. Systemic toxicity (4 to 24 hours after ingestion)
   - Metabolic acidosis
   - Fever
   - Hyperglycemia
   - Bleeding
   - Shock
   - Death (may occur)
4. Hepatic injury (48 to 96 hours)
   - Seizures
   - Coma
5. Rarely, pyloric stenosis develops at 2 to 5 weeks.

Comments

Factors related to frequency of iron poisoning:

- Widespread availability
- Packaging of large quantities in individual containers
- Lack of parental awareness of iron toxicity
- Resemblance of iron tablets to candy (e.g., M&M's)

Toxic dose is based on the amount of elemental iron in various salts (sulphate, gluconate, fumarate), which ranges from 20 to 33%; ingestions of 60 mg/kg are considered dangerous.

Treatment

Emesis or lavage may be used.

For toxic doses lavage may be necessary for all chewable tablets or liquids if spontaneous vomiting has not occurred.

Chelation therapy with deferoxamine is used in severe intoxication (may turn urine a red to orange colour).

If intravenous deferoxamine is given too rapidly, hypotension, facial flushing, rash, urticaria, tachycardia, and shock may occur; stop the infusion, maintain the intravenous line with normal saline, and notify the health care provider immediately.

Plants

Clinical Manifestations

Depends on type of plant ingested

May cause local irritation of oropharynx and entire gastrointestinal tract

May cause respiratory, renal, and central nervous system symptoms

Topical contact with plants can cause dermatitis

Comments

Plants are some of the most frequently ingested substances.

Plant ingestions rarely cause serious health concerns, although some can be fatal.

Plants can also cause choking and allergic reactions.

Treatment

Induce emesis.

Wash from skin or eyes.

Supportive care as needed.

EMERGENCY

Poisoning

1. Assess the victim:
   - Initiate cardiorespiratory support if needed (circulation, airway, breathing).
   - Take vital signs; re-evaluate routinely.
   - Treat other symptoms, such as seizures.
2. Terminate exposure:
   - Empty mouth of pills, plant parts, or other material.
   - Flush any body surface (including the eyes) exposed to a toxin with large amounts of moderately warm water or saline.
   - Remove contaminated clothes, especially if a pesticide, acid, alkali, or hydrocarbon is involved.
   - Bring victim of an inhalation poisoning into fresh air.
3. Identify the poison:
   - Question the victim and witnesses.
   - Look for environmental cues (empty container, nearby spill, odour on breath) and save all evidence of poison (container, vomitus, urine).
   - In the absence of other evidence, be alert to signs and symptoms of potential poisoning, including symptoms of ocular or dermal exposure.
   - Call the regional poison control centre or other competent emergency facility for immediate advice regarding treatment.
4. Remove poison and prevent absorption:
   - Place child in side-lying, sitting, or kneeling position with their head below the chest to prevent aspiration.

NURSING ALERT

Each province and territory has its own regional poison control centre, thus it is important to have the emergency number posted near the telephone and added to cell phone contacts.

Based on the initial telephone assessment, the PCC will counsel the parents to begin treatment at home or to take the child to an emergency facility. When a call is taken, the name and telephone number of the caller are recorded to re-establish contact if the connection is interrupted. Because most poisonings are managed in the home, expert advice is essential in minimizing adverse effects. When the exact quantity or type of ingested toxin is not known, admission to a health care facility with pediatric emergency treatment services for laboratory evaluation and surveillance during the time after ingestion is critical.

Assessment. The first and most important principle in dealing with a poisoning is to *treat the child first, not the poison*. This requires an immediate concern for life support. Vital signs are taken, and respiratory or circulatory support is instituted as needed. The child's condition is routinely re-evaluated. Because shock is a complication of several types of household poisons, particularly corrosives, measures to reduce the effects of shock, beginning with the CAB (circulation, airway, and breathing) of resuscitation, are important. Establishing and maintaining vascular access for rapid intravascular volume expansion is vital in the treatment of pediatric shock.

The emergency department nurse's responsibility is to be prepared for immediate intervention with all of the necessary equipment. Because time and speed are critical factors in recovery from serious poisonings, anticipation of potential difficulties and complications may mean the difference between life and death.

Gastric Decontamination. Pediatric poisonings are common, yet they rarely result in significant morbidity and mortality (Bronstein et al., 2012). The treatment for ingestion of poison will depend on the type of poison ingested. Gastrointestinal decontamination (GID) is used if necessary, depending on the potential toxicity of the poison and the risks versus benefits. GID with agents such as ipecac or activated charcoal or through gastric lavage is not routinely recommended for treating most childhood poisonings; each toxic ingestion should be treated individually. While specific antidotes may be administered for certain poisonings, no emetic or other substance should be given at home without consultation with a PCC or health care provider.

Syrup of ipecac is an emetic that exerts its action through irritation of the gastric mucosa and by stimulation of the vomiting centre. As stated earlier, it is no longer recommended for routine treatment of poison ingestion (Glenn, 2015).

A commonly used method of GID is the use of *activated charcoal (AC)*, an odourless, tasteless, fine black powder that adsorbs many compounds, creating a stable complex. AC is mixed with water or a saline cathartic to form a slurry. Slurries are neither gritty nor distasteful but resemble black mud. To increase the child's acceptance of AC, the nurse should mix it with small amounts of chocolate milk, fruit syrup, or cola drinks and serve it through a straw in an opaque container with a cover (e.g., a disposable coffee cup and lid) or an ordinary cup covered with aluminum foil. For small children, an NG tube may be required to administer AC. However, recent data indicate that, except in cases of severe poisoning, the use of AC has not significantly improved clinical outcomes (Buckley et al., 2016). AC has the best results when administered 30 to 60 minutes after poison ingestion. Potential complications from the use of AC include aspiration (usually in patients with impaired gag reflexes), constipation, and intestinal obstruction (in multiple doses) (Albertson et al., 2011).

If the child is admitted to an emergency facility, gastric lavage may be performed to empty the stomach of the toxic agent; however, this procedure is associated with serious complications (GI perforation, hypoxia, aspiration). There is no conclusive evidence that gastric lavage decreases morbidity (Benson et al., 2013). In addition, gastric lavage may be of little use if used beyond 1 hour of ingestion (Albertson et al., 2011). Conditions that may be appropriate for performing gastric lavage include presentation within 1 hour of ingestion of a toxin, ingestion in a patient who has decreased GI motility, the ingestion of a toxic amount of a **sustained-release medication**, and a massive or life-threatening amount of poison (Albertson et al., 2011). When gastric lavage is used, the patient requires a protected airway, possible sedation, and the largest-diameter tube that can be inserted to facilitate passage of gastric contents.

Specific antidotes are available to counteract a minority of poisonings. They are highly effective and should be available in all emergency facilities. The supply of antidotes should be checked routinely and replaced as used or according to expiration dates. Antidotes available to treat toxin ingestion include N-acetylcysteine for acetaminophen poisoning, oxygen for carbon monoxide inhalation, naloxone for opioid overdose, flumazenil for benzodiazepines (diazepam) overdose, digoxin immune Fab (Digibind) for digoxin toxicity, amyl nitrate for cyanide, and antivenom for certain poisonous bites.

Prevention of Recurrence. The ultimate objective is to prevent poisonings from occurring or recurring. Education regarding home safety can be an effective method to prevent poisonings (Glenn, 2015). One effective counselling method is first to discuss the difficulties of constantly watching and safeguarding young children (see Family-Centred Care box: Accidental Poisoning). In this way, the challenging task of raising children can lead to a discussion of injury prevention as part of the parental role. A

visit to the home, especially after repeat poisonings, is recommended as part of the follow-up care to assess hazards, and to evaluate appropriate injury-proofing measures. One method of identifying risk areas is to ask specific questions or to have the parent complete a questionnaire designed to isolate factors that predispose children to poisoning. Another approach is to encourage parents to bend down to the child's eye level and survey the home environment for potential hazards, then try to open cabinets and reach shelves to access poisons.

FAMILY-CENTRED CARE

Accidental Poisoning

An accidental poisoning is more than a physical emergency for the child—it usually represents an emotional crisis for the parents, particularly in terms of guilt, self-reproach, and insecurity in the parenting role. The emergency department is no place to admonish the family for negligence, lack of appropriate supervision, or failure to injury-proof the home. Rather, it is a time to calm and support the child and parents while exploring the circumstances of the injury in a nonjudgemental way. If the nurse prematurely attempts to discuss ways of preventing such an incident from recurring, the parents' anxiety will block out any suggestions or offered guidance. Therefore, it is preferable for the nurse to delay the discussion until the child's condition is stabilized or, if the child is discharged immediately after emergency treatment, to make a community health referral or send a packet of information.

Passive measures (those that do not require active participation) have been the most successful in preventing poisoning and include using child-resistant closures and limiting the number of tablets in one container. However, these measures alone are not sufficient to prevent poisoning, because most toxic agents in the home do not have safety closures. Therefore *active measures* (those that require participation) are essential. Guidelines for preventing the occurrence or recurrence of a poisoning are listed in the Guidelines box: Poison Prevention.

GUIDELINES

Poison Prevention

- Assess possible contributing factors in occurrence of injury, such as discipline, parent–child relationship, developmental ability, environmental factors, and behaviour issues.
- Institute anticipatory guidance for possible future injuries based on child's age and developmental level.
- Provide assistance with environmental manipulation, such as lead removal, when necessary.
- Educate parents regarding safe storage of toxic substances.
- Advise parents to place medications out of sight of children.
- Teach children the hazards of ingesting nonfood items.
- Advise parents against using plants for teas or medicine.
- Discuss issues of discipline and offer strategies for effective discipline.
- Instruct parents in correct administration of medications for therapeutic purposes and discontinuation of medication if there is evidence of mild toxicity.
- Advise parents to contact the poison control centre or health care provider immediately when a poisoning occurs.
- Post the phone number of the regional poison control centre with emergency phone list by the telephone and add to cell phone contacts.
- Include by the telephone the home address with nearest cross street in case an ambulance is needed. (In an emergency, family members may not remember the house address, and babysitters may not be aware of the information.)

Heavy Metal Poisoning

Heavy metal poisoning can occur from the ingestion of a variety of substances, the most common being lead. Other sources that are important in potential childhood poisoning are iron and mercury. *Mercury toxicity*, a rare form of heavy metal poisoning, has occurred in children from a variety of sources such as predator fish (king mackerel, shark, swordfish, tile fish), broken thermometers or thermostats, broken fluorescent light bulbs, disk batteries, topical medications, gas regulators, cathartics, and interior latex house paint. Mercury toxicity can also occur at a community level: Grassy Narrows First Nation is a small First Nations community in northwestern Ontario whose water supply is contaminated with mercury as a result of industrial pollution. Today, almost 90% of Grassy Narrows community members suffer from symptoms of mercury poisoning (Pulitzer Center, 2019).

Elemental mercury (also called *metallic mercury* or *quicksilver*) is nontoxic if ingested and if the GI tract is healthy (e.g., has no fistulas). However, mercury is volatile at room temperature and enters the bloodstream after it is inhaled, causing toxicity (tremors, memory loss, insomnia, gingivitis, diarrhea, anorexia, weight loss). The classic form of mercury poisoning is called *acrodynia* (or "painful extremities").

! NURSING ALERT

Mercury thermometers are no longer recommended because the inhaled vapours can cause toxicity if the thermometer is broken. To prevent inhalation, spilled mercury must be cleaned up quickly, using disposable towels and rubber gloves and washing the hands well after removing the spill.

Heavy metals have an affinity for certain essential tissue chemicals, which must remain free for adequate cell functioning. When metals are bound to these substances, cellular enzyme systems are inactivated. Treatment involves **chelation**, use of a chemical compound that combines with the metal for rapid and safe excretion.

Lead Poisoning

In North America, lead poisoning emerged in the early 1900s, when white lead was added to paints and tetraethyl lead was added to gasoline as an antiknock compound. Lead content in paint was decreased in 1975 in Canada; the use of lead in paint and leaded gasoline has since been banned in Canada. Public health interventions have progressively lowered blood lead levels (BLLs) in Canadian children over recent decades (Buka et al., 2019). Currently, lead poisoning in Canadian children is extremely rare. However, children may continue to be exposed to lead, especially in areas where water utilities continue to rely on now-aging lead pipes. Recent effects of increased lead exposure in water have caused crises as recently as 2015 in Flint, Michigan, USA, highlighting the need for continued vigilance (Buka et al., 2019).

Causes of Lead Poisoning. Although there are numerous sources of lead (Box 46.22), in most instances of acute childhood lead poisoning, the source is food, drinking water, nonintact lead-based paint in an older home, or lead-contaminated bare soil in the yard. Microparticles of lead gain entrance into a child's body through ingestion or inhalation and, in the case of an exposed pregnant person, by placental transfer. When measured, a pregnant person's lead level is nearly the same as that of their unborn child. A level of lead not harmful to an adult can be harmful to the fetus.

Inhalation exposure usually occurs during renovation and remodelling activities in the home, whereas ingestion happens during normal day-to-day play and mouthing activities. Sometimes a child actually swallows loose chips of lead-based paint because it has a sweet taste.

BOX 46.22 Sources of Lead*

Lead-based paint in deteriorating condition
Lead solder
Lead crystal
Battery casings
Lead fishing sinkers
Lead curtain weights
Lead bullets
The following may contain lead:
- Ceramic ware
- Water
- Pottery
- Pewter
- Dyes
- Industrial factories
- Vinyl miniblinds
- Playground equipment
- Collectible toys
- Artists' paints
- Pool cue chalk
- Some imported toys or children's metal jewellery

Occupations and hobbies involving lead:
- Battery and aircraft manufacturing
- Lead smelting
- Brass foundry work
- Radiator repair
- Construction work
- Bridge repair work
- Painting contracting
- Mining
- Ceramics work
- Stained-glass making
- Jewellery making

*Health Canada issues alerts and recalls for products that contain lead and that may unexpectedly pose a hazard to young children.

Water and food may also be contaminated with lead. A child does not need to eat loose paint chips to be exposed to the toxin; normal hand-to-mouth behaviour, coupled with the presence of lead dust in the environment that has settled over decades, is the usual method of poisoning (Buka et al., 2019).

Because of family, cultural, or ethnic traditions, a source of lead may be a routine part of life for a child. Nurses must educate themselves about the practices of their patients and identify when such products may be a source of lead. The use of pottery or dishes containing lead may be an issue, as may the use of folk remedies for stomachaches or the use of some cosmetics. Other risk factors for having an elevated BLL include poverty, age younger than 6 years, dwelling in urban areas, and living in older rental homes where lead decontamination may not be a priority. However, any child is at risk for lead poisoning if hazardous conditions for lead are present in the environment.

Pathophysiology and Clinical Manifestations. Lead can affect any part of the body, including the renal, hematological, and neurological systems (Figure 46.13). Of most concern for young children is the developing brain and nervous system, which are more vulnerable than those of an older child or adult. Lead in the body moves via an equilibration process among the blood, the soft tissues and organs, and the bones and teeth. Lead ultimately settles in the bones and teeth, where it remains inert and in storage. This makes up the largest portion of the body burden, approximately 75 to 90%. At the cellular level it competes with molecules of calcium, interfering with the regulating action of calcium. The neurological system is of most concern when young children are exposed to lead. The developing brain is especially vulnerable. Lead disrupts the biochemical processes and may directly affect the release of neurotransmitters, may cause alterations in the blood–brain barrier, and may interfere with the regulation of synaptic activity.

There is also a relationship between anemia and lead poisoning. Children who are iron deficient absorb lead more readily than those with sufficient iron stores. Lead can interfere with the binding of iron onto the **heme** molecule. This sometimes creates a picture of anemia, even though the child is not iron deficient. Lead toxicity to the erythrocytes leads to the release of the enzyme erythrocyte protoporphyrin (EP). Because EP is not sensitive to BLLs of lower lead levels, it is no longer used as a screening test. The BLL test is currently used for screening and diagnosis. However, elevation of the EP level is a good indicator of toxicity from lead and reflects the length of exposure and body burden of lead in the individual child.

Although adults have been shown to suffer adverse renal effects from occupational lead exposure, few studies document renal effects in children at other than extremely high lead levels. Nonetheless, because lead can affect the renal integrity of both children and adults, the renal system of a child is still considered a potential target for its harmful effects.

! NURSING ALERT

Acute signs of lead poisoning include nausea, vomiting, constipation, anorexia, and abdominal pain. Additional clinical manifestations are hypophosphatemia, glycosuria, and aminoaciduria.

Diagnostic Evaluation. Children with lead poisoning rarely have symptoms, even at levels requiring chelation therapy. A diagnosis of lead poisoning is based only on the lead testing of a venous blood specimen from a venipuncture. Blood must be collected carefully to avoid contamination by lead on the skin.

Scientific evidence indicates that health effects occur below the current Canadian blood lead intervention level of 10 mcg/dL. While health effects have been associated with BLLs as low as 1 to 2 mcg/dL, effects observed at these levels are indeterminate. Although Canada has one of the lowest lead blood levels in the world, it is still important to further reduce lead exposure, as there is currently no safe level of blood lead at which children may not experience adverse health effects (Health Canada, 2013).

Screening for Lead Poisoning. When primary prevention fails, the secondary prevention effort of screening for elevated BLLs can be used to identify affected children much earlier than in the past. Screening may be necessary in areas where there are unusual sources of lead exposure, such as historic or ongoing soil contamination from a smelter or if higher BLLs have been observed (Health Canada, 2013).

Therapeutic Management. The degree of concern, urgency, and need for medical intervention changes as the lead level increases. Education is one of the most important elements of the treatment process. Several areas that the nurse should discuss with the family of every child who has an elevated BLL (5 mcg/dL or higher) are listed in Table 46.10.

Chelation therapy. *Chelation* is a process of removing lead from circulating blood and, theoretically, some lead from organs and tissues.

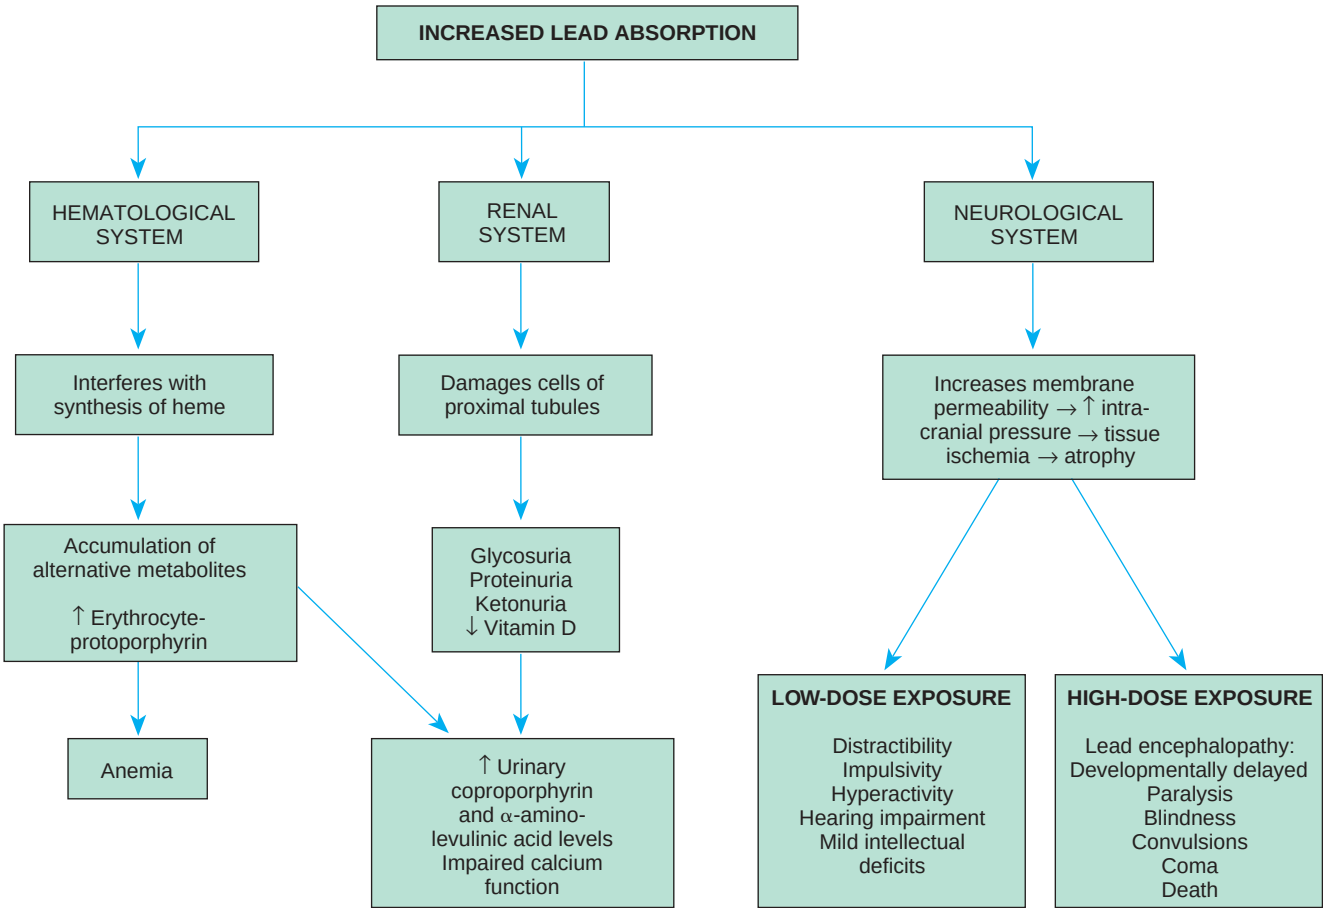

Fig. 46.13 Main effects of lead on body systems.

TABLE 46.10 Managing Lead Toxicity Based on Blood Lead Level (BLL)*

Blood Lead Level	
5 to 14 mcg/dL	Review lab results with the child's family. Perform routine health maintenance, including neurodevelopmental screening, and assess nutrition. Take a careful PEHH to identify potential sources of exposure. Provide preliminary advice about reducing or eliminating exposure source(s). Contact local public health authority for guidance. Re-test venous BLL at 1 to 3 months to ensure the child's lead level is not rising. If it is stable or decreasing, retest in 3 months. Provide nutritional counselling related to calcium and iron. Recommend having a fresh fruit with every meal because iron absorption quadruples when taken with vitamin C–containing foods. Encourage the consumption of iron-enriched foods (e.g., cereals, meats). Ensure iron sufficiency with adequate laboratory testing (CBC, ferritin, CRP) and treatment. Consider starting a multivitamin with iron. Complete a full neurodevelopmental assessment and follow-up. Lead's effects on development may manifest over years.
15 to 44 mcg/dL	Perform steps as described above for BLLs 5 to 14 mcg/dL. Confirm the BLL with repeat venous sample at 1 to 4 weeks. Additional, specific evaluation of the child, such as abdominal X-ray should be considered based on the PEHH. Gut decontamination may be considered if ingested foreign objects are visualized on X-ray. Contact local poison control centre for assistance. Chelation is not typically recommended for asymptomatic patients.
>44 mcg/dL	Follow guidance for BLLs 15 to 44 mcg/dL. Confirm BLL with repeat venous testing at 48 hours. Consider hospitalization and/or chelation therapy in consultation with local poison control centre. Mitigating lead exposures at home, identifying other possible sources, assessing the family's social situation, and chronicity of the exposure will influence management.

CBC, Complete blood count; *CRP*, C-reactive protein; *PEHH*, pediatric environmental health history.
*To convert mcmoL/L to mcg/dL, multiply by 20.72. For example: 0.483 mcmoL/L = 10 mcg/dL.
Source: Buka, I., Hervouet-Zeiber, C., Canadian Paediatric Society, Paediatric Environmental Health Section. (2019). Lead toxicity with a new focus: Addressing low-level lead exposure in Canadian children. *Paediatrics & Child Health, 24*(4), 293. https://www.cps.ca/en/documents/position/lead-toxicity.

It is unclear whether chelation affects lead stores in bones. Although not an antidote in the truest sense, it does serve a similar purpose in that the toxic substance or poison is removed from the body. However, chelation does not counteract any effects of the lead.

Historically, a chelating agent that has been used consistently is calcium disodium edetate ($CaNa_2EDTA$ or calcium EDTA). British anti-Lewisite (BAL, dimercaprol, dimercaptopropanol) is used in conjunction with EDTA. All the agents have potential toxic adverse effects and contraindications. Renal, hepatic, and hematological parameters must be monitored.

Because of the equilibration process among blood, soft tissues, and other sites in the body, there is often a rebound of the BLL after chelation. After the body burden of lead is reduced enough to stabilize the BLL, rebound ceases. Multiple chelation treatments may be necessary. Adequate hydration is essential during therapy because the chelates are excreted via the kidneys.

Severe lead toxicity (lead level $\geq$70 mcg/dL) requires immediate inpatient treatment, whether symptoms are present or not. BAL is contraindicated in children with peanut allergies or hepatic insufficiency, nor should it be given in conjunction with iron. It should also be used with caution in children with renal impairment or hypertension; children must be monitored for hemolysis with presence of glucose 6-phosphate dehydrogenase deficiency. BAL must be given only at a deep intramuscular site, in repeated doses over several days. Calcium EDTA should be given intravenously or intramuscularly (in a different site from BAL). The IV route should not be used in children with cerebral edema.

For lead levels of 45 to 69 mcg/dL and an absence of symptoms, DMSA can be used. The capsule is opened and sprinkled on a small amount of food or may be swallowed whole. DMSA can be used in conjunction with iron. Adverse effects include nausea, vomiting, diarrhea, loss of appetite, rash, elevated LFTs, and neutropenia. Because the chelates are excreted via the kidneys, adequate hydration is essential.

An oral chelating agent, d-penicillamine, is sometimes used to treat lead poisoning, but low doses should be used in children, and monitoring of renal function and blood counts during administration is essential (Dapul & Laraque, 2014).

Prognosis. Although most of the pathophysiological effects of lead are reversible, the most serious consequences of both high and low lead exposure are the effects on the CNS. In children with lead encephalopathy, permanent brain damage can result in intellectual disability, behaviour changes, possible paralysis, and seizures. However, moderate- to low-dose exposure may also cause permanent neurological deficits. Increased distractibility, short attention span, impulsivity, reading disabilities, and school failure have been associated with lead exposure. There is some evidence that treatment of moderate levels of lead poisoning can result in cognitive improvement (Centers for Disease Control and Prevention, Advisory Committee on Childhood Lead Poison Prevention, 2012).

Nursing Care. The primary nursing goal in lead poisoning is to prevent the child's initial or further exposure to lead. For children with low-level exposure, this requires identifying the sources of lead in the environment. Careful history-taking is the most useful and valuable tool and should concentrate on personal risk questions. Suggestions for reducing lead in the child's environment are listed in the Community Focus box: Reducing Blood Lead Levels.

COMMUNITY FOCUS

Reducing Blood Lead Levels

- Make sure the child does not have access to peeling paint or chewable surfaces painted with lead-based paint, especially window sills and wells.
- If a house was built before 1978 and has hard-surface floors, wet mop them at least once per week. Wipe other hard surfaces (e.g., window sills, baseboards). If there are loose paint chips in an area, such as a window well, use a wet disposable cloth to pick them up and discard them. Do not vacuum hard-surfaced floors or window sills or wells, because this spreads dust. Use vacuum cleaners with agitators to remove dust from rugs rather than vacuum cleaners with suction only. If a rug is known to contain lead dust and cannot be washed, it should be discarded.
- Wash and dry child's hands and face frequently, especially before eating.
- Wash toys and pacifiers frequently.
- If soil around the home is or is likely to be contaminated with lead (e.g., if the home was built before 1978 or is near a major highway), plant grass or other ground cover; plant bushes around the outside of the house so that the child cannot play there.
- During remodelling of older homes, be sure to follow correct procedures. Be certain children and pregnant persons are not in the home, day or night, until the process is completed. After deleading, thoroughly clean house using cleaning solution to damp mop and dust before inhabitants return.
- In areas where the lead content of water exceeds the drinking water standard and a particular faucet has not been used for 6 hours or more, "flush" the cold-water pipes by running the water until it becomes as cold as it will get (30 seconds to more than 2 minutes). The more time water has been sitting in pipes, the more lead it may contain.*
- Use only cold water for consumption (drinking, cooking, and especially for making infant formula).
- Hot water dissolves lead more quickly than cold water and thus contains higher levels of lead. First-flush water may be used for nonconsumption uses.
- Have water tested by a competent laboratory. This action is especially important for apartment dwellers; flushing may not be effective in high-rise buildings or in other buildings with lead-soldered central piping.
- Do not store food in open cans, particularly if cans are imported.
- Do not use pottery or ceramic ware that was inadequately fired or is meant for decorative use for food storage or service. Do not store drinks or food in lead crystal.
- Avoid traditional remedies or cosmetics that contain lead.
- Make sure that home exposure is not occurring from parental occupations or hobbies. Household members employed in occupations such as lead smelting should shower and change into clean clothing before leaving work. Construction and lead abatement workers may also bring home lead contaminants.
- Make sure the child eats regular meals, because more lead is absorbed on an empty stomach.
- Make sure the child's diet contains sufficient iron and calcium and does not include excessive fat.

For general information on lead go to Health Canada's lead information page: http://www.hc-sc.gc.ca/ewh-semt/contaminants/lead-plomb/asked_questions-questions_posees-eng.php.

*More information on quality of drinking water is available on Health Canada's website: http://www.hc-sc.gc.ca/ewh-semt/water-eau/drink-potab/index-eng.php.

For children undergoing chelation therapy, the nurse needs to prepare the child for the injections and institute measures to reduce injection pain. Chelating agents are administered deeply into a large muscle mass. To lessen the pain from EDTA, the local anaesthetic procaine is injected with the medication. Rotation of sites is essential to prevent the formation of painful areas of fibrotic tissue. Because EDTA and lead are toxic to the kidneys, the nurse needs to keep records of fluid intake and output and assess the results of urinalysis to monitor renal functioning.

! NURSING ALERT

Calcium EDTA is only administered when there is adequate urinary output. Children receiving the medication intramuscularly must be able to maintain adequate oral intake of fluids.

Discharge planning for children with lead poisoning must include thorough education of families regarding safety from lead hazards, clear instructions regarding medication administration and follow-up, and confirmation that the child will be discharged to a home without lead hazards. Although caution must be used to avoid alarming parents unnecessarily, it is important that they know the risk implications for their child's behaviour and cognitive function. Nurses should observe the development and behaviour of children who are hospitalized. Any concerns that are identified should be thoroughly evaluated. Referral to a child development or speech and language specialist may be indicated.

As in any situational crisis, parents need support and understanding if their child is treated for lead poisoning. Many families at the highest risk for lead poisoning have the fewest resources to adhere to measures such as relocation or removing lead from the environment where the child experiences exposure. Nurses should advocate on behalf of families at risk to ensure that homes and communities are safe and lead free.

KEY POINTS

- Common nutritional disorders of infancy and early childhood may result from vitamin and mineral deficiency or excess, severe acute malnutrition, and food intolerance.
- Severe acute malnutrition may occur as a complication of underlying disease, lack of parental education about infant nutrition, inappropriate management of food allergy, or incorrect preparation of formula.
- Food intolerance encompasses food allergies and food sensitivities, which can have a number of systemic and local clinical manifestations.
- Infants are subject to fluid depletion because of their greater surface area relative to body mass, high rate of metabolism, and immature kidney function.
- Dehydration can be classified as isotonic, hypotonic, and hypertonic.
- Vomiting and diarrhea account for significant fluid depletion, especially in infants and small children.
- The amount, frequency, and characteristics of stool and vomitus are important nursing observations.
- Diarrhea can be caused by an inflammatory process of infectious origin, a toxic reaction to ingestion of poisonous substances, dietary indiscretions, or infections outside the alimentary tract. The primary treatment of diarrhea is the use of an oral rehydrating solution.
- Hirschsprung disease requires surgical removal of aganglionic segments of bowel.
- Postoperative care of the child with abdominal surgery involves assessing the abdomen and providing hydration and nutrition, IV fluids, proper positioning, wound care, and psychological support.
- Nursing care related to gastroesophageal reflux is aimed at identifying children with suggestive symptoms, helping parents with home care feeding and positioning, and caring for the child undergoing surgical intervention.
- Intestinal parasitic diseases constitute the most common infections in the world; giardiasis and enterobiasis are the most widespread parasitic infections among children in Canada.
- Although the cause of appendicitis is poorly understood, it is typically a result of obstruction of the lumen, usually by a fecalith. Common signs and symptoms are right lower quadrant abdominal pain, tenderness, and fever.
- Meckel diverticulum is a congenital malformation of the GI tract characterized by bloody stools.
- Inflammatory bowel disease (IBD) refers to ulcerative colitis (UC) and Crohn disease (CD).
- Peptic ulcers are poorly understood, but contributing factors include interference with the normal protective mechanisms of the mucosal lining and the presence of *Helicobacter pylori*.
- Viral hepatitis is most commonly caused by hepatitis A (HAV), hepatitis B (HBV) and hepatitis C (HCV) viruses.
- HAV is spread by the fecal–oral route, whereas HBV and HCV are transmitted primarily by the parenteral route. The most effective measure in prevention and control of hepatitis in any setting is hand hygiene.
- Structural disorders of the GI tract include cleft lip (CL), cleft palate (CP), esophageal atresia (EA), transesophageal fistula (TEF), anorectal malformations, and biliary atresia (BA).
- BA is a serious disorder, causing progressive liver failure, which is an indication for liver transplantation.
- CL, CP, and CL/P are the most common facial malformations; they may involve nutritional, dental, and speech issues.
- Hernias related to the GI tract can be minor (umbilical) or life-threatening (diaphragmatic, gastroschisis, omphalocele).
- General signs of abdominal obstruction include colicky abdominal pain, nausea and vomiting, abdominal distension, and decreased stool output.
- HPS is recognized by characteristic projectile vomiting, malnutrition, dehydration, and a palpable mass in the epigastrium and is relieved by pyloromyotomy.
- Intussusception is one of the most common causes of intestinal obstruction during infancy and is characterized by abdominal pain and blood in stools. Treatment is either nonsurgical hydrostatic reduction or surgical reduction.
- Malabsorption syndromes are disorders associated with some degree of impaired digestion or absorption. They include digestive, absorptive, and anatomical defects.
- Celiac disease is characterized by intolerance to gluten. It is thought to be either an inborn error of metabolism or an immunological response.
- Short bowel syndrome is characterized by a loss of intestine resulting in a diminished ability to absorb a regular diet normally.

Specialized enteral and parenteral nutrition is a major element of care for these children.

- Although the incidence of poisoning has decreased in the past 30 years as a result of more stringent packaging regulations, childhood poisoning remains a serious health concern.
- The major principles of treatment for poisoning include assessment and the CABs of resuscitation (cardiovascular supportive measures, airway, and breathing), minimization of poison absorption, prevention of complications, family support, and prevention of recurrence.
- Communication with the area poison control centre is essential in the treatment of any poisoning.
- The most important factor contributing to lead poisoning is its availability in the child's environment. Lead-based paint is the most toxic source of lead.
- Because of increasing awareness of the detrimental effects of low levels of lead on the developing nervous system, acceptable BLLs have been decreasing; but children with cognitive and health effects are still seen. The latest guidelines recommend using a BLL reference value of 5 mcg/dL to guide treatment.

Cardiovascular Conditions

Cheryl Sams
Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Design a plan for assisting a child during a cardiac diagnostic procedure.
2. Demonstrate an understanding of the hemodynamics, distinctive manifestations, and therapeutic management of congenital heart disease.
3. Outline a care plan for an infant or child with heart failure.
4. Describe the care for a child who has hypoxia.
5. Describe the care for an infant or a child with a congenital heart defect and its surgical repair.
6. Discuss the nurse's role in helping the child and family cope with congenital heart disease.
7. Describe the care for a child with bacterial endocarditis.
8. Differentiate between rheumatic fever and rheumatic heart disease.
9. List the criteria for selected cholesterol screening of children.
10. Discuss the assessment and management of hypertension in children and adolescents.
11. Outline a care plan for a child with Kawasaki disease.
12. Describe the emergency treatment for shock, including anaphylaxis.

CARDIOVASCULAR DYSFUNCTION

Cardiovascular disorders in children are divided into two major groups, congenital heart disease and acquired heart disorders. *Congenital heart disease (CHD)* includes primarily anatomical abnormalities present at birth that result in abnormal cardiac function. The clinical consequences of congenital heart defects fall into two broad categories: **heart failure (HF)** and **hypoxemia**. *Acquired cardiac disorders* are disease processes or abnormalities that occur after birth and can be seen in the normal heart or in the presence of congenital heart defects. They result from various factors, including infection, autoimmune responses, environmental factors, and familial tendencies. The pathophysiology review found in Figure 47.1 describes the flow of blood through the heart.

History and Physical Examination

Taking an accurate health history is an important first step in assessing an infant or child for possible heart disease. Parents may have specific concerns, such as an infant with poor feeding or fast breathing, or a 7-year-old who can no longer keep up with friends on the soccer field. Others may not realize that their child has a medical condition because their baby has always been pale and fussy.

In assessing infants it is important to ask details about the birthing parent's health history, pregnancy, and birth history. Parents with chronic health conditions, such as diabetes or lupus, are more likely to have infants with heart disease. Some medications, such as phenytoin (Dilantin), are teratogenic to the fetus. Alcohol use or illicit drug use during pregnancy increases the risk of congenital heart defects. Exposures to infections, such as rubella, early in pregnancy may result in congenital anomalies. Infants with low birth weight resulting from intrauterine growth restriction are more likely to have congenital anomalies. High-birth-weight infants also have an increased incidence of heart disease.

A detailed family history is also important. There is an increased incidence of congenital cardiac defects if either parent or a sibling has a heart defect. Some diseases, such as **Marfan syndrome**, and some cardiomyopathies are hereditary. A family history of frequent fetal loss, sudden infant death, and sudden death in adults may indicate heart disease. Congenital heart defects are seen in many syndromes such as Down and Turner syndromes.

The physical assessment of suspected cardiac disease begins with observation of general appearance and proceeds with more specific observations. The following elements are supplementary to the general assessment techniques described for physical examination of the chest and heart in Chapter 33.

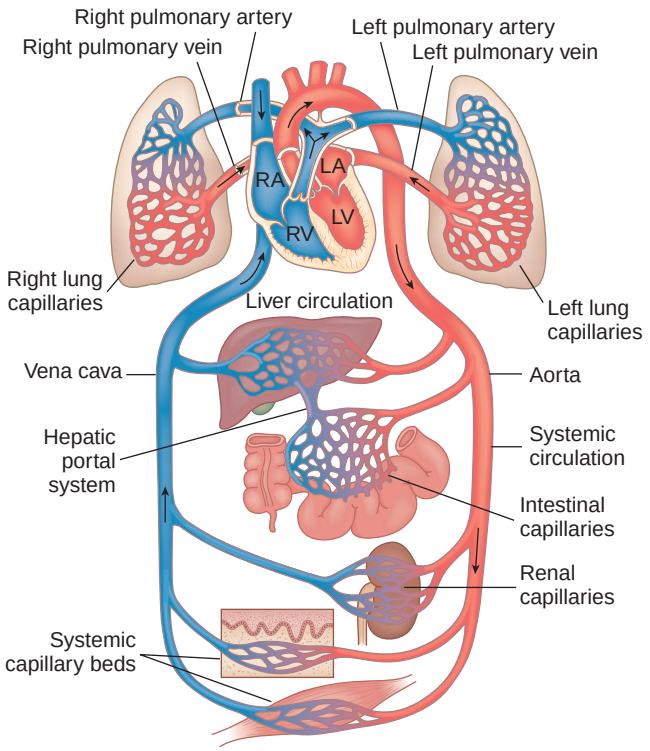

Fig. 47.1 Diagram showing serially connected pulmonary and systemic circulatory systems and how to trace the flow of blood. Right heart chambers propel unoxygenated blood through the systemic circulation. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From McCance, K. L., & Heuther, S. E. [2010]. *Pathophysiology: The biological basis for disease in adults and children* [6th ed.]. Mosby.)

Inspection. The following features need to be assessed:

Nutritional state—Failure to thrive or poor weight gain is associated with heart disease.

Colour—Cyanosis is a common feature of CHD; pallor is associated with poor perfusion.

Chest deformities—An enlarged heart sometimes distorts the chest configuration.

Unusual pulsations—Visible pulsations of the neck veins are seen in some patients.

Respiratory excursion—This refers to the ease or difficulty of respiration (e.g., **tachypnea**, dyspnea, expiratory grunt).

Clubbing of fingers—This is associated with cyanosis.

Palpation and Percussion. On palpation or percussion the following should be assessed:

Chest—These manoeuvres help discern heart size and other characteristics (e.g., thrills) associated with heart disease.

Abdomen—Hepatomegaly or splenomegaly may be evident.

Peripheral pulses—Rate, regularity, and amplitude (strength) may reveal discrepancies.

Auscultation. Listen for the following:

Heart rate and rhythm—Listen for fast heart rates (*tachycardia*), slow heart rates (*bradycardia*), or irregular rhythms.

Character of heart sounds—Listen for distinct or muffled sounds, murmurs, and additional heart sounds.

Diagnostic Evaluation

A variety of invasive and noninvasive tests may be used in the diagnosis of heart disease (Table 47.1). Some of the more common diagnostic tools that require nursing assessment and intervention are described in the following sections.

TABLE 47.1 Procedures for Cardiac Diagnosis

Procedure	Description
Chest radiograph (X-ray)	Provides information on heart size and pulmonary blood flow patterns
Electrocardiography	Graphic measure of electrical activity of heart
Holter monitor	24-hr continuous electrocardiogram (ECG) recording used to assess dysrhythmias
Echocardiography	Use of high-frequency sound waves obtained by a transducer to produce an image of cardiac structures
Transthoracic	Done with transducer on chest
M-mode	One-dimensional graphic view used to estimate ventricular size and function
Two-dimensional	Real-time, cross-sectional views of heart used to identify cardiac structures and cardiac anatomy
Doppler	Identifies blood flow patterns and pressure gradients across structures
Fetal	Imaging fetal heart in utero
Transesophageal (TEE)	Transducer placed in esophagus behind heart to obtain images of posterior heart structures or in patients with poor images from chest approach
Cardiac catheterization	Imaging study using radiopaque catheters placed in a peripheral blood vessel and advanced into heart to measure pressures and oxygen levels in heart chambers and visualize heart structures and blood flow patterns
Hemodynamics	Measures pressures and oxygen saturations in heart chambers
Angiography	Use of contrast material to illuminate heart structures and blood flow patterns
Biopsy	Use of special catheter to remove tiny samples of heart muscle for microscopic evaluation; used in assessing infection, inflammation, or muscle dysfunction disorders and to evaluate for rejection after heart transplant
Electrophysiology (EPS)	Special catheters with electrodes used to record electrical activity from within heart; used to diagnose rhythm disturbances
Exercise stress test	Monitoring of heart rate, blood pressure, ECG, and oxygen consumption at rest and during progressive exercise on a treadmill or bicycle
Cardiac magnetic resonance imaging (MRI)	Noninvasive imaging technique; used in evaluation of vascular anatomy outside of heart (e.g., coarctation of the aorta, vascular rings), estimates of ventricular mass and volume; uses for MRI are expanding

Electrocardiogram. *Electrocardiography* is used to measure the electrical activity of the heart; it provides a graphic display and supplies information on heart rate and rhythm, abnormal rhythms or conduction, ischemic changes, and other information. A standard electrocardiogram (ECG) uses 12 leads to get different views of the heart. An ECG takes about 15 minutes to perform; infants and young children may be fussy with lead placement.

Bedside cardiac monitoring with the ECG is commonly used in pediatrics, especially in the care of children with heart disease. An alarm can be set with parameters for individual patient requirements and will sound if the heart rate is above or below the set parameters. Gelfoam electrodes are commonly used and placed on the right side of the chest (above the level of the heart) and the left side of the chest, and a ground electrode is placed on the abdomen. Electrodes should be changed every 1 or 2 days because they irritate the skin. Bedside monitors are an adjunct to patient care and should never be substituted for direct assessment and auscultation of heart sounds. The nurse should assess the patient, not the monitor.

! NURSING ALERT

Electrodes for cardiac monitoring are often colour coded: white for right, green (or red) for ground, and black for left. Always check to ensure that these colours are placed correctly.

Echocardiography. Echocardiography involves the use of ultrahigh-frequency sound waves to produce an image of the heart's structure. A transducer placed directly on the chest wall delivers repetitive pulses of ultrasound and processes the returned signals (echoes). It is the most frequently used test for describing cardiac anatomy and detecting cardiac dysfunction in children. In many cases, a prenatal diagnosis of CHD can be made by fetal echocardiography.

Although the test is noninvasive, painless, and associated with no known side effects, it can be stressful for children. A full echocardiogram can take 1 hour, and the child must lie quietly in the standard echocardiographic positions (on left side with arms above head). Therefore, infants and young children may need a mild sedative; older children benefit from psychological preparation for the test. The distraction of a movie or music is often helpful.

Cardiac Magnetic Resonance Imaging. Cardiac magnetic resonance imaging (MRI) is often used to define unresolved anatomical pathways when a child may have smaller physical landmarks where the transducer can obtain cardiac images (poor acoustic windows) or a complex structure that is difficult to visualize by ultrasound alone. In current practice, cardiac MRI is increasingly used in conjunction with other imaging modalities for assessment for anatomical evaluation, quantitative assessment of chamber size and function, flow quantification, and tissue characterization (Banka & Geva, 2016).

Cardiac Catheterization. Cardiac catheterization is an invasive diagnostic procedure in which a radiopaque catheter is inserted through a peripheral blood vessel into the heart. The catheter is usually introduced through percutaneous technique, in which the catheter is threaded through a large-bore needle that is inserted into the vein. The catheter is guided through the heart with the aid of fluoroscopy. After the tip of the catheter is within a heart chamber, contrast material is injected, and films are taken of the dilution and circulation of the material (angiography). Types of cardiac catheterizations include the following:

- **Diagnostic catheterizations**—These studies are used to diagnose congenital cardiac defects, particularly in symptomatic infants and before surgical repair. They are divided into (1) right-sided catheterizations, in which the catheter is introduced through a vein (usually the femoral vein) and threaded to the right atrium (most common), and (2) left-sided catheterizations, in which the catheter is threaded through an artery into the aorta and then into the heart.
- **Interventional catheterizations** (therapeutic catheterizations)—A balloon catheter or other device is used to alter the cardiac anatomy. Examples include dilating stenotic valves or vessels or closing abnormal connections (Table 47.2).
- **Electrophysiology studies**— Catheters with tiny electrodes that record the impulses of the heart directly from the conduction system are used to evaluate dysrhythmias. Other catheters can destroy abnormal pathways that cause rapid rhythms (called *ablation*).

Nursing care. Cardiac catheterization has become a routine diagnostic procedure and may be done on an outpatient basis. However, it is not without risks, especially in newborns and seriously ill infants and children. Possible complications include acute hemorrhage from the entry site (more likely with interventional procedures because larger catheters are used), low-grade fever, nausea, vomiting, loss of pulse in the catheterized extremity (usually transient, resulting from a clot, hematoma, or intimal tear), and transient dysrhythmias (generally catheter induced) (Krasemann, 2015). Rare risks include stroke, seizures, tamponade, and death.

Preprocedural care. A complete nursing assessment is necessary to ensure a safe procedure with minimum complications. This assessment

TABLE 47.2 Current Interventional Cardiac Catheterization Procedures in Children

Intervention	Diagnosis
Balloon atrioseptostomy: Use well established in newborns; may also be done under echocardiographic guidance	Transposition of great arteries Some complex single-ventricle defects
Balloon dilation: Treatment of choice	Valvular pulmonic stenosis Branch pulmonary artery stenosis Congenital valvular aortic stenosis Rheumatic mitral stenosis Recurrent coarctation of aorta Further follow-up required in: Native coarctation of aorta in patients older than 7 months Congenital mitral stenosis
Coil occlusion: Accepted alternative to surgery	PDA (<4 mm)
Transcatheter device closure: Several devices used in clinical trials	ASD
Amplatzer septal occluder: Approved for ASD closure	ASD
VSD devices: Used in clinical trials	ASD
Stent placement	Pulmonary artery stenosis Coarctation of the aorta in adolescents Used to treat other lesions Investigational
RF ablation	Some tachydysrhythmias

ASD, Atrial septal defect; *PDA*, patent ductus arteriosus; *RF*, radiofrequency; *VSD*, ventricular septal defect.

should include accurate height (essential for correct catheter selection) and weight. Obtaining a history of allergic reactions is important because some of the contrast agents are iodine based. Specific attention to signs and symptoms of infection is crucial. Severe diaper rash may be a reason to cancel the procedure if femoral access is required. Because assessment of pedal pulses is important after catheterization, the nurse should assess and mark pulses (dorsalis pedis, posterior tibial) before the child goes to the catheterization room. The presence and quality of pulses in both feet should be clearly documented. Baseline oxygen saturation using pulse oximetry in children with cyanosis is also recorded.

Preparing the child and family for the procedure is the joint responsibility of the patient care team. School-age children and adolescents benefit from a description of the catheterization laboratory and a chronological explanation of the procedure, emphasizing what they will see, feel, and hear. Older children and adolescents may bring earphones and favourite music so they can listen during the catheterization procedure. Preparation materials such as picture books, videos, or tours of the catheterization laboratory may be helpful. Preparation should be geared to the child's developmental level. The child's caregivers often benefit from the same explanations. Additional information, such as the expected length of the catheterization, description of the child's appearance after catheterization, and usual postprocedure care, should be outlined. (See also Preparing the Child and Family for Invasive Procedures section later in this chapter)

Methods of sedation vary among institutions and may include oral or intravenous (IV) medications (see Chapter 44). The child's age, heart defect, clinical status, and type of catheterization procedure planned are considered when sedation is determined. General anaesthesia may be needed for some interventional procedures. Children are allowed nothing by mouth (NPO) for 4 to 6 hours or more before the procedure, according to institutional guidelines. Infants and patients with polycythemia may need IV fluids to prevent dehydration and hypoglycemia.

Postprocedural care. Post-catheterization care may occur in a recovery unit, hospital room, or critical care unit depending on the patient's acuity and care needs. Some catheterizations may be done as outpatient procedures, but most patients having interventional procedures are observed overnight in the hospital. They are placed on a cardiac monitor and a pulse oximeter for the first few hours of recovery. The most important nursing responsibility is observation of the following for signs of complications:

- Pulses, especially below the catheterization site, for equality and symmetry. (Pulse distal to the site may be weaker for the first few hours after catheterization but should gradually increase in strength.)
- Temperature and colour of the affected extremity, since coolness or blanching may indicate arterial obstruction
- Vital signs, which are taken as frequently as every 15 minutes, with special emphasis on heart rate, which is counted for 1 full minute for evidence of dysrhythmias or bradycardia
- Blood pressure (BP), especially for hypotension, which may indicate hemorrhage from cardiac perforation or bleeding at the site of initial catheterization
- Dressing, for evidence of bleeding or hematoma formation in the femoral or antecubital area
- Fluid intake, both IV and oral, to ensure adequate hydration. (Blood loss in the catheterization laboratory, the child's NPO status, and diuretic actions of dyes used during the procedure put children at risk for hypovolemia and dehydration.)
- Blood glucose levels for hypoglycemia, especially in infants, who should receive dextrose-containing IV fluids

NURSING ALERT

If bleeding occurs, direct continuous pressure is applied 2.5 cm above the percutaneous skin site to localize pressure over the vessel puncture.

Depending on hospital policy, the child may be kept in bed with the affected extremity maintained straight for 4 to 6 hours after venous catheterization and 6 to 8 hours after arterial catheterization to facilitate healing of the cannulated vessel. If younger children have difficulty staying in bed, they can be held in the parent's lap with the leg maintained in the correct position. The child's usual diet can be resumed as soon as tolerated, beginning with sips of clear liquids and advancing as the condition allows. The child should be encouraged to void to clear the contrast material from the blood. Generally, there is only slight discomfort at the percutaneous site. To prevent infection, the catheterization area is protected from possible contamination. If the child wears diapers, the dressing can be kept dry by covering it with a piece of plastic film and sealing the edges of the film to the skin with tape. However, the nurse must be careful to continue observing the site for any evidence of bleeding (see Family-Centred Care box: Care After Cardiac Catheterization and Clinical Reasoning Case Study: Cardiac Catheterization).

FAMILY-CENTRED CARE

Care After Cardiac Catheterization

- Remove pressure dressing the day after catheterization. A clean, dry bandage should be changed daily for 5 days after the procedure.
- Keep site clean and dry. Avoid tub baths and swimming for the first 3 days; children may shower or have a sponge bath the first day after catheterization.
- Observe site for redness, swelling, drainage, and bleeding. Monitor for fever. Observe the catheter leg for coolness. Notify health care provider if these occur. If the site bleeds, apply pressure for 15 minutes. If the bleeding continues, keep applying pressure and go to your nearest emergency department.
- Resume regular diet without restrictions.
- Use acetaminophen or ibuprofen for pain.
- Keep follow-up appointments per health care provider's instruction.

Modified from AboutKidsHealth. (2021). *Heart catheterization: Caring for your child after the procedure*. https://www.aboutkidshealth.ca/article?contentid=1214&language=english

CLINICAL REASONING CASE STUDY

Cardiac Catheterization

Tommy, a 3-year-old child with tetralogy of Fallot, has just returned to his hospital room from the cardiac catherization recovery room. His mother calls you to the bedside to tell you that he is vomiting and bleeding. You arrive to find Tommy anxious, pale, crying, and sitting in a puddle of blood.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about Tommy's situation?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. Risks of cardiac catheterization
   b. Association between vomiting and bleeding after cardiac catheterization
   c. Concerns related to acute blood loss
3. What priorities for nursing care should be established for Tommy?

CONGENITAL HEART DISEASE

The incidence of CHD in children in Canada is approximately 12 of 1 000 births, and 50% of these infants show signs and symptoms before the first year of life (Narvey et al., 2017). CHD is the major cause of death (other than prematurity) in the first year of life. *Critical congenital heart disease* (CCHD) is defined as more severe disease with often duct-dependent lesions that require intervention early in life for optimal outcome. These account for about 25% of all CHD cases diagnosed in Canada (Wong et al., 2017). Although there are more than 35 well-recognized cardiac defects, the most common heart anomaly is ventricular septal defect (VSD).

The Canadian Pediatric Cardiology Association has recommended that all healthy newborns have pulse oximetry screening (POS) as part of their physical examination. When an abnormal saturation level is determined, the probability of having CCHD is 5.5 times greater than when a normal result is obtained. Newborns with abnormal screening results should undergo a comprehensive assessment and echocardiography (Wong et al., 2017). Box 47.1 lists conditions that POS can be used to screen for (see Chapter 26, Screening for Critical Congenital Heart Disease).

! NURSING ALERT

Nurses can increase the accuracy of the pulse oximetry screening and minimize false positive results by screening after 24 hours and by testing the right hand and either foot.

The exact etiology of most congenital cardiac defects is unknown. Most are thought to be a result of multifactorial inheritance: a complex interaction of **genetic** and environmental factors. Risk factors that are known to increase the incidence of CHD in the birth parent include chronic illnesses such as diabetes or poorly controlled phenylketonuria, alcohol consumption, and exposure to environmental toxins and infections. Family history of a cardiac defect in a parent or sibling increases the likelihood of a cardiac anomaly. In general, when one child is affected, the risk for recurrence in siblings is about 3%, and for those who have a child with hypoplastic left heart syndrome (HLHS) the risk for CHD in subsequent children is reported to be 10% (Park, 2014). The risk of CHD increases if a first-degree relative (parent or sibling) is affected.

Congenital heart anomalies are often associated with **chromosome** abnormalities, syndromes, or congenital defects in other body systems. Trisomy 21 (Down syndrome), 13, and 18 are highly correlated with congenital heart defects. Syndromes associated with heart defects include DiGeorge syndrome, a syndrome characterized by deletion of part of chromosome 22q11 (interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, and posterior malaligned VSDs); Noonan syndrome (pulmonic valve anomalies and cardiomyopathy); Williams syndrome (aortic and pulmonic stenosis); and Holt-Oram syndrome (upper limb anomalies and atrial septal defect). Extracardiac defects such as tracheoesophageal fistula, renal abnormalities, and diaphragmatic hernia are seen in association with heart anomalies.

BOX 47.1 Heart Lesions Detectable Using Pulse Oximetry Screening (POS)

Most Consistently Cyanotic
Hypoplastic left heart syndrome
Pulmonary atresia with intact ventricular septum
Total anomalous pulmonary venous return
Tetralogy of Fallot
Transposition of the great arteries
Tricuspid atresia
Truncus arteriosus

May Be Cyanotic
Coarctation of the aorta
Double outlet right ventricle
Ebstein anomaly
Interrupted aortic arch
Defects with single ventricle physiology

Pulse oximetry screening in newborns to enhance detection of critical congenital heart disease. *Paediatrics & Child Health, 22*(8), 494–498. Updated 2020. https://www.cps.ca/en/documents/position/pulse-oximetry-screening.

Circulatory Changes at Birth

During fetal life, blood carrying oxygen and nutritive materials from the placenta enters the fetal system through the umbilicus via the large umbilical vein. The blood then travels to the liver, where it divides. Part of the blood enters the portal and hepatic circulation of the liver, and the remainder travels directly to the inferior vena cava (IVC) by way of the ductus venosus. Oxygenated blood enters the heart via the IVC. Because of the higher pressure of blood entering the right atrium, it is directed posteriorly in a straight pathway across the right atrium and through the *foramen ovale* to the left atrium. In this way, the better-oxygenated blood enters the left atrium and ventricle to be pumped through the aorta to the head and upper extremities. Blood from the head and upper extremities entering the right atrium from the superior vena cava is directed downward through the tricuspid valve into the right ventricle. From there it is pumped through the pulmonary artery, where the major portion is shunted to the descending aorta via the *ductus arteriosus*. Only a small amount flows to and from the nonfunctioning fetal lungs (Figure 47.2, *A*).

Before birth the high pulmonary vascular resistance created by the collapsed fetal lung causes greater pressures in the right side of the heart and the pulmonary arteries. At the same time, the free-flowing placental circulation and the ductus arteriosus produce a low vascular resistance in the remainder of the fetal vascular system. With the cessation of placental blood flow from clamping of the umbilical cord and the expansion of the lungs at birth, the hemodynamics of the fetal vascular system undergo pronounced and abrupt changes (see Figure 47.2, *B*).

With the first breath, the lungs are expanded, and increased oxygen causes pulmonary vasodilation. With the removal of the placenta, pulmonary pressures start to fall as systemic pressures start to rise. Normally, the foramen ovale closes as the pressure in the left atrium exceeds the pressure in the right atrium. The ductus arteriosus starts to close in the presence of increased oxygen concentration in the blood and other factors.

Altered Hemodynamics

To appreciate the physiology of heart defects, it is necessary to understand the role of pressure gradients, flow, and resistance within the circulation. As blood is pumped through the heart, it (1) flows from an area of high pressure to one of lower pressure and (2) takes the path of least resistance. In general, the higher the pressure gradient, the greater the rate of flow; the higher the resistance, the lower the rate of flow.

Normally, the pressure on the right side of the heart is lower than that on the left side, and the resistance in the pulmonary circulation is less than that in the systemic circulation. Vessels entering or exiting

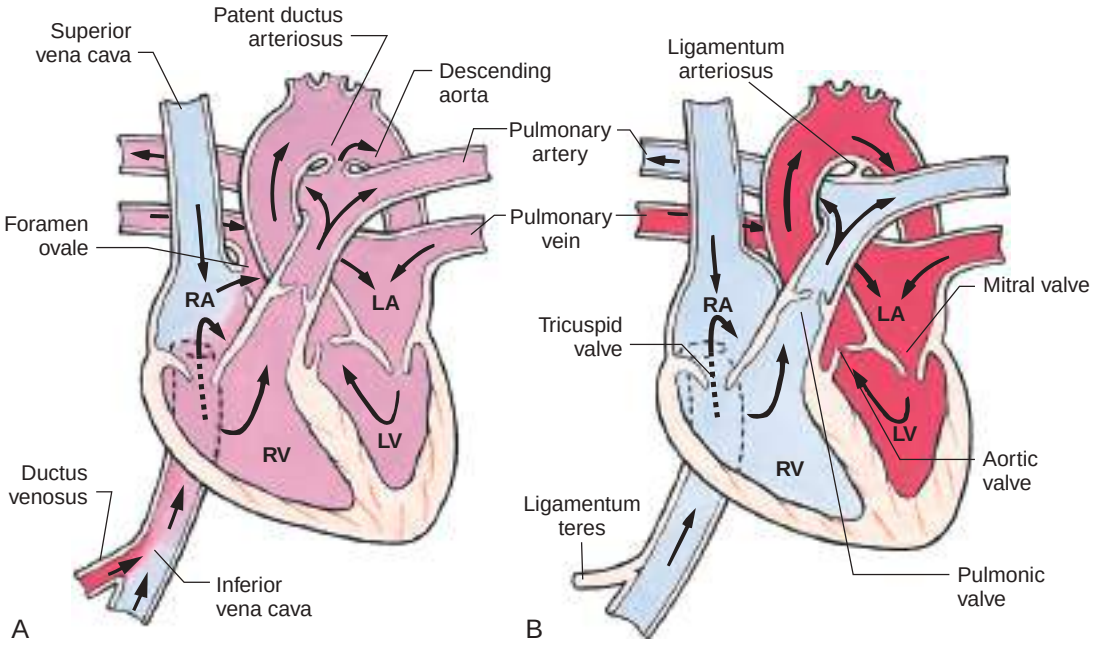

Fig. 47.2 Changes in circulation at birth. **A:** Prenatal circulation. **B:** Postnatal circulation. *Arrows* indicate direction of blood flow. Although four pulmonary veins enter the LA, for simplicity this diagram shows only two. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

these chambers have corresponding pressures. Therefore, if an abnormal connection exists between the heart chambers (such as a septal defect), blood will necessarily flow from an area of higher pressure (left side) to one of lower pressure (right side). Such a flow of blood is termed a *left-to-right shunt*. Anomalies resulting in cyanosis may result from a change in pressure so that the blood is shunted from the right to the left side of the heart (*right-to-left shunt*) because of either increased pulmonary vascular resistance or obstruction to blood flow through the pulmonic valve and artery. Cyanosis may also result from a defect that allows mixing of oxygenated and deoxygenated blood within the heart chambers or great arteries, such as occurs in truncus arteriosus.

Classification of Defects

There are typically two classification systems used to categorize congenital heart defects. Traditionally, cyanosis, a physical characteristic, has been used as the distinguishing feature, dividing the anomalies into acyanotic defects and cyanotic defects. In clinical practice, this system is problematic because children with acyanotic defects may develop cyanosis. Also, more often, those children with cyanotic defects may appear pink and have more clinical signs of HF.

A more useful classification system is based on hemodynamic characteristics (blood flow patterns within the heart). These blood flow patterns are (1) increased pulmonary blood flow; (2) decreased pulmonary blood flow; (3) obstruction to blood flow out of the heart; and (4) mixed blood flow, in which saturated and desaturated blood mix within the heart or great arteries. As a comparison, both classification systems are outlined in Figure 47.3.

With the hemodynamic classification system, the clinical manifestations of each group are more uniform and predictable. Defects that allow blood flow from the higher-pressure left side of the heart to the lower-pressure right side (left-to-right shunt) result in increased pulmonary blood flow and cause HF. Obstructive defects impede blood flow out of the ventricles; obstruction on the left side of the heart results in HF, whereas severe obstruction on the right side causes cyanosis.

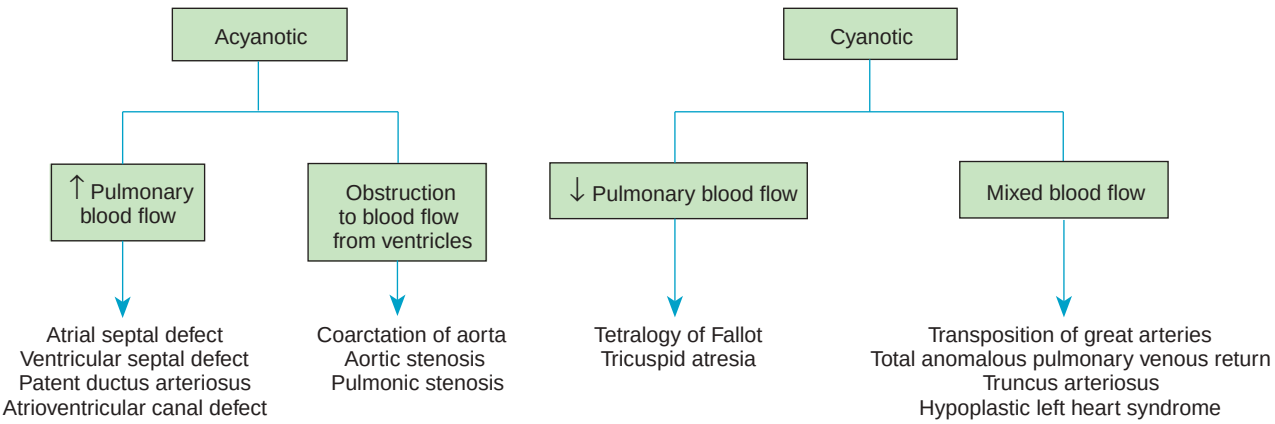

Fig. 47.3 Comparison of acyanotic–cyanotic and hemodynamic classification systems of congenital heart disease.

Defects that cause decreased pulmonary blood flow result in cyanosis. Mixed lesions present a variable clinical picture based on the degree of mixing and amount of pulmonary blood flow; hypoxemia (with or without cyanosis) and HF usually occur together. Using this classification system, the clinical presentation and management of the most common defects are outlined in the following sections.

The outcomes of surgical treatment for patients with moderate to severe disease vary. Patient risk factors for increased morbidity and mortality include prematurity or low birth weight, a genetic syndrome, multiple cardiac defects, a noncardiac congenital anomaly, and age at time of surgery (newborns are a higher risk group). For example, aortic stenosis or coarctation manifesting in the first week of life is more severe and carries a higher mortality than if it becomes apparent at 1 year of age. Outcomes for surgical repair of similar congenital heart defects also vary among treatment centres. In general, the outcomes of surgical procedures have steadily improved in the past decade, with mortality rates for many severe defects below 10%, and the incidence of complications and length of hospital stay have declined. Advances in treatment have helped 9 out of 10 children with CHD survive to adulthood (Bernstein, 2020c).

Defects With Increased Pulmonary Blood Flow. In this group of cardiac defects, intracardiac communications along the septum or an abnormal connection between the great arteries allows blood to flow from the higher-pressure left side of the heart to the lower-pressure right side of the heart (Figure 47.4). Increased blood volume on the right side of the heart increases pulmonary blood flow at the expense of systemic blood flow. Clinically, patients demonstrate signs and symptoms of HF. Atrial septal defect (ASD), VSD, and patent ductus arteriosus (PDA) are typical anomalies in this group (Box 47.2).

Obstructive Defects. Obstructive defects are those in which blood exiting the heart meets an area of anatomical narrowing (*stenosis*), causing obstruction to blood flow. The pressure in the ventricle and great artery before the obstruction is increased, and the pressure in the area beyond the obstruction is decreased. The location of the narrowing is usually near the valve (Figure 47.5), as follows:

Valvular—At the site of the valve itself
Subvalvular—Narrowing in the ventricle below the valve (also referred to as the *ventricular outflow tract*)
Supravalvular—Narrowing in the great artery above the valve

Coarctation of the aorta (narrowing of the aortic arch), aortic stenosis, and pulmonic stenosis are typical defects in this group (Box 47.3). Hemodynamically, there is a pressure load on the ventricle and decreased cardiac output. Clinically, infants and children exhibit signs of HF. Children with mild obstruction may be asymptomatic. Rarely, as in severe pulmonic stenosis, hypoxemia may be seen.

Defects With Decreased Pulmonary Blood Flow. In this group of defects, there is obstruction of pulmonary blood flow and an anatomical defect (ASD or VSD) between the right and left sides of the heart (Figure 47.6). Because blood has difficulty exiting the right side of the heart via the pulmonary artery, pressure on the right side increases, exceeding left-sided pressure. This allows desaturated blood to shunt right to left, causing desaturation in the left side of the heart and in the systemic circulation. Clinically, these patients have hypoxemia and usually appear cyanotic. Tetralogy of Fallot and tricuspid atresia are the most common defects in this group (Box 47.4).

Mixed Defects. Many complex cardiac anomalies are classified together in the mixed category (Box 47.5) because survival in the postnatal period depends on the mixing of blood from the pulmonary and systemic circulations within the heart chambers. Hemodynamically, fully saturated systemic blood flow mixes with the desaturated pulmonary blood flow, causing a relative desaturation of the systemic blood flow. Pulmonary congestion occurs because the differences in pulmonary artery pressure and aortic pressure favour pulmonary blood flow.

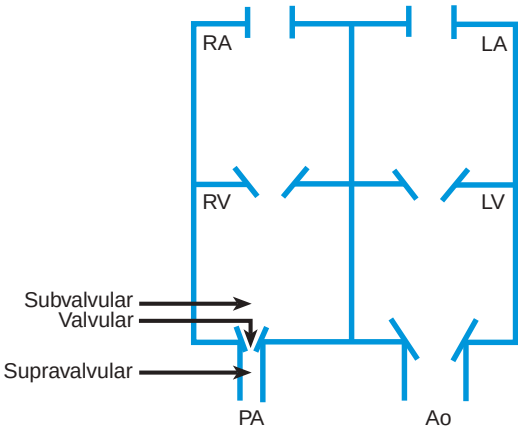

Fig. 47.5 Obstruction to ventricular ejection can occur at the valvular level (shown), below the valve (subvalvular), or above the valve (supravalvular). Pulmonary stenosis is shown here. *Ao*, Aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle.

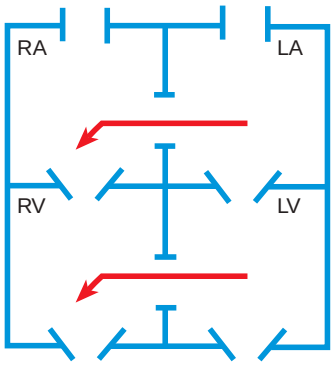

Fig. 47.4 Hemodynamics in defects with increased pulmonary blood flow. *LA*, Left atrium; *LV*, left ventricle; *RA*, right atrium; *RV*, right ventricle.

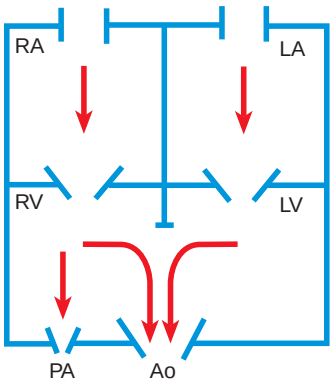

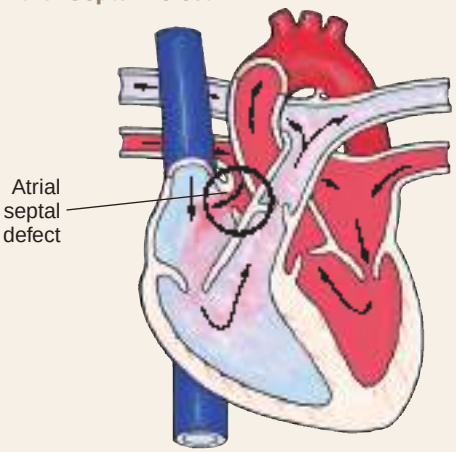

Fig. 47.6 Hemodynamic defects with decreased pulmonary blood flow. *Ao*, aorta; *LA*, left atrium; *LV*, left ventricle; *PA*, pulmonary artery; *RA*, right atrium; *RV*, right ventricle.

BOX 47.2 Defects With Increased Pulmonary Blood Flow

Atrial Septal Defect

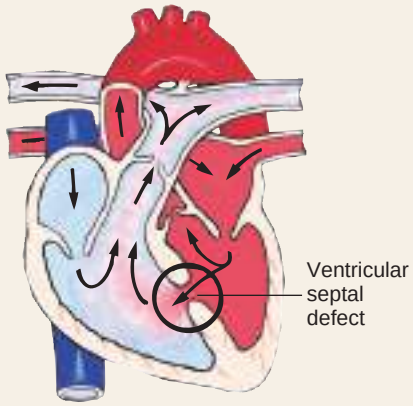
Description—Abnormal opening between the atria, allowing blood from the higher-pressure left atrium to flow into the lower-pressure right atrium. There are three types of atrial septal defects (ASDs):

Ostium primum (ASD 1)—Opening at lower end of septum; may be associated with mitral valve abnormalities

Ostium secundum (ASD 2)—Opening near centre of septum

Sinus venosus defect—Opening near junction of superior vena cava and right atrium; may be associated with partial anomalous pulmonary venous connection

Pathophysiology—Because left atrial pressure slightly exceeds right atrial pressure, blood flows from the left to the right atrium, causing an increased flow of oxygenated blood into the right side of the heart. Despite the low pressure difference, a high rate of flow can still occur because of low pulmonary vascular resistance and the greater distensibility of the right atrium, which further reduces flow resistance. This volume is well tolerated by the right ventricle because it is delivered under much lower pressure than with a ventricular septal defect (VSD). Although there is right atrial and ventricular enlargement, cardiac failure is unusual in an uncomplicated ASD. Pulmonary vascular changes usually occur only after several decades if the defect is left unrepaired.



Clinical manifestations—Patients may be asymptomatic. They may develop heart failure (HF). There is a characteristic systolic murmur with a fixed split second heart sound. There may also be a diastolic murmur. Patients are at risk for atrial dysrhythmias (probably caused by atrial enlargement and stretching of conduction fibres) and pulmonary vascular obstructive disease and emboli formation later in life from chronically increased pulmonary blood flow.

Surgical treatment—Surgical patch closure (pericardial patch or Dacron patch) is done for moderate to large defects. Open repair with cardiopulmonary bypass is usually performed before school age. In addition, the sinus venosus defect requires patch placement, so the anomalous right pulmonary venous return is directed to the left atrium with a baffle. The ASD 1 type may require mitral valve repair or, rarely, replacement of the mitral valve.

Nonsurgical treatment—ASD 2 closure with a device during cardiac catheterization is becoming commonplace and can be done as an outpatient procedure. The Amplatzer Septal Occluder is most commonly used. Smaller defects that have a rim around them for attachment of the device can be closed with a device; large, irregular defects without a rim require surgical closure. Successful closure in appropriately selected patients yields results similar to those from surgery but involves shorter hospital stays and fewer complications. Patients receive low-dose aspirin for 6 months (Bernstein, 2020a; Park, 2014).

Prognosis—Operative mortality is very low (less than 0.5%).

Ventricular Septal Defect

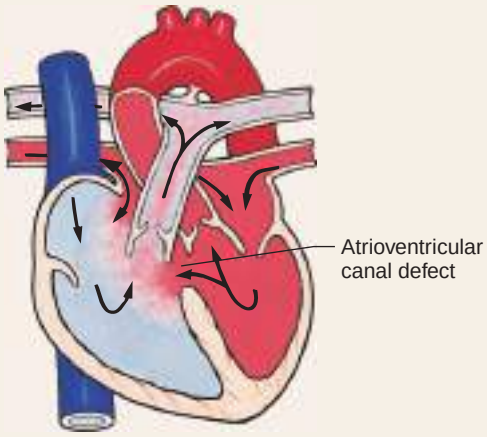
Description—Abnormal opening between the right and left ventricles. VSD may be classified according to location: membranous (accounting for 80%) or muscular. It may vary in size from a small pinhole to absence of the septum, which results in a common ventricle. VSDs are frequently associated with other defects, such as pulmonary stenosis, transposition of the great vessels, patent ductus arteriosus (PDA), atrial defects, and coarctation of the aorta. Many VSDs (20 to 60%) close spontaneously. Spontaneous closure is most likely to occur during the first year of life in children with small or moderate defects. A left-to-right shunt is caused by the flow of blood from the higher-pressure left ventricle to the lower-pressure right ventricle.

Pathophysiology—Because of the higher pressure within the left ventricle and because the systemic arterial circulation offers more resistance than the pulmonary circulation, blood flows through the defect into the pulmonary artery. The increased blood volume is pumped into the lungs, which may eventually result in increased pulmonary vascular resistance. Increased pressure in the right ventricle as a result of left-to-right shunting and pulmonary resistance causes the muscle to hypertrophy. If the right ventricle is unable to accommodate the increased workload, the right atrium may also enlarge as it attempts to overcome the resistance offered by incomplete right ventricular emptying.

Clinical manifestations—HF is common. A characteristic loud holosystolic murmur is heard best at the left sternal border. Patients are at risk for bacterial endocarditis and pulmonary vascular obstructive disease.

Surgical treatment

Palliative—Pulmonary artery banding (placement of a band around the main pulmonary artery to decrease pulmonary blood flow) may be done in infants with multiple muscular VSDs or complex anatomy. Improvements in surgical techniques and postoperative care make complete repair in infancy the preferred approach.



Complete repair (procedure of choice)—Small defects are repaired with sutures. Large defects usually require that a knitted Dacron patch be sewn over the opening. Cardiopulmonary bypass is used for both procedures. The approach for the repair is generally through the right atrium and the tricuspid valve. Postoperative complications include residual VSD and conduction disturbances.

Prognosis—Risks depend on the location of the defect, the number of defects, and the presence of other associated cardiac defects. Single membranous defects are associated with low mortality (less than 1%); multiple muscular defects can carry a higher risk for infants, especially infants younger than 2 months of age (Bernstein, 2020a; Park, 2014).

Continued

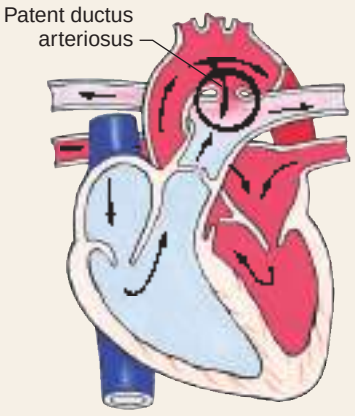
BOX 47.2 Defects With Increased Pulmonary Blood Flow—cont'd

Atrioventricular Canal Defect

Description—Incomplete fusion of the endocardial cushions. This defect consists of a low ASD that is continuous with a high VSD and clefts of the mitral and tricuspid valves, which create a large central atrioventricular (AV) valve that allows blood to flow between all four chambers of the heart. The directions and pathways of flow are determined by pulmonary and systemic resistance, left and right ventricular pressures, and the compliance of each chamber, although flow is generally from left to right. It is the most common cardiac defect in children with Down syndrome.

Pathophysiology—The alterations in hemodynamics depend on the severity of the defect and the child's pulmonary vascular resistance. Immediately after birth, while the newborn's pulmonary vascular resistance is high, there is minimum shunting of blood through the defect. When this resistance falls, left-to-right shunting occurs, and pulmonary blood flow increases. The resultant pulmonary vascular engorgement predisposes the child to development of HF.

Clinical manifestations—Patients usually have moderate to severe HF. There is a loud systolic murmur. There may be mild cyanosis that increases with crying. Patients are at high risk for developing pulmonary vascular obstructive disease.



Surgical treatment

Palliative—Pulmonary artery banding is occasionally done in small infants with severe symptoms. Complete repair in infancy is most common.

Complete repair—Surgical repair consists of patch closure of the septal defects and reconstruction of the AV valve tissue (either repair of the mitral valve cleft or fashioning of two AV valves). Postoperative complications include heart block, HF, mitral regurgitation, dysrhythmias, and pulmonary hypertension.

Prognosis—Operative mortality has been 3 to 10%. Factors that increase surgical risk are younger age, severe AV valve regurgitation, hypoplasia of the left ventricle and severe failure preoperatively, as well as other heart defects (Park, 2014). A potential later issue is mitral regurgitation, which may require valve replacement.

Patent Ductus Arteriosus

Description—Failure of the fetal ductus arteriosus (artery connecting the aorta and pulmonary artery) to close within the first weeks of life. The continued patency of this vessel allows blood to flow from the higher-pressure aorta to the lower-pressure pulmonary artery, which causes a left-to-right shunt.

Pathophysiology—The hemodynamic consequences of PDA depend on the size of the ductus and the pulmonary vascular resistance. At birth the resistance in the pulmonary and systemic circulations is almost identical so that the resistance in the aorta and pulmonary artery is equalized. As the systemic pressure comes to exceed the pulmonary pressure, blood begins to shunt from the aorta across the duct to the pulmonary artery (left-to-right shunt). The additional blood is recirculated through the lungs and returned to the left atrium and left ventricle. The effect of this altered circulation is increased workload on the left side of the heart, increased pulmonary vascular congestion and possibly resistance, and potentially increased right ventricular pressure and hypertrophy.

Clinical manifestations—Patients may be asymptomatic or show signs of HF. There is a characteristic machinery-like murmur. A widened pulse pressure and bounding pulses result from runoff of blood from the aorta to the pulmonary artery. Patients are at risk for bacterial endocarditis and pulmonary vascular obstructive disease in later life from chronic excessive pulmonary blood flow.

Medical management—Intravenous administration of indomethacin (prostaglandin inhibitor) has proved successful in closing a PDA in preterm infants and some newborns. It should be noted that this infusion should not be given via umbilical lines as this can cause a dramatic shift in the cerebral blood flow.

Surgical treatment—Surgical division or ligation of the patent vessel is performed via a left thoracotomy. In another technique, video-assisted thoracoscopic surgery, a thoracoscope and instruments are inserted through three small incisions on the left side of the chest to place a clip on the ductus. The technique is used in some centres and eliminates the need for a thoracotomy, thereby speeding postoperative recovery.

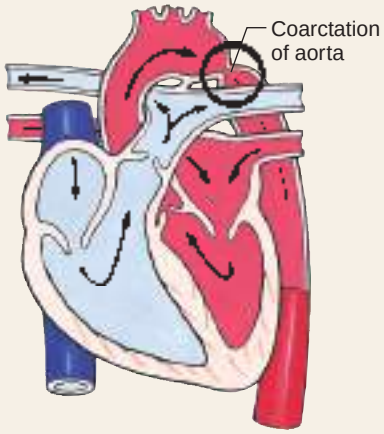
Nonsurgical treatment—In many centres, coils to occlude the PDA are placed in patients in the catheterization laboratory. Preterm or small infants (with small-diameter femoral arteries) and patients with large or unusual PDAs may require surgery.

Prognosis—Both surgical and nonsurgical procedures can be done at low risk with 0% mortality. PDA closure in very preterm infants has a higher mortality rate because of the additional significant medical issues. Complications are rare, but can include injury to the laryngeal nerve, paralysis of the left hemidiaphragm, or injury to the thoracic duct (Park, 2014). Many infants with small PDAs are asymptomatic and can be discharged home with a referral to a pediatric cardiologist, if necessary, for follow-up to ensure closure.

Cardiac output decreases because of a volume load on the ventricle. Clinically, these patients have a variable picture that combines some degree of desaturation (although cyanosis is not always visible) and signs of HF. Some defects, such as transposition of the great arteries (TGA), cause severe cyanosis in the first days of life and later cause HF. Others, such as truncus arteriosus, cause severe HF in the first weeks of life and mild desaturation.

CLINICAL CONSEQUENCES OF CONGENITAL HEART DISEASE

Heart Failure



Heart failure is the inability of the heart to pump an adequate amount of blood to the systemic circulation at normal filling pressures to meet the body's metabolic demands. In children, HF most frequently occurs secondary to structural abnormalities (e.g., septal defects) that result in increased blood volume and pressure within the heart. It can also result from myocardial failure in which the contractility of the ventricle is impaired. This can occur with cardiomyopathy, dysrhythmias, or severe electrolyte disturbances. HF can also occur because of excessive demands on a normal heart muscle, such as sepsis or severe anemia.

Pathophysiology. HF is often separated into two categories: right-sided and left-sided failure. In *right-sided failure*, the right ventricle is unable to pump blood effectively into the pulmonary artery, resulting in increased pressure in the right atrium and systemic venous circulation. Systemic venous hypertension causes hepatosplenomegaly and occasionally **edema**. In *left-sided failure*, the left ventricle is unable to pump blood into the systemic circulation, resulting in increased pressure in the left atrium and pulmonary veins. The lungs become congested with blood, causing elevated pulmonary pressures and pulmonary edema.

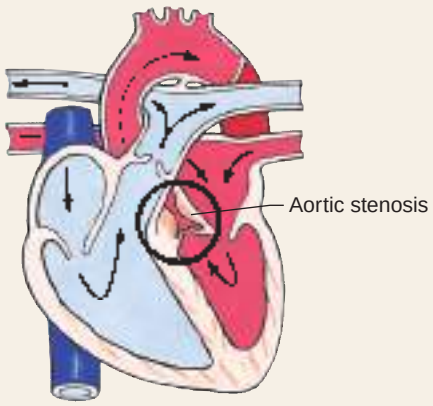
Although each type of HF produces different signs and symptoms, clinically it is unusual to observe solely right- or left-sided failure in children. Because each side of the heart depends on adequate function of the other side, failure of one chamber causes a reciprocal change in the opposite chamber.

BOX 47.3 Obstructive Defects

Coarctation of the Aorta

Description—There is localized narrowing near the insertion of the ductus arteriosus, which results in increased pressure proximal to the defect (head and upper extremities) and decreased pressure distal to the obstruction (body and lower extremities).

Pathophysiology—The effect of a narrowing within the aorta is increased pressure proximal to the defect and decreased pressure distal to it (lower extremities).



Clinical manifestations—The patient may have high blood pressure and bounding pulses in the arms, weak or absent femoral pulses, and cool lower extremities with lower blood pressure. There are signs of heart failure (HF) in infants. In infants with critical coarctation, the hemodynamic condition may deteriorate rapidly with severe acidosis and hypotension. Mechanical ventilation and inotropic support are often necessary before surgery. Older children may experience dizziness, headaches, fainting, and epistaxis resulting from hypertension. Patients are at risk for hypertension, ruptured aorta, aortic aneurysm, and stroke.

Surgical treatment—Surgical repair is the treatment of choice for infants younger than 6 months of age and for patients with long-segment stenosis or complex anatomy; it may be performed for all patients with coarctation. Repair is by resection of the coarctated portion with an end-to-end anastomosis of the aorta or enlargement of the constricted section using a graft of prosthetic material or a portion of the left subclavian artery. Because this defect is outside the heart and pericardium, cardiopulmonary bypass is not required, and a thoracotomy incision is used. Postoperative hypertension is treated with intravenous sodium nitroprusside, esmolol, or milrinone followed by oral medications, such as angiotensin-converting enzyme inhibitors or beta blockers. Residual permanent hypertension after repair of coarctation of the aorta (COA) seems to be related to age and time of repair. To prevent both hypertension at rest and exercise-provoked systemic hypertension after repair, elective surgery for COA is advised within the first 2 years of life. There is a 15 to 30% risk of recurrence in patients who underwent surgical repair as infants (Beekman, 2016). Percutaneous balloon angioplasty techniques have proved to be effective in relieving residual postoperative coarctation gradients.

Nonsurgical treatment—Balloon angioplasty is being performed as a primary intervention for COA in older infants and children. In adolescents, stents may be placed in the aorta to maintain patency. Balloon angioplasty has a higher associated rate of recoarctation than surgical repair, and the rate of complication, particularly femoral artery injury, is high during infancy.

Prognosis—Mortality is less than 5% in patients with isolated coarctation; risk is increased in infants with other complex cardiac defects (Park, 2014).

Aortic Stenosis

Continued

BOX 47.3 Obstructive Defects—cont'd

Description—Narrowing or stricture of the aortic valve, causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary vascular congestion. The prominent anatomical consequence of aortic stenosis (AS) is the hypertrophy of the left ventricular wall, which eventually leads to increased end-diastolic pressure resulting in pulmonary venous and pulmonary arterial hypertension. Left ventricular hypertrophy also interferes with coronary artery perfusion and may result in myocardial infarction or scarring of the papillary muscles of the left ventricle, which causes mitral insufficiency. Valvular stenosis, the most common type, is usually caused by malformed cusps that result in a bicuspid rather than tricuspid valve or fusion of the cusps. Subvalvular stenosis is a stricture caused by a fibrous ring below a normal valve; supravalvular stenosis occurs infrequently. Valvular AS is a serious defect for the following reasons: (1) the obstruction tends to be progressive; (2) sudden episodes of myocardial ischemia, or low cardiac output, can result in sudden death; and (3) surgical repair rarely results in a normal valve. This is one of the rare instances in which strenuous physical activity may be curtailed because of the cardiac condition.

Pathophysiology—A stricture in the aortic outflow tract causes resistance to ejection of blood from the left ventricle. The extra workload on the left ventricle causes hypertrophy. If left ventricular failure develops, left atrial pressure increases; this causes increased pressure in the pulmonary veins, which results in pulmonary vascular congestion (pulmonary edema).

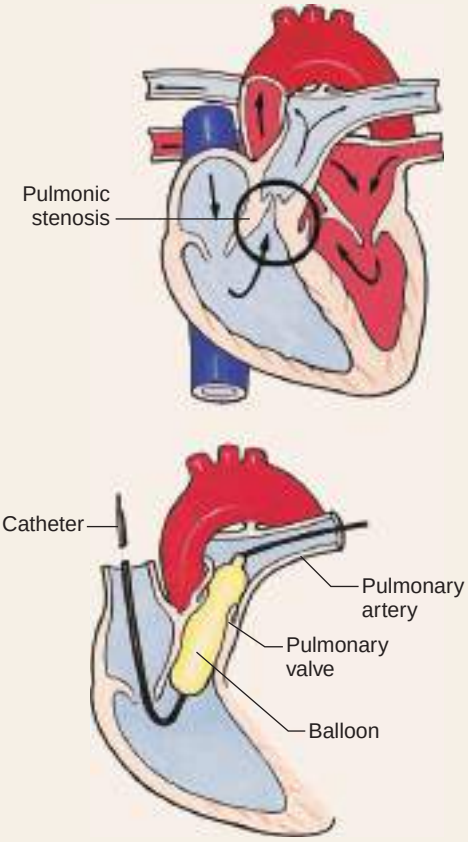
Clinical manifestations—Newborns with critical AS demonstrate signs of decreased cardiac output with faint pulses, hypotension, tachycardia, and poor feeding. Children show signs of exercise intolerance, chest pain, and dizziness when standing for a long period. A systolic ejection murmur may or may not be present. Patients are at risk for bacterial endocarditis, coronary insufficiency, and ventricular dysfunction.

Valvular Aortic Stenosis

Surgical treatment—Aortic valvotomy is performed under inflow occlusion. It is rarely used because balloon dilation done in the catheterization laboratory is the first-line procedure. Newborns with critical AS and small left-sided structures may undergo a stage 1 Norwood procedure (see Hypoplastic Left Heart Syndrome, Box 47.5).

Prognosis—Aortic valve replacement offers a good treatment option and may lead to normalization of left ventricular size and function. Aortic valvotomy remains a palliative procedure, and approximately 25% of patients require additional surgery within 10 years for recurrent stenosis. A valve replacement may be required at the second procedure. An aortic homograft with a valve may also be used (extended aortic root replacement), or the pulmonary valve may be moved to the aortic position and replaced with a homograft valve (Ross procedure).

Nonsurgical treatment—The narrowed valve is dilated using balloon angioplasty in the catheterization laboratory. This procedure is usually the first intervention.



Prognosis—Complications include aortic insufficiency or valvular regurgitation, tearing of the valve leaflets, and loss of pulse in the catheterized limb.

Subvalvular Aortic Stenosis

Surgical treatment—The procedure may involve incising a membrane if one exists or cutting the fibromuscular ring. If the obstruction results from narrowing of the left ventricular outflow tract and a small aortic valve annulus, a patch may be required to enlarge the entire left ventricular outflow tract and annulus and replace the aortic valve; this is known as the *Konno procedure*.

Prognosis—Mortality from surgical repairs of subvalvular AS is less than 5%; however, about 20% of these patients develop recurrent subaortic stenosis and require additional surgery (Friedland-Little et al., 2016).

Pulmonic Stenosis

Description—Narrowing at the entrance to the pulmonary artery. Resistance to blood flow causes right ventricular hypertrophy and decreased pulmonary blood flow. Pulmonary atresia is the extreme form of pulmonic stenosis (PS) in that there is total fusion of the commissures and no blood flows to the lungs. The right ventricle may be hypoplastic.

Pathophysiology—When PS is present, resistance to blood flow causes right ventricular hypertrophy. If right ventricular failure develops, right atrial pressure increases; this may result in reopening of the foramen ovale, shunting of unoxygenated blood into the left atrium, and systemic cyanosis. If PS is severe, HF occurs, and systemic venous engorgement is noted. An associated defect such as a patent ductus arteriosus partially compensates for the obstruction by shunting blood from the aorta to the pulmonary artery and into the lungs.

Clinical manifestations—Patients may be asymptomatic; some have mild cyanosis or HF. Progressive narrowing causes increased symptoms. Newborns with severe narrowing will be cyanotic. A loud systolic ejection murmur at the upper left sternal border may be present. However, in severely ill patients the murmur may be much softer because of decreased cardiac output and shunting of blood. Cardiomegaly is evident on chest radiographic films. Patients are at risk for bacterial endocarditis.

Surgical treatment—In infants, transventricular (closed) valvotomy (Brock procedure) is used; in children, pulmonary valvotomy with cardiopulmonary bypass. The need for surgical treatment is rare with widespread use of balloon angioplasty techniques.

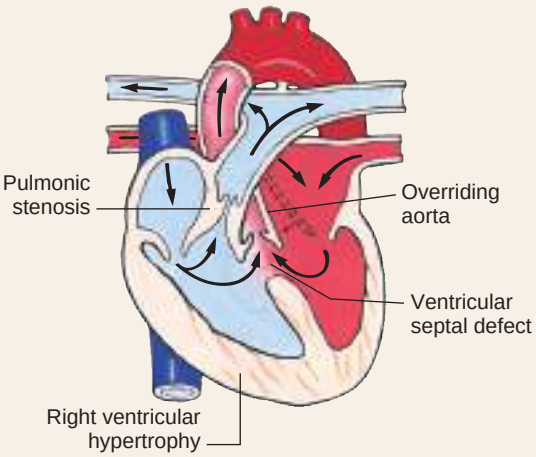
Continued

BOX 47.3 Obstructive Defects—cont'd

Nonsurgical treatment—Balloon angioplasty is done in the cardiac catheterization laboratory to dilate the valve. A catheter is inserted across the stenotic pulmonic valve into the pulmonary artery, and a balloon at the end of the catheter is inflated and rapidly passed through the narrowed opening (see figure above). The procedure is associated with few complications and has proved to be highly effective. It is the treatment of choice for discrete PS in most centres and can be done safely in newborns.

Prognosis—Risk is low for both surgical and nonsurgical procedures; mortality is lower than 1%, slightly higher in newborns (Park, 2014). Both balloon dilation and surgical valvotomy leave the pulmonic valve incompetent because they involve opening the fused valve leaflets; however, these patients are clinically asymptomatic. Long-term issues with restenosis or valve incompetence may occur.

If the abnormalities precipitating HF are not corrected, the heart muscle becomes damaged. Despite compensatory mechanisms, the heart is unable to maintain an adequate cardiac output. Decreased blood flow to the kidneys continues to stimulate sodium and water reabsorption, leading to fluid overload, increased workload on the heart, and congestion in the pulmonary and systemic circulations (Figure 47.7).



Clinical Manifestations. The signs and symptoms of HF can be divided into three groups: (1) impaired myocardial function, (2) pulmonary congestion, and (3) systemic venous congestion (Box 47.6) (Bernstein, 2020b). Because these hemodynamic changes occur from different causes and at differing times, the clinical presentation may vary among children.

Diagnostic Evaluation. Diagnosis is made on the basis of clinical symptoms such as tachypnea and tachycardia at rest, dyspnea, retractions, activity intolerance (especially during feeding in infants), weight gain caused by fluid retention, and hepatomegaly. A chest X-ray film demonstrates cardiomegaly and increased pulmonary blood flow. Ventricular hypertrophy, abnormal rhythm, or decreased voltages appear on the ECG. An echocardiogram is done to determine the cause of HF, such as a congenital heart defect or poor ventricular function.

Therapeutic Management. The goals of treatment are to (1) improve cardiac function (increase contractility and decrease afterload), (2) remove accumulated fluid and sodium (decrease preload), (3) decrease cardiac demands, and (4) improve tissue oxygenation and decrease oxygen consumption. For most infants diagnosed with HF, the cause is CHD. Infants are stabilized on medical therapy and then referred for surgical repair. Currently, many children are surgically repaired in the newborn and early infancy stages before the onset of HF symptoms. For children newly diagnosed with HF, the cause may be worsening ventricular function after a previous cardiac repair, cardiomyopathy, dysrhythmia, or other causes. In addition to management of HF, the underlying cause is treated, if possible.

BOX 47.4 Defects With Decreased Pulmonary Blood Flow

Tetralogy of Fallot

Description—The classic form includes four defects: (1) ventricular septal defect (VSD), (2) pulmonic stenosis (PS), (3) overriding aorta, and (4) right ventricular hypertrophy. Tetralogy of Fallot occurs in 5 to 10% of all congenital heart diseases (CHDs) and is the most common cyanotic lesion (Park, 2014).

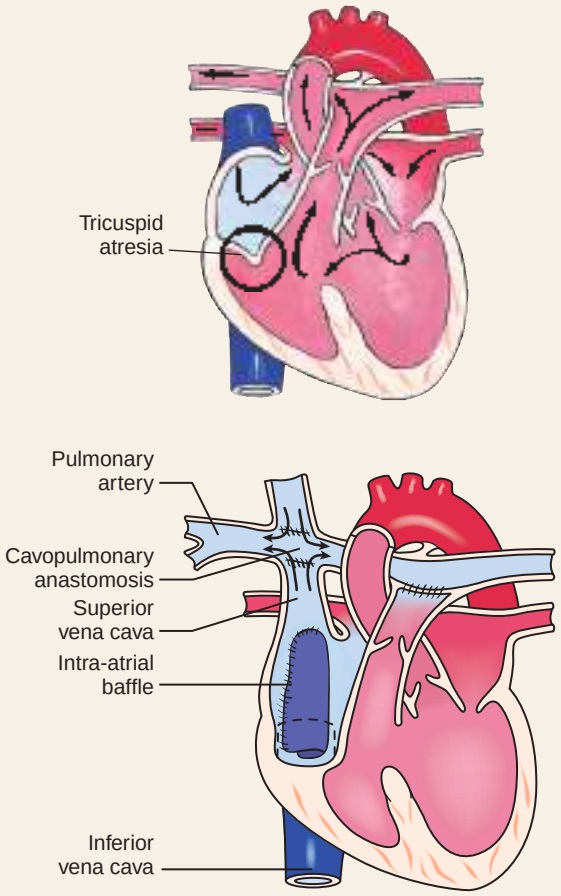
Pathophysiology—The alteration in hemodynamics varies widely, depending primarily on the degree of PS and also on the size of the VSD and the pulmonary and systemic resistance to flow. Because the VSD is usually large, pressures may be equal in the right and left ventricles. Therefore, the shunt direction depends on the difference between pulmonary and systemic vascular resistance. If pulmonary vascular resistance is higher than systemic resistance, the shunt is from right to left. If systemic resistance is higher than pulmonary resistance, the shunt is from left to right. PS decreases blood flow to the lungs and, consequently, the amount of oxygenated blood that returns to the left side of the heart. Depending on the position of the aorta, blood from both ventricles may be distributed systemically.

Clinical manifestations—Some infants may be acutely cyanotic at birth; others have mild cyanosis that progresses over the first year of life as the PS worsens. There is a characteristic systolic murmur that is often moderate in intensity. There may be acute episodes of cyanosis and hypoxia, called *blue spells* or *tet spells*. Anoxic spells occur when the infant's oxygen requirements exceed the blood supply, usually during crying or after feeding. Patients are at risk for emboli, seizures, and loss of consciousness or sudden death following an anoxic spell.

Surgical treatment

Palliative shunt—In infants who cannot undergo primary repair, a palliative procedure to increase pulmonary blood flow and increase oxygen saturation may be performed. The preferred procedure is a modified Blalock-Taussig shunt operation, which provides blood flow to the pulmonary arteries from the left or right subclavian artery via a tube graft (see Table 47.4). However, in general, shunts are avoided because they may result in pulmonary artery distortion.

Complete repair—Elective repair is usually performed in the first year of life. Indications for repair include increasing cyanosis and the development of hypercyanotic spells. Complete repair involves closure of the VSD and resection of the infundibular stenosis, with placement of a pericardial patch to enlarge the right ventricular outflow tract. In some repairs the patch may extend across the pulmonary valve annulus (transannular patch),



Continued

BOX 47.4 Defects With Decreased Pulmonary Blood Flow—cont'd

making the pulmonary valve incompetent. The procedure requires a median sternotomy and the use of cardiopulmonary bypass.

Prognosis—The operative mortality for total correction of tetralogy of Fallot is less than 2 to 3% during the first 2 years of life (Park, 2014). Infants younger than 3 months of age and children older than 4 years of age, as well as those with other CHD or hypoplasia of the pulmonary annulus and trunk have a higher mortality rate. With improved surgical techniques there is a lower incidence of dysrhythmias and sudden death; surgical heart block is rare. Heart failure may occur postoperatively.

Tricuspid Atresia

Description—The tricuspid valve fails to develop; consequently, there is no communication from the right atrium to the right ventricle. Blood flows through an atrial septal defect (ASD) or a patent foramen ovale to the left side of the heart and through a ventral septal defect (VSD) to the right ventricle and out to the lungs. The condition is often associated with PS and transposition of the great arteries. There is complete mixing of unoxygenated and oxygenated blood in the left side of the heart, which results in systemic desaturation, and varying amounts of pulmonary obstruction, which causes decreased pulmonary blood flow.

Pathophysiology—At birth the presence of a patent foramen ovale (or other atrial septal opening) is required to permit blood flow across the septum into the left atrium; the patent ductus arteriosus allows blood flow to the pulmonary artery into the lungs for oxygenation. A VSD allows a modest amount of blood to enter the right ventricle and pulmonary artery for oxygenation. Pulmonary blood flow usually is diminished.

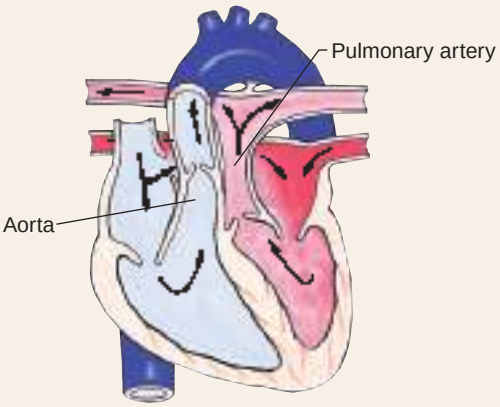
Clinical manifestations—Cyanosis is usually seen in the newborn period. There may be tachycardia and dyspnea. Older children have signs of chronic hypoxemia with clubbing.

Therapeutic management—For the newborn whose pulmonary blood flow depends on the patency of the ductus arteriosus, a continuous infusion of prostaglandin E_1 is started until surgical intervention can be arranged.

Surgical treatment—Palliative treatment is the placement of a shunt (pulmonary–to–systemic artery anastomosis) to increase blood flow to the lungs. If the ASD is small, an atrial septostomy is performed during cardiac catheterization. Some children have increased pulmonary blood flow and require pulmonary artery banding to lessen the volume of blood to the lungs. A bidirectional Glenn shunt (cavopulmonary anastomosis) may be performed at 4 to 9 months as a second stage.

Modified Fontan procedure—Systemic venous return is directed to the lungs without a ventricular pump through surgical connections between the right atrium and the pulmonary artery. A fenestration (opening) is sometimes made in the right atrial baffle to relieve pressure. The patient must have normal ventricular function and a low pulmonary vascular resistance for the procedure to be successful. The modified Fontan procedure separates oxygenated and unoxygenated blood inside the heart and eliminates the excess volume load on the ventricle but does not restore normal anatomy or hemodynamics. This operation is also the final stage in the correction of many complex defects with a functional single ventricle, including hypoplastic left heart syndrome.

Prognosis—Surgical mortality following the Fontan procedure is less than 3% (Park, 2014). In one study the overall survival rate after the Fontan operation was above 95% at follow-up of 50 months (Hirsch et al., 2008). Postoperative complications include dysrhythmias, systemic venous hypertension, pleural and pericardial effusions, and ventricular dysfunction. Long-term concerns are the development of protein-losing enteropathy, atrial dysrhythmias, late ventricular dysfunction, and developmental delays.



Improve Cardiac Function. Three groups of medications are used to enhance myocardial function in HF: (1) digitalis glycosides (digoxin), which improve contractility; (2) angiotensin-converting enzyme (ACE) inhibitors, which reduce the afterload on the heart and thus make it easier for the heart to pump; and (3) beta blockers. Myocardial efficiency is improved through the administration of digitalis glycosides. The beneficial effects are increased cardiac output, decreased heart size, decreased venous pressure, and relief of edema. In pediatrics, digoxin (Lanoxin) is used almost exclusively because of its more rapid onset. Note that for infants the dose is calculated in micrograms (1 000 mcg = 1 mg).

Treatment consists of (1) a digitalizing dosage, given orally or intravenously in divided doses over 24 hours to produce optimal cardiac effects, and (2) a maintenance dosage, given orally twice a day to maintain blood levels. During digitalization the child is monitored by means of an ECG to observe for the desired effects (prolonged PR interval and reduced ventricular rate) and to detect adverse effects, especially dysrhythmias. The Canadian Cardiovascular Society Guidelines state that the addition of digoxin alone does not result in improved contractility or clinical symptoms and that adjunct therapy including, but not limited to, vasodilator agents, diuretics agents, beta blockers, and ACE inhibitors is recommended for infants and children with HF (Kantor et al., 2013).

ACE inhibitors are also used in the treatment of HF; these medications inhibit the normal function of the renin–angiotensin system in the kidney. ACE inhibitors block the conversion of angiotensin I

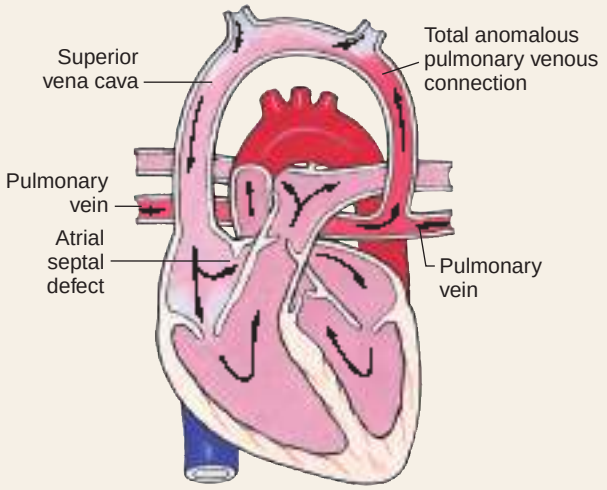
BOX 47.5 Mixed Defects

Transposition of the Great Arteries, or Transposition of the Great Vessels

Description—The pulmonary artery leaves the left ventricle, and the aorta exits from the right ventricle, with no communication between the systemic and pulmonary circulations.

Pathophysiology—Associated defects such as septal defects or patent ductus arteriosus (PDA) must be present to permit blood to enter the systemic circulation or the pulmonary circulation for mixing of saturated and desaturated blood. The most common defect associated with transposition of the great arteries (TGA) is a patent foramen ovale. At birth there is also a PDA, although in most instances this closes after the newborn period. Another associated defect may be a ventricular septal defect (VSD). The presence of a VSD increases the risk of heart failure (HF) because it permits blood to flow from the right to the left ventricle, into the pulmonary artery, and finally to the lungs. However, it also produces high pulmonary blood flow under high pressure, which can result in high pulmonary vascular resistance.

Clinical manifestations—These depend on the type and size of the associated defects. Newborns with minimum communication are severely cyanotic and have depressed function at birth. Those with large septal defects or a PDA may be less cyanotic but have symptoms of HF. Heart sounds vary according to the type of defect present. Cardiomegaly is usually evident a few weeks after birth.



Therapeutic management (to provide intracardiac mixing)—The administration of intravenous prostaglandin E_1 may be initiated to keep the ductus arteriosus open to temporarily increase blood mixing and provide an oxygen saturation of 75% or to maintain cardiac output. During cardiac catheterization or under echocardiographic guidance, a balloon atrial septostomy (Rashkind procedure) may also be performed to increase mixing by opening the atrial septum.

Surgical treatment—An arterial switch procedure is the procedure of choice performed in the first weeks of life. It involves transecting the great arteries, anastomosing the main pulmonary artery to the proximal aorta (just above the aortic valve), and anastomosing the ascending aorta to the proximal pulmonary artery. The coronary arteries are switched from the proximal aorta to the proximal pulmonary artery to create a new aorta. Reimplantation of the coronary arteries is critical to the infant's survival, and they must be reattached without torsion or kinking to provide the heart with its supply of oxygen. The advantage of the arterial switch procedure is the re-establishment of normal circulation, with the left ventricle acting as the systemic pump. Potential complications of the arterial switch include narrowing at the great artery anastomoses and coronary artery insufficiency.

Rastelli procedure—This procedure is the operative choice in infants with TGA, VSD, and severe pulmonic stenosis. It involves closure of the VSD with a baffle, so left ventricular blood is directed through the VSD into the aorta. The pulmonic valve is then closed, and a conduit is placed from the right ventricle to the pulmonary artery to create a physiologically normal circulation. Unfortunately, this procedure requires multiple conduit replacements as the child grows.

Prognosis— Mortality rate varies depending on the anatomy and procedure performed. The operative mortality rate for newborns with TGA and intact ventricular septum is 6% (Park, 2014). Potential long-term conditions include suprapulmonic stenosis and neoaortic dilation and regurgitation, as well as coronary artery obstruction.

Total Anomalous Pulmonary Venous Connection

Description—Rare defect characterized by failure of the pulmonary veins to join the left atrium. Instead, the pulmonary veins are abnormally connected to the systemic venous circuit via the right atrium or various veins draining toward the right atrium, such as the superior vena cava (SVC). The abnormal attachment results in mixed blood being returned to the right atrium and shunted from the right to the left through an atrial septal defect (ASD). Total anomalous pulmonary venous connection (TAPVC; also called *total anomalous pulmonary venous return* or *total anomalous pulmonary venous drainage*) is classified according to the pulmonary venous point of attachment as follows:

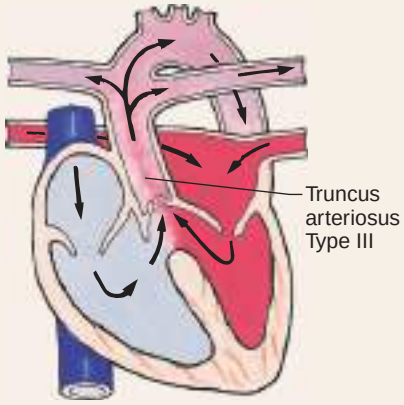
Supracardiac—Attachment above the diaphragm, such as to the SVC (most common form) (see Figure 47.10)

Cardiac—Direct attachment to the heart, such as to the right atrium or coronary sinus

Infradiaphragmatic—Attachment below the diaphragm, such as to the inferior vena cava (most severe form)

Pathophysiology—The right atrium receives all the blood that normally would flow into the left atrium. As a result, the right side of the heart hypertrophies, whereas the left side, especially the left atrium, may remain small. An associated ASD or patent foramen ovale allows systemic venous blood to shunt from the higher-pressure right atrium to the left atrium and into the left side of the heart. As a result, the oxygen saturation of the blood in both sides of the heart (and ultimately in the systemic arterial circulation) is the same. If the pulmonary blood flow is large, pulmonary venous return is also large, and the amount of saturated blood is relatively high. However, if there is obstruction to pulmonary venous drainage, pulmonary venous return is impeded, pulmonary venous pressure rises, and pulmonary interstitial edema develops and eventually contributes to HF. Infradiaphragmatic TAPVC is often associated with obstruction to pulmonary venous drainage and is a surgical emergency.

Continued



BOX 47.5 Mixed Defects—cont'd

Clinical manifestations—Most infants develop cyanosis early in life. The degree of cyanosis is inversely related to the amount of pulmonary blood flow—the more pulmonary blood, the less cyanosis. Children with unobstructed TAPVC may be asymptomatic until pulmonary vascular resistance decreases during infancy, increasing pulmonary blood flow, with resulting signs of HF. Cyanosis becomes worse with pulmonary vein obstruction; once obstruction occurs, the infant's condition usually deteriorates rapidly. Without intervention, cardiac failure will progress to death.

Surgical treatment—Corrective repair is performed in early infancy. The surgical approach varies with the anatomical defect. However, in general, the common pulmonary vein is anastomosed to the back of the left atrium, the ASD is closed, and the anomalous pulmonary venous connection is ligated. The cardiac type is most easily repaired; the infradiaphragmatic type carries the highest morbidity and mortality because of the higher incidence of pulmonary vein obstruction. Potential postoperative complications include reobstruction; bleeding; dysrhythmias, particularly heart block; pulmonary artery hypertension; and persistent HF.

Prognosis—Mortality is between 5 and 10% for infants without obstruction, and it can be as high as 20% for infants with the infradiaphragmatic type (Park, 2014).

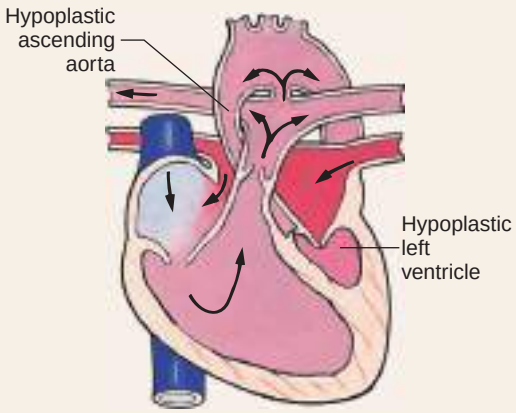
Truncus Arteriosus

Description—Failure of normal septation and division of the embryonic bulbar trunk into the pulmonary artery and the aorta, which results in development of a single vessel that overrides both ventricles. Blood from both ventricles mixes in the common great artery, which leads to desaturation and hypoxemia. Blood ejected from the heart flows preferentially to the lower-pressure pulmonary arteries, so pulmonary blood flow is increased and systemic blood flow is reduced. There are three types:

Type I—A single pulmonary trunk arises near the base of the truncus and divides into the left and right pulmonary arteries.

Type II—The left and right pulmonary arteries arise separately but in close proximity and at the same level from the back of the truncus.

Type III—The pulmonary arteries arise independently from the sides of the truncus.



Pathophysiology—Blood ejected from the left and right ventricles enters the common trunk so that pulmonary and systemic circulations are mixed. Blood flow is distributed to the pulmonary and systemic circulations according to the relative resistances of each system. The amount of pulmonary blood flow depends on the size of the pulmonary arteries and the pulmonary vascular resistance. Generally, resistance to pulmonary blood flow is less than systemic vascular resistance, which results in preferential blood flow to the lungs. Pulmonary vascular disease develops at an early age in patients with truncus arteriosus.

Clinical manifestations—Most infants are symptomatic with moderate to severe HF and variable cyanosis, poor growth, and activity intolerance. There is a holosystolic murmur at the left sternal border with a diastolic murmur present if truncal regurgitation is present. Thirty-five percent of patients have 22q11 deletions (Goldmuntz & Crenshaw, 2016).

Surgical treatment—Early repair is performed in the first month of life. It involves closing the VSD so that the truncus arteriosus receives the outflow from the left ventricle, excising the pulmonary arteries from the aorta and attaching them to the right ventricle by means of a homograft. Currently, homografts (segments of cadaver aorta and pulmonary artery that are treated with antibiotics and cryopreserved) are preferred over synthetic conduits to establish continuity between the right ventricle and pulmonary artery. Homografts are more flexible and easier to use during the procedure and appear less prone to obstruction. Postoperative complications include persistent HF, bleeding, pulmonary artery hypertension, dysrhythmias, and residual VSD. Because conduits are not living tissue, they will not grow along with the child and may also become narrowed with calcifications. One or more conduit replacements will be needed in childhood.

Prognosis—Mortality is greater than 10%; future operations are required to replace the conduits.

Hypoplastic Left Heart Syndrome

Description—Underdevelopment of the left side of the heart, resulting in a hypoplastic left ventricle and aortic atresia. Most blood from the left atrium flows across the patent foramen ovale to the right atrium, to the right ventricle, and out the pulmonary artery. The descending aorta receives blood from the PDA supplying systemic blood flow.

Pathophysiology—An ASD or patent foramen ovale allows saturated blood from the left atrium to mix with desaturated blood from the right atrium and to flow through the right ventricle and out into the pulmonary artery. From the pulmonary artery, the blood flows both to the lungs and through the ductus arteriosus into the aorta and out to the body. The amount of blood flow to the pulmonary and systemic circulations depends on the relationship between the pulmonary and systemic vascular resistances. The coronary and cerebral vessels receive blood by retrograde flow through the hypoplastic ascending aorta.

Clinical manifestations—The patient has mild cyanosis and signs of HF until the PDA closes, followed by progressive deterioration with cyanosis and decreased cardiac output, leading to cardiovascular collapse. The condition is usually fatal in the first months of life without intervention.

Continued

BOX 47.5 Mixed Defects—cont'd

Therapeutic management—Newborns require stabilization with mechanical ventilation and inotropic support preoperatively. A prostaglandin E_1 infusion is needed to maintain ductal patency and ensure adequate systemic blood flow.

Surgical treatment—A multistage approach is used. The first stage is a Norwood procedure, which involves an anastomosis of the main pulmonary artery to the aorta to create a new aorta, shunting to provide pulmonary blood flow (usually with a modified Blalock-Taussig shunt), and creation of a large ASD. Postoperative complications include imbalance of systemic and pulmonary blood flow, bleeding, low cardiac output, and persistent HF. A modification of the first-stage repair is the use of a right ventricle–to–pulmonary artery homograft conduit instead of a shunt to supply pulmonary blood flow (Sano procedure). The second stage is often a bidirectional Glenn shunt procedure (see Figure 47.10) or a hemi-Fontan operation. Both involve anastomosing the SVC to the right pulmonary artery so that SVC flow bypasses the right atrium and flows directly to the lungs. The procedure is usually done at 3 to 6 months of age to relieve cyanosis and reduce the volume load on the right ventricle. The final repair is a modified Fontan procedure (see Tricuspid Atresia, Box 47.4).

Transplantation—Heart transplantation in the newborn period is another option for these infants. Challenges include the shortage of newborn organ donors, risk of rejection, long-term issues with chronic immunosuppression, and infection (see Heart Transplantation section later in this chapter).

Prognosis—For the first-stage repair, survival rates vary from 5 to 10% (Bernstein, 2020b). Improved outcomes have been associated with early diagnosis and repair and increased monitoring in the hospital and at home. Long-term issues with repair include worsening ventricular function, tricuspid regurgitation, recurrent aortic arch narrowing, dysrhythmias, and developmental delays. There is a risk of mortality between surgical procedures. The mortality for the later two operations is less than 5%.

to angiotensin II so that, instead of vasoconstriction, vasodilation occurs. Vasodilation results in decreased pulmonary and systemic vascular resistance, decreased BP, and a reduction in afterload. It also reduces the secretion of aldosterone, which reduces preload by preventing volume expansion from fluid retention and lowers the risk for hypokalemia. Common medications used in pediatrics are captopril (Capoten), enalapril (Vasotec), and lisinopril. The principal adverse effects of ACE inhibitors are hypotension, cough, and renal dysfunction.

Beta blockers, specifically carvedilol, are also used in the treatment of some children with chronic HF. The alpha- and beta-adrenergic receptors are blocked, causing decreased heart rate, decreased BP, and vasodilation. Beta blockers, used routinely for adults with HF, are used selectively in children, as the cause of HF in children and infants is much different from that in adults. Adverse effects include dizziness, headache, and hypotension.

Cardiac resynchronization therapy (CRT) using biventricular pacing is an effective treatment in adult patients with HF and is beginning to be applied to the pediatric population. Along with the pharmacological therapies discussed above, CRT has the potential to improve cardiac function in this group of patients, including those with a single ventricle (Rossano, 2020).

! NURSING ALERT

Because ACE inhibitors also block the action of aldosterone, the addition of potassium supplements or spironolactone (Aldactone) to the medication regimen of patients taking diuretics is usually not needed and may cause hyperkalemia.

Remove accumulated fluid and sodium. Treatment consists of diuretics, possible fluid restriction, and possible sodium restriction. Diuretics are the mainstay of therapy to eliminate excess water and salt in order to prevent reaccumulation. The most frequently used medications are listed in Table 47.3. Furosemide and the thiazides are potassium-losing diuretics, so potassium supplements may be prescribed, and rich sources of the electrolyte are encouraged in the diet.

! NURSING ALERT

A fall in the serum potassium level enhances the effects of digitalis, increasing the risk of digoxin toxicity. Increased serum potassium levels diminish digoxin's effect. Therefore, serum potassium levels (normal range 3.5 to 5.5 mmol/L) must be monitored carefully.

Fluid restriction may be required in the acute stages of HF and must be calculated carefully to avoid dehydrating the child, especially if cyanotic CHD and significant polycythemia are present. Infants rarely need fluid restrictions because HF makes feeding so difficult that they struggle to take maintenance fluids.

Sodium-restricted diets are used less often in children than in adults to control HF because of their potential negative effects on appetite and ultimate growth. If salt intake is restricted, additional table salt and highly salted foods are avoided.

Decrease cardiac demands. To lessen the workload on the heart, metabolic needs are minimized by (1) providing a neutral thermal environment to prevent cold stress in newborns, (2) treating any existing infections, (3) reducing the effort of breathing (by placement in semi-Fowler position), (4) using medication to sedate an irritable child, and (5) providing for rest and decreasing environmental stimuli.

Improve tissue oxygenation. All of the preceding measures serve to increase tissue oxygenation, by either improving myocardial function or lessening tissue oxygen demands. In addition, supplemental cool, humidified oxygen may be administered to increase the amount of available oxygen during inspiration. Oxygen administration is especially helpful in patients with pulmonary edema, intercurrent respiratory tract infections, and increased pulmonary vascular resistance (oxygen is a vasodilator that decreases pulmonary vascular resistance).

! NURSING ALERT

Oxygen is a medication and is administered only with an appropriate order. In some uncommon circumstances in patients with complex hemodynamics, oxygen can be detrimental.

An oxygen hood, nasal cannula, or face mask is used to deliver oxygen. Nasal cannulas are ideal for long-term oxygen administration because the child can be ambulatory and can easily eat and drink. Cool humidification is necessary to counteract the drying effect of oxygen. The amount of cool humidity needs to be carefully regulated to prevent chilling.

Nursing Care. The infant or child with HF may be acutely ill, and some children may require critical care until the symptoms improve. Expert nursing care is essential to reduce the cardiac demands that strain the failing heart muscle. During this time, the child and family require emotional support. Although the objectives of nursing care, discussed below, are the same, interventions differ, depending on the

Hepatomegaly
Peripheral edema, especially periorbital
Ascites
Neck vein distension (children)

TABLE 47.3 Diuretics Used in Heart Failure

Actions	Comments	Nursing Care Management
Furosemide (Lasix)—Blocks reabsorption of sodium and water in proximal renal tubule and interferes with reabsorption of sodium	Medication of choice in severe heart failure Causes excretion of chloride and potassium (hypokalemia may precipitate digitalis toxicity)	Begin to record output as soon as medication is given. Observe for dehydration caused by profound diuresis. Observe for adverse effects (nausea and vomiting, diarrhea, ototoxicity, hypokalemia, dermatitis, postural hypotension). Encourage foods high in potassium or give potassium supplements. Monitor chloride and acid–base balance with long-term therapy. Observe for signs of digoxin toxicity.
Chlorothiazide—Acts directly on distal tubules to decrease sodium, water, potassium, chloride, and bicarbonate absorption	Less frequently used medication Causes hypokalemia, acidosis from large doses	Observe for adverse effects (nausea, weakness, dizziness, paresthesia, muscle cramps, skin eruptions, hypokalemia, acidosis). Encourage foods high in potassium or give potassium supplements, or both.
Spironolactone (Aldactone)—Blocks action of aldosterone, which promotes retention of sodium and excretion of potassium	Weak diuretic Has potassium-sparing effect; frequently used with thiazides, furosemide Poorly absorbed from gastrointestinal tract Takes several days to achieve maximum actions	Observe for adverse effects (skin rash, drowsiness, ataxia, hyperkalemia). Do not administer potassium supplements.

child's age (see Nursing Care Plan: The Child With Heart Failure, available on Evolve).

Assisting in measures to improve cardiac function. The nurse's responsibility in administering digoxin includes calculating and administering the correct dosage, observing for signs of toxicity, and instituting parental teaching on medication administration at home. The child's **apical pulse rate** is always checked before administering digoxin. As a general rule, the medication is not given if the pulse is below 90 to 110 beats per minute (bpm) in infants and young children or below 70 bpm in older children (the cutoff point for adults is 60 bpm). However, because the pulse rate varies in children in different age groups, the written medication order should specify at what heart rate the medication is withheld. The nurse should also use judgement in evaluating the pulse rate. If it is significantly lower than the previous recording, the dose should be withheld until the health care provider most responsible for the patient is notified.

The apical rate is taken because a pulse deficit (radial pulse rate lower than apical) may be present with decreased cardiac output. It is **auscultated** for a full minute to evaluate alterations in rhythm. If the child is monitored by means of an ECG, a rhythm strip is obtained and attached to the chart for rate and rhythm analysis, such as abnormal lengthening of the PR interval (more than 50% increase over predigitalization interval) and dysrhythmias.

Digoxin is a potentially dangerous medication because of its narrow margin of safety of therapeutic, toxic, and lethal doses. Many toxic responses are extensions of its therapeutic effects. The nurse must maintain a high index of suspicion for signs of toxicity when administering digoxin (Box 47.7).

Because digoxin toxicity can occur from accidental overdose, great care must be taken in properly calculating and measuring the dosage. When converting milligrams to micrograms to millilitres, the nurse needs to carefully check the placement of the decimal point, since an error causes a significant change in dosage. For example, 0.1 mg is 10 times the dosage of 0.01 mg.

BOX 47.7 Common Signs of Digoxin Toxicity in Children

Gastrointestinal
Nausea
Vomiting
Anorexia

Cardiac
Bradycardia
Dysrhythmias

! NURSING ALERT

Infants rarely receive more than 1 mL (50 mcg, or 0.05 mg) in one dose; a higher dose is an immediate warning of a dosage error. To ensure safety, always compare and check the calculation with another staff member before giving the medication.

These same principles are taught to parents in preparation for discharge, although the correct dose in millilitres is usually specified on the container, thus reducing potential errors in calculation. The nurse needs to watch the parent measure the elixir in the dropper and stress the level mark as the meniscus of the fluid that is observed at eye level. Other instructions for administering digoxin are listed in the Family-Centred Care box: Administering Digoxin, and Clinical Reasoning Case Study: Digoxin Toxicity.

Parents are also advised of the signs of toxicity. According to the health care provider's preference, they may be taught to take the pulse before giving the medication. A return demonstration of the procedure from the parents or another principal caregiver is included as part of the teaching plan. Their level of anxiety in counting the pulse should be assessed because overconcern about the heart rate may result in excessive withholding of the medication.

FAMILY-CENTRED CARE

Administering Digoxin

- Give digoxin at regular intervals, usually every 12 hours.
- Administer the medication carefully by slowly directing it to the side and back of the mouth.
- Do not mix the medication with foods or other fluids, since refusal to consume these results in inaccurate intake of the medication.
- If the child has teeth, give water after administering the medication; whenever possible, brush the teeth to prevent tooth decay from the sweetened liquid.
- If a dose is missed, do not give an extra dose or increase the dose. Stay on the same medication schedule.
- If the child vomits, do not give a second dose.
- If more than two consecutive doses have been missed, notify the primary health care provider.
- Frequent vomiting, poor feeding, or slow heart rate can be signs of toxicity; if they occur, contact the primary health care provider.
- If the child becomes ill, notify the primary health care provider immediately.
- Keep digoxin in a safe place, preferably in a locked cabinet.
- In case of accidental overdose of digoxin, call the nearest poison control centre immediately.

CLINICAL REASONING CASE STUDY

Digoxin Toxicity

A home care nurse is visiting a 3-month-old infant at home who began receiving digoxin and furosemide (Lasix) 5 days ago for management of heart failure (HF). A brief assessment indicates that the infant appears well but is not very active, has a weak suck reflex, and does not exhibit much spontaneous movement during interaction with the mother. The mother mentions that the infant is a good baby and does not cry much except when he is very hungry. She also mentions that he vomited several times yesterday and twice this morning; this was not perceived as unusual because her 3-year-old did the same thing and was diagnosed with gastroesophageal reflux. Further assessment of the infant reveals an irregular heartbeat of 86 to 104 beats/min at rest; the heart rhythm is also noted to be irregular. No murmur or other significant sounds are auscultated.

1. Evidence—Is there sufficient evidence to draw conclusions about this infant?
2. Assumptions— What assumptions can be made about the following factors?
   a. Adverse effects of furosemide
   b. Adverse effects of digoxin
   c. Infants with HF
3. What implications and priorities for nursing care can be drawn at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to this infant.

Monitoring afterload reduction. For patients receiving ACE inhibitors for afterload reduction, the nurse should carefully monitor BP before and after dose administration, observe for symptoms of hypotension, and notify the health care provider if BP is low. Numerous medications affecting the kidney can potentiate renal dysfunction; thus children taking multiple diuretics and an ACE inhibitor require careful assessment of serum electrolytes and renal function.

Decreasing cardiac demands. The infant requires rest and conservation of energy for feeding. Every effort should be made to organize nursing activities to allow for uninterrupted periods of sleep. Whenever possible, parents need to be encouraged to stay with their infant to provide the holding, rocking, and cuddling that help children sleep more soundly. To minimize disturbing the infant, changing bed linen and complete bathing should be done only when necessary. Feeding should be planned to accommodate the infant's sleep and wake patterns. The child is fed at the first sign of hunger, such as when sucking on fists, rather than waiting until they cry, because the stress of crying exhausts the limited energy supply. Because infants with HF tire easily and may sleep through feedings, smaller feedings every 3 hours or breastfeeding on demand may be helpful. Gavage feedings may be instituted to provide adequate nutrition and allow the infant to rest.

Every effort should be made to minimize unnecessary stress. Older children need an explanation of what is happening to them to decrease anxiety about their illness and necessary treatments such as cardiac monitoring, oxygen administration, and medications. Outlining a plan for the day, preparing the child for tests and procedures, providing quiet activities, and providing adequate rest periods are all helpful interventions for older children. Some infants and children require sedation during the acute phase of illness to allow them to rest.

Temperature needs to be monitored carefully because hyperthermia or hypothermia increases the need for oxygen. Febrile states should be reported to the primary health care provider, since infection must be treated promptly. Maintaining body temperature is of special importance in children who are receiving cool, humidified oxygen and in infants, who tend to be diaphoretic and lose heat by way of evaporation.

Skin breakdown from edema is prevented with a change of position every 2 hours (from side to side while in semi-Fowler position) and use of a pressure-relieving mattress or bed. The skin, especially over the sacrum, should be checked for evidence of redness from pressure.

Reducing respiratory distress. Careful assessment, positioning, and oxygen administration can reduce respiratory distress. Respirations are counted for 1 full minute during a resting state. Any evidence of increased respiratory distress should be reported, since this may indicate worsening HF.

Infants should be positioned to encourage maximum chest expansion, with the head of the bed elevated; they should sit up in an infant seat or be held at a 45-degree angle. Children may prefer to sleep on several pillows and remain in a semi-Fowler or high-Fowler position during waking hours. Safety restraints, such as those used with infant seats, should be applied low on the abdomen and loosely enough to provide both safety and maximum expansion.

The infant or child is often given humidified supplemental oxygen via oxygen hood, nasal cannula, or mask. The child's response to oxygen therapy needs to be carefully evaluated by noting respiratory rate, ease of respiration, colour, and especially oxygen saturation as measured by oximetry.

Respiratory tract infections can exacerbate HF and should be treated appropriately and prevented if possible. The child should be protected from persons with respiratory tract infections and have a noninfectious roommate. Thorough hand hygiene should be practised before and after caring for any hospitalized child. Antibiotics may be given to combat respiratory tract infection. The nurse needs to ensure that the medication is given at equally divided times over a 24-hour schedule to maintain high blood levels of the antibiotic.

Maintaining nutritional status. Meeting the nutritional needs of infants with HF or serious cardiac defects is a nursing challenge. The metabolic rate of these infants is greater because of poor cardiac function and increased heart and respiratory rates. Their caloric needs are greater than those of the average infant because of their increased metabolic rate, yet their ability to take in adequate calories is hampered by their fatigue. Feeding for a fragile infant with serious CHD is similar to exercising for an adult, and these infants often do not have the energy or cardiac reserve to do extra work. The nurse needs to seek measures to enable the infant to feed easily without excess fatigue and to increase the caloric density of the formula.

The infant should be well rested before feeding and fed soon after awakening so as not to expend energy on crying. A 3-hour feeding schedule works well for many infants. (Feeding every 2 hours does not provide enough rest between feedings, and a 4-hour schedule requires an increased volume of feeding, which many infants are unable to take.) The feeding schedule should be individualized to the infant's needs. A feeding goal of 150 mL/kg/day and at least 120 kcal/kg/day is common for newborns with significant heart disease. Newborns can be breastfed or bottle fed. A soft preemie nipple or a slit in a regular nipple to enlarge the opening decreases the infant's energy expenditure while sucking from a bottle. Infants should be well supported and fed in a semi-upright position. The infant may need to rest frequently and may need to have the jaw and cheeks stroked to encourage sucking. Generally, giving an infant about a half-hour to complete a feeding is reasonable. Prolonging the feeding time can exhaust the infant and decrease the rest period between feedings.

Infants with feeding difficulties are often gavage fed using a nasogastric tube to supplement their oral intake and ensure adequate calories. If they are very stressed and fatigued, in respiratory distress, or tachypneic to 80 to 100 breaths/min, oral feedings may be withheld and all nutrition given by gavage feedings. Gavage feedings are usually a temporary measure until the infant's medical status improves and nutritional needs can be met through oral feedings. Some infants with severe HF, neurological deficits, or significant gastroesophageal reflux may need placement of a gastrostomy tube to allow adequate nutrition.

The caloric density of formulas is frequently increased by concentration and then adding Polycose, medium-chain triglyceride oil, or corn oil. Infant formulas provide 20 kcal/30 mL, and the use of additives can increase the calories to 30 kcal/30 mL or more. This allows the infant to obtain more calories despite a smaller volume intake of formula. The caloric density of the formula needs to be increased slowly (by 2 kcal/30 mL/day) to prevent diarrhea or formula intolerance. Breastfeeding parents should be encouraged to provide the infant with high-calorie feedings and may feed expressed breast milk that has been fortified to increase caloric intake, which can be given using a supplemental nurser while the child nurses at the breast (see Figure 27.10). A diet plan specific to the individual infant's needs should be calculated and prescribed by the dietitian in collaboration with the other health personnel. The nurse should reinforce this information with the parents as necessary.

Assisting in measures to promote fluid loss. When diuretics are given, the nurse needs to record fluid intake and output and monitor body weight at the same time each day to evaluate the benefit from the medication. Because profound diuresis may cause dehydration and electrolyte imbalance (loss of sodium, potassium, chloride, bicarbonate), the nurse should observe for signs indicating either complication, as well as signs and symptoms suggesting reactions to the medications. Diuretics should be given early in the day to children who have obtained toilet independence, to avoid the need to urinate at night. If potassium-losing diuretics are given, the nurse can encourage intake of foods high in potassium, such as bananas, oranges, whole grains, legumes, and leafy vegetables, and administer prescribed supplements. Serum potassium levels should be checked frequently.

Fluid restriction is rarely necessary in infants because of their difficulty in feeding. However, if fluids are restricted, the nurse can plan fluid intake schedules for a 24-hour period, allowing for most fluids during waking hours. Toddlers and preschoolers should be given small amounts of liquid in small cups so that the containers appear full. Older children can be placed in charge of recording fluid intake.

If salt is limited, the nurse needs to discuss food sources of sodium with the family and discourage their bringing salt-containing treats to the child. At mealtime, the child's tray should be checked to make sure the appropriate diet is being given.

Supporting the child and family. HF is a serious complication of heart disease. Parents and older children are usually acutely aware of the critical nature of the condition. Because stress places additional demands on cardiac function, the nurse should focus on reducing anxiety through anticipatory preparation, frequent communication with the parent regarding the child's progress, and constant reassurance that everything possible is being done.

The nurse must teach the family about the medications that need to be administered and alert them to the signs of worsening HF that require medical attention, such as increased sweating, decreased urinary output (noted in fewer wet diapers or infrequent use of the toilet), or poor feeding. Every effort should be made to improve the family's adherence to the medication schedule by adapting the schedule to their usual home routines, avoiding giving medications during the night, making it as simple as possible, and using charts or visual aids to remember when to give medications (see Chapter 44). Written instructions regarding correct administration of digoxin are essential (see Family-Centred Care box: Administering Digoxin), including an explanation of the signs of toxicity.

If HF is the end stage of a severe heart defect, the nurse should care for this child as for any child who is terminally ill, using the principles discussed in Chapter 41.

Hypoxemia

Hypoxemia refers to an arterial oxygen tension (or pressure, Pa_{O_2}) that is less than normal and can be identified by a decreased arterial saturation or a decreased Pa_{O_2}. *Hypoxia* is a reduction in tissue oxygenation that is caused by low oxygen saturations and Pa_{O_2} and results in impaired cellular processes. *Cyanosis* is a blue discoloration in the mucous membranes, skin, and nail beds of the child with reduced oxygen saturation. It results from the presence of deoxygenated hemoglobin (hemoglobin not bound to oxygen) in whole blood. Cyanosis is usually apparent when arterial oxygen saturations are below 80 to 85%. Determination of cyanosis is subjective. It can vary depending on skin pigment, quality of light, colour of the room, or clothing worn by the child. The presence of cyanosis may not accurately reflect arterial hypoxemia because both oxygen saturation and the amount of circulating hemoglobin are involved. Children with severe anemia may not be cyanotic despite severe hypoxemia because the hemoglobin level may be too low to produce the characteristic blue colour. Conversely, patients with polycythemia may appear cyanotic despite a near-normal Pa_{O_2}. Heart defects that cause hypoxemia and cyanosis result from desaturated venous blood (blue blood) entering the systemic circulation without passing through the lungs.

Clinical Manifestations. Over time, two physiological changes occur in the body in response to chronic hypoxemia: polycythemia and clubbing. *Polycythemia*, an increased number of red blood cells, increases the oxygen-carrying capacity of the blood. However, anemia may result if iron is not readily available for the formation of

Fig. 47.8 Clubbing of the fingers.

hemoglobin. Polycythemia increases the viscosity of the blood and crowds out clotting factors. *Clubbing*, a thickening and flattening of the tips of the fingers and toes, is thought to occur because of chronic tissue hypoxemia and polycythemia (Figure 47.8). Infants with mild hypoxemia may be asymptomatic except for cyanosis and exhibit near-normal growth and development. Those with more severe hypoxemia may exhibit fatigue with feeding, poor weight gain, tachypnea, and dyspnea. Severe hypoxemia resulting in tissue hypoxia is manifested by clinical deterioration and signs of poor perfusion.

Hypercyanotic spells, also referred to as *blue spells* or *tet spells* because they are often seen in infants with tetralogy of Fallot, may occur in any child whose heart defect includes obstruction to pulmonary blood flow and communication between the ventricles. The infant becomes acutely cyanotic and hyperpneic because a sudden infundibular spasm decreases pulmonary blood flow and increases right-to-left shunting (the proposed mechanism in tetralogy of Fallot). Spells, rarely seen before 2 months of age, occur most frequently in the first year of life. They occur more often in the morning and may be preceded by feeding, crying, defecation, or stressful procedures. Because profound hypoxemia causes cerebral hypoxia, hypercyanotic spells require prompt assessment and treatment to prevent brain damage or possibly death.

Persistent cyanosis as a result of cyanotic heart defects places the child at risk for significant neurological complications. Cerebrovascular accident (CVA, stroke), brain abscess, and developmental delays (especially in motor and cognitive development) may result from chronic hypoxia.

Diagnostic Management. Cyanosis in a newborn can be the result of cardiac, pulmonary, metabolic, or hematological disease, although cardiac and pulmonary causes occur most often. To distinguish between the two, a hyperoxia test is helpful. The infant is placed in a 100% oxygen environment, and blood parameters are monitored. A Pao_2 of 100 mm Hg or higher suggests lung disease, and a Pao_2 lower than 100 mm Hg suggests cardiac disease (Park, 2014). An accurate history, chest X-ray, and especially an echocardiogram aid in the diagnosis of cyanotic heart disease.

Therapeutic Management. Newborns generally exhibit cyanosis within the first few days of life as the ductus arteriosus, which provided pulmonary blood flow, begins to close. Prostaglandin E_1, which causes vasodilation and smooth muscle relaxation, thus increasing dilation and patency of the ductus arteriosus, is administered intravenously to re-establish pulmonary blood flow. The use of prostaglandins has been life-saving for newborns with ductus-dependent cardiac defects. The increase in oxygenation allows the newborn to be stabilized and have a complete diagnostic evaluation performed before further treatment is needed.

Hypercyanotic spells occur suddenly, and prompt recognition and treatment are essential. In the hospital setting, spells are often seen during blood drawing or IV insertion, when the child is highly agitated, or after cardiac catheterization. Treatment of a hypercyanotic spell is outlined in the Guidelines box: Treating Hypercyanotic Spells. Placing the infant in the knee–chest position reduces the venous return from the legs (which is desaturated) and increases systemic vascular resistance, which diverts more blood into the pulmonary artery (Figure 47.9). Morphine, administered subcutaneously or through an existing IV line, helps reduce infundibular spasm. A spell indicates the need for prompt surgical treatment, if possible. In infants with defects not amenable to surgical repair, a shunt may be created surgically to increase blood flow to the lungs. Several commonly used shunt procedures are described in Table 47.4 and Figure 47.10.

GUIDELINES

Treating Hypercyanotic Spells

- Place infant in knee–chest position (see Figure 47.9).
- Use a calm, comforting approach.
- Administer 100% blow-by oxygen.
- Give morphine subcutaneously or through existing intravenous (IV) line.
- Begin IV fluid replacement and volume expansion if needed.
- Repeat morphine administration as required.

The cyanotic infant and child should be well hydrated to keep the hematocrit and blood viscosity within acceptable limits to reduce the risk of CVAs. Fevers need to be carefully evaluated because bacteremia can result in bacterial endocarditis. The infant should be monitored closely for anemia because of the risk of CVA and the reduced arterial oxygen-carrying capacity that occurs. Iron supplementation and possibly blood transfusion are used as needed.

Respiratory tract infections or reduced pulmonary function from any cause can worsen hypoxemia in the cyanotic child. Aggressive pulmonary hygiene, chest physiotherapy, administration of antibiotics,

Fig. 47.9 Infant held in knee–chest position.

TABLE 47.4 Selected Shunt Procedures for Children With Cardiac Defects

Shunt Type	Comments
Modified Blalock-Taussig shunt—Subclavian artery to pulmonary artery using Gore-Tex or Impra tube graft	Shunt flow sometimes excessive, requiring use of diuretics Possibility of thrombosis; Aspirin usually prescribed postoperatively Easy to ligate at time of definitive correction Shunt size fixed and may become too small as child grows
Sano modification—Right ventricular to pulmonary artery conduit using Gore-Tex graft	Prevents diastolic runoff of systemic blood into the pulmonary arteries Provides a higher diastolic blood pressure and seemingly better coronary perfusion Used in place of the modified Blalock-Taussig shunt in the Norwood procedure
Central shunt—Ascending aorta to main pulmonary artery using Gore-Tex graft	Length of shunt acts to restrict blood flow; possibility of symptoms of heart failure; diuretic therapy sometimes required Uncommon; used when modified Blalock-Taussig shunt cannot be used Easy to insert and remove at time of repair Possibility of thrombosis; Aspirin usually prescribed postoperatively
Bidirectional Glenn shunt (cavopulmonary anastomosis)—Superior vena cava to side of right pulmonary artery; blood flow to both lungs	Done as a second shunt; often used as a staging step to a Fontan procedure Can be incorporated into eventual modified Fontan procedure Relieves severe cyanosis and decreases volume overload on ventricle Carries risk of embolic events (mixing defect); Aspirin often prescribed Pulmonary arteriovenous fistulas may occur months or years later, causing desaturation (uncommon finding)

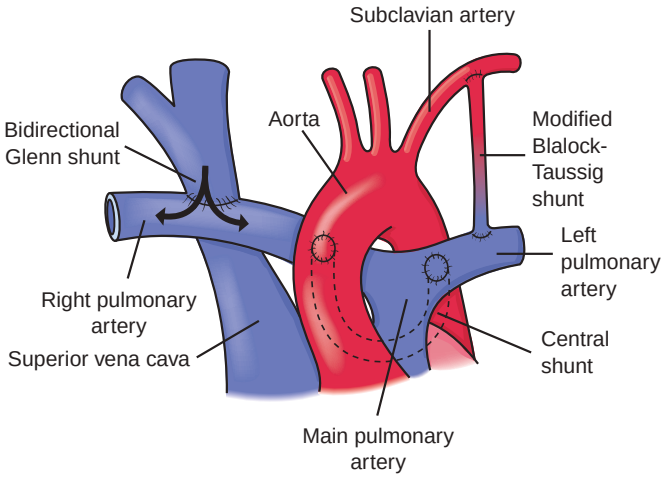

Fig. 47.10 Schematic diagram of cardiac shunts.

and use of oxygen to improve arterial saturations are important interventions.

Nursing Care. The general appearance of infants and children with significant cyanosis poses unique concerns. Blue lips and fingernails are obvious signs of their hidden cardiac defect. Clubbing and small, thin stature in older children further indicate severe heart disease. Adolescents are especially concerned about their body image; children with cyanosis are often teased about their appearance and singled out as different. When asked what surgery will do, many children reply, "Make me pink." Their joy and excitement after surgery are evident when they see their pink fingers. Parents are often fearful of their child's bluish colour because cyanosis is usually associated with lack of oxygen and severe illness. They also must deal with comments from relatives, friends, and strangers about their child's abnormal colour. They need a simple explanation of hypoxemia and cyanosis and reassurance that cyanosis does not imply a lack of oxygen to the brain. Their questions and fears need to be addressed in a calm, supportive manner, and positive aspects of their child's growth and development should be emphasized. They need to be taught the treatment for hypercyanotic spells (see Guidelines box: Treating Hypercyanotic Spells).

Dehydration must be prevented in hypoxemic children because it potentiates the risk of CVAs. Fluid status should be monitored carefully, with accurate intake and output and daily weight measurements. Maintenance fluid therapy is the minimum requirement, supplemental fluids should be readily available, and gavage feeding or IV hydration is given to children unable to take adequate oral fluids. Fever, vomiting, and diarrhea can cause dehydration and require prompt treatment. Parents need to be instructed in the importance of adequate fluid intake and measures to prevent dehydration. An oral electrolyte solution should be available at home in the event that the infant is unable to tolerate breast milk or formula. The primary care provider should be notified of fever, vomiting, diarrhea, or other concerns.

Preventive measures and accurate assessment of respiratory infection are important nursing considerations. Any compromise in pulmonary function will increase the infant's hypoxemia. Thorough hand hygiene and protection from individuals with an obvious respiratory tract infection are essential. Aggressive pulmonary hygiene, treatment with antibiotics or antiviral agents as indicated, and supplemental oxygen to decrease hypoxemia are also necessary measures. Infants may need to be gavage fed or given parenteral hydration if respiratory distress prevents oral feeding.

! NURSING ALERT

Intracardiac shunting of blood from the right side (desaturated) to the left side of the heart allows air in the venous system to go directly to the brain, resulting in an air embolism. Therefore, all IV lines should have filters in place to prevent air from entering the system, the entire tubing should be checked for air, all connections should be taped securely, and any air should be removed.

NURSING CARE OF THE FAMILY AND CHILD WITH CONGENITAL HEART DISEASE

When a child is born with a severe cardiac anomaly, the parents are faced with the immense psychological and physical tasks of adjusting

to the birth of a child with special needs. The following discussion is primarily directed (1) toward the family of an infant who has a serious heart defect and requires home care before definitive repair and (2) toward preparation and care of the child and family when invasive procedures (catheterization and surgery) are performed. For nursing care related to the child with hypoxemia and HF, see earlier discussions of these topics.

Nursing care of the child with a congenital heart defect begins as soon as the diagnosis is suspected. Increasingly, this diagnosis is being made prenatally, thus nurses are having to counsel and support families as they prepare for the birth of these newborns.

Helping the Family Adjust to the Disorder

When parents first learn of the heart defect, they are initially in shock, then experience anxiety and fear that their child will die. The family generally needs time to grieve before they can assimilate the meaning of the defect. Unfortunately, the demands for medical treatment may not allow this process to the extent the family might like, necessitating instead that the parents immediately give **informed consent** for diagnostic-therapeutic procedures. The nurse can be instrumental in supporting parents in their loss, assessing their level of understanding, supplying information as needed, and helping other members of the health care team understand the parents' reactions (see Family-Centred Care box: Diagnosis of Heart Disease).

FAMILY-CENTRED CARE

Diagnosis of Heart Disease

Remember that we don't have your experience. We don't see children every day who have heart disease. We would have been upset finding out our child had to have his tonsils out. How could we ever be prepared for this? Please remember, we only know people who have trivial heart murmurs. How could we ever expect this to happen? And to us, this is the worst problem we've ever heard of.

We still fear most what we don't know and understand. Be honest with us. If you don't know either, tell us. But at least don't leave us wondering about what you know and we don't. Not knowing anything really can be worse than knowing something bad. Be honest, but don't strip us of hope…

Please, remember we are trying to learn complex information in a moment of time. And trying to learn it in a context of great pain and emotional investment. This is our lives you're talking about. Please be thorough but keep it simple. Tell us again, maybe even again and again, when we can hear better.

From Schrey, C., & Schrey, M. (1994). A parent's perspective: Our needs and our message. *Critical Care Nursing Clinics of North America, 6*(1), 113–119.

Severely ill newborns usually remain in the hospital. Parent–newborn attachment is supported by encouraging parents to hold, touch, and look at their child and providing time for the parents to spend with their newborn in private.

The effect of a child with a serious heart defect on the family is complex. No family member, regardless of the degree of positive adjustment, is unaffected. Mothers frequently feel inadequate in their mothering ability because of the more complex care that infants with congenital heart defects require. They often feel exhausted from the pressures of caring for these children and the other family members. Fathers or partners and siblings may feel neglected and resentful, a reaction similar to the feelings toward family members with other chronic conditions (see Chapter 41). Often, parents do not feel confident leaving the child in another's care. Although the fears are justified, they can be minimized by gradually teaching someone (a reliable relative or neighbour) how to care for the child.

The need to maintain discipline and set consistent limits can be difficult for parents. Using behaviour modification techniques in the form of either concrete awards (e.g., a favourite activity) or social reinforcement (e.g., approval) can be effective. However, these techniques are most beneficial if used *before* the child learns to control the family. It is necessary to begin discussions with parents while the child is in infancy regarding the need for discipline, to prevent later issues as the child gets older.

Another issue that may develop within family relationships is the child's overdependency. This is often the result of parental fear that the child may die. The nurse can help parents recognize the eventual hazards of continuing dependency and protectiveness as the child grows older and learn ways to foster optimum development. Unless parents are shown what activities the child can do, they may focus on physical limitations and encourage dependency.

The child also needs opportunities for social interaction with peers. These children do not need to be prevented from playing with other children because of concern regarding overexertion. Children usually limit their activities if allowed to set their own pace.

A child with CHD may constitute a long-term family crisis. Frequently, the continuing unremitting stresses of care—physical exhaustion, financial costs, emotional upset, fear of death, and concern for the child's future—are not fully appreciated by those caring for the family. Even when the child's condition is stabilized or corrected, the family may need to make adjustments in their lifestyle. Introducing them to other families with similarly affected children can help them adjust to the daily stresses.

Educating the Family About the Disorder

After absorbing the initial news of the CHD diagnosis, when parents are ready to hear more about the heart condition, they require a clear explanation based on their level of understanding. A review of the basic structure and function of the heart is helpful before describing the defect. A simple diagram, pictures, or a model of the heart can help parents visualize the heart and the congenital defect. Parents appreciate receiving written information about the specific condition, and a glossary of frequently used terms is helpful. Parents also require information about prognosis and treatment options. Health care providers should take advantage of subsequent encounters to assess parental understanding of the condition and clarify information as needed.

Increasingly, families are using the Internet as a source of information about heart disease in children (see Additional Resources at the end of this chapter). They are also finding support through contacts with other parents and parent groups. It is important for parents to realize that not all websites offer medically accurate information and that information from other parents might not be applicable to their own situation. Some children with rare, complex heart defects require individualized treatment plans, and general information on the Internet or in books may not apply to their child. Parents should discuss with their health care team, in particular their cardiologist, information they have received from other sources.

Information given to the child must be tailored to their developmental age. As the child matures, the level of information should be revised to meet their cognitive level. Preschoolers need basic information about what they will experience more than what is actually occurring physiologically. School-age children benefit from a concrete explanation of the defect. Including the child at this age early in their own health care and education about their condition will improve self-care and their own accountability (Mickley et al., 2013). Preadolescents and adolescents often appreciate a more detailed description of how the defect affects their heart. Children of all ages need to express their feelings concerning the diagnosis.

Helping the Family Manage the Illness at Home

As the child's principal caregivers, the parents need to develop a positive, supportive working relationship with the health care team. Because most children spend the majority of their time at home, with episodic trips to the hospital, parents manage their child's illness on a daily basis. They monitor for signs of illness, give medications and treatments, bring their child to appointments, work with a variety of caregivers, and alert the team about health concerns. Successful relationships are partnerships between parents and caregivers that are built on mutual trust and respect. Good communication among the family, the cardiology specialists, and the primary care provider is essential. As children reach adolescence, they begin to take a larger role in managing their illness and making decisions about their own care.

Parents should be aware of the symptoms of their child's cardiac condition and signs of worsening clinical status. Parents of children who may develop HF should be familiar with the symptoms (see Box 47.6) and know when to contact the health care provider. Parents of children with cyanosis should be informed about fluid management and hypercyanotic spells (see earlier discussion in this chapter). Parents should have an information sheet with their child's diagnosis, significant treatments such as surgical procedures, allergies, other health care issues, current medications, and health care providers' contact numbers available in case of emergencies and to share with other caregivers such as teachers, babysitters, and day care providers.

The family also needs to be knowledgeable about the therapeutic management of the disorder and the roles that surgery, other procedures, medications, and a healthy lifestyle play in maintaining good health. Medications play a critical role in managing some cardiac conditions such as dysrhythmias and severe HF; anticoagulation is used for artificial valves, and antirejection medications are needed after heart transplantation. Some patients must take multiple medications daily for their lifetime. Many medications can be dangerous if taken incorrectly and require close monitoring. Parents need to be taught the correct procedure for giving medications and cautioned to keep them in a safe area to prevent accidental ingestion.

Another area of parental concern is the child's level of physical activity. Most children do not need to restrict activity, and the best approach is to treat the child normally and allow self-limited activity. Exceptions to self-determined activity primarily involve strenuous recreational and competitive sports among children with specific cardiac conditions. Activities and exercise restrictions should be discussed with the child's cardiologist. Regular exercise can assist the child with CHD in maintaining a healthy weight, foster healthy development, enhance their self-esteem, and be a means of acceptance into peer groups (Longmuir et al., 2013).

Infants and children with CHD require good nutrition. Breastfeeding should be possible for many infants with CHD; the parent should be provided adequate support and education. Nonetheless, adequate nutrition for infants with HF or complex congenital defects is difficult to attain because of their high caloric requirements and inability to suck effectively due to fatigue and tachypnea. Instructing parents in feeding methods that decrease the infant's work and giving high-calorie formula are important interventions (see Maintaining Nutritional Status section earlier in this chapter for discussion of feeding the infant with HF). Children with severe cardiac defects are often anorexic, and encouraging them to eat can be a challenge. Consultation with a dietitian is often helpful. The child should be given a choice of available high-nutrient foods.

Infants with heart disease should be immunized according to the current guidelines. Immunization schedules may need to be modified around times of acute illness or surgical procedures. Infants and children less than 24 months at the start of respiratory syncytial virus (RSV) season who have unrepaired heart defects, cyanotic lesions, or pulmonary hypertension should receive the vaccine for RSV monthly during RSV season (November to April in North America) (Robinson et al., 2015/2018).

Infants and children who have serious heart disease are at risk for developmental delays. Multiple factors can influence neurodevelopmental outcomes, including genetics (chromosome abnormalities and microdeletions), socioeconomic status, preoperative factors (including prematurity, cyanosis, shock), intraoperative factors (use of cardiopulmonary bypass, deep hypothermic circulatory arrest), and postoperative factors (hemodynamic instability, hypoxia, **acidosis**, cardiac arrest, stroke, ischemic events). Researchers at the Hospital for Sick Children found that the risk for arterial ischemic stroke/cerebral sinovenous thrombosis was 5.4 strokes per 1 000 children undergoing a cardiac surgery (Domi et al., 2008).

Patients who have undergone surgery entailing cardiopulmonary bypass, especially in the newborn period, should be watched carefully during their early school years for signs of mild to moderate learning disabilities or attention deficit disorders, which are often amenable to early remedial intervention. The risk is higher in patients who have undergone repair using hypothermic total circulatory arrest than in those where systemic blood flow is maintained using open heart surgery (Bernstein, 2020c). Recent efforts to limit the time of deep hypothermic circulatory arrest and provide better neuroprotection during infant surgery may improve outcomes in the future.

Preparing the Child and Family for Invasive Procedures

Chapter 44 provides an extensive discussion of the principles for preparing children for invasive procedures. The following discussion highlights some important aspects of preparation for cardiac catheterization and cardiac surgery.

The expected outcomes for preprocedure preparation include reducing anxiety, improving the ability of children to assist with procedures, enhancing recovery, developing trust with caregivers, and improving long-term emotional and behavioural adjustments after procedures. Important factors to consider in planning preparation strategies are the child's cognitive development, previous hospital experiences, the child's temperament and coping style, timing of preparation, and involvement of the parents. The most beneficial preparation strategies usually combine information giving and coping skills training, such as breathing exercises, distraction techniques, guided imagery, or other behavioural interventions.

Outpatient preoperative and precatheterization workups are common for most elective procedures. Children are then admitted on the morning of the procedure. Preprocedure teaching is often done in the clinic setting or at home and may include a tour of the critical care unit (CCU) and inpatient facilities. Children of different ages and developmental levels require different amounts of information and different approaches. Young children should be prepared close in time to the event, whereas older children and adolescents may benefit from teaching several weeks in advance. Parents should be included in the preparation session to support their child and learn about upcoming events.

Topics to include in preoperative or precatheterization preparation include information on the environment, equipment, and procedures that the child will encounter during and after the procedure. Information about what the child will see, hear, and feel should be included, especially for older children and adolescents. Some of the sensory experiences of being in a CCU or catheterization laboratory include sights (monitors, many people, much equipment), sounds (beeping noises, alarms, voices), and sensations (lines and dressings, tape, discomfort, thirst). Familiar aspects of the environment, such as BP cuffs,

stethoscopes, or oximeter probes, are reviewed, and new equipment, such as monitors, IV lines, and oxygen masks, is described. Comforting aspects of the environment, such as play areas, chairs for parents, and televisions, are emphasized. Many patients who will be sedated during catheterization or receiving opioid pain relievers after surgery will have minimal recall of that period and will not need detailed information about the equipment or procedures used. Information should be specific to the planned procedure for each patient.

A discussion of ways in which the child can cope with the experience should be included. Bringing a familiar stuffed animal or comfort object will help a young child relieve anxiety, whereas older children can be advised to bring headphones and favourite music to the catheterization laboratory as the music will help distract them during the procedure. Recovery topics after catheterization include lying still to prevent bleeding at the catheter site, advancing diet, controlling pain, and monitoring. After surgery, the nurse should review the importance of ambulation, coughing, deep breathing, drinking, and eating and describe pain management and monitoring routines. Simple coping strategies for use during painful procedures should be reviewed; these include distraction techniques such as counting, blowing, singing, or telling stories.

Children and their families should have a choice about taking a CCU tour. Exposure to the CCU environment can actually increase anxiety in some children, particularly young children, those with previous hospital experiences, and those who are highly anxious. The day before the procedure is usually ample time to allow the child to ask questions and to prevent undue fantasizing about the experience. The child should be protected from the frightening sights in the unit; equipment not in view after surgery, such as equipment located behind or below the bed, needs less attention. The child and parents should be encouraged to ask questions or to explore further any equipment in the room, but they should not be pushed to assimilate more information than they are able.

The child should be assured that the parents will be there when the child wakes up; they should be allowed to accompany their child as far as possible to the operating suite (see Surgical Procedures, Chapter 44). After all of the equipment and procedures have been explained, it is important to talk about "getting well" and going home.

Providing Postoperative Care

Immediate postoperative care is usually provided by specially trained nurses in CCUs. Many of the procedures, such as arterial pressure and central venous pressure (CVP) monitoring, and the observations related to vital functions require advanced educational training (the reader should refer to critical care texts for further information). However, nurses caring for the child before surgery and during the convalescent period need to be familiar with the major principles of care. Selected complications that may occur postoperatively are described in Box 47.8.

Observing Vital Signs. Vital signs and BP are recorded frequently until the patient is stable. Heart rate and respirations are counted for 1 full minute, compared with the ECG monitor, and recorded with activity. The heart rate is normally increased after surgery. Arterial and venous pressures may be monitored. The nurse needs to observe cardiac rhythm and notify the primary health care provider of any changes in regularity. Dysrhythmias may occur postoperatively secondary to anaesthetics, acid–base and electrolyte imbalance, hypoxia, surgical intervention, or trauma to conduction pathways.

At least hourly, the lungs should be auscultated for breath sounds. Diminished or absent sounds may indicate an area of atelectasis or a pleural effusion or pneumothorax, which necessitates further medical assessment. Temperature changes are typical during the early postoperative period. Hypothermia is expected immediately after surgery from hypothermia procedures, effects of anaesthesia, and loss of body heat to the cool environment. During this period, the child needs to be kept warm to prevent additional heat loss. Infants may be placed under radiant heat warmers. During the next 24 to 48 hours the body temperature may rise to 37.7°C or slightly higher as part of the inflammatory response to tissue trauma. After this period an elevated temperature is most likely a sign of infection and warrants immediate investigation for probable cause.

Intra-arterial monitoring of BP is commonly done after open heart surgery. A catheter is passed into the radial artery or other artery, and the other end is attached to an electronic monitoring system, which provides a continuous recording of the BP. The intra-arterial line is maintained with a low-rate, constant infusion of heparinized saline to prevent clotting.

Several IV lines are inserted preoperatively: a peripheral IV to give fluids and medications, and a CVP, which is usually inserted in a large vessel in the neck. Additional intracardiac monitoring lines are sometimes placed intraoperatively in the right atrium, left atrium, or pulmonary artery. Intracardiac lines allow assessment of pressures inside the cardiac chambers, providing vital information about volume status,

BOX 47.8 Selected Complications After Cardiac Surgery and Treatment Approaches

Cardiac

Heart failure—Digoxin, diuretics
Low cardiac output—Intravenous inotropes
Dysrhythmias—Identification, medication treatment, possible pacing, cardioversion
Tamponade (blood or fluid in the pericardial space constricting the heart)—Prompt removal of fluid by pericardiocentesis

Respiratory

Atelectasis—Chest physiotherapy, coughing, deep breathing, ambulation
Pulmonary edema—Diuretics
Pleural effusions—Diuretics, possible chest tube drainage
Pneumothorax—Possible chest tube drainage

Neurological

Seizures—Assessment, antiepileptic medications
Cerebrovascular accident (CVA; stroke), cerebral edema, neurological deficits—Assessment and treatment

Infectious Disease

Infections (especially wound, pneumonia, otitis media, and sepsis)—Antibiotics

Hematological

Anemia—Iron supplementation, possible transfusion
Postoperative bleeding—Initially, clotting factors, blood products; may need repeat surgery to locate and ligate source of bleeding

Other

Postpericardiotomy syndrome (syndrome of fever, leukocytosis, friction rub, pericardial and pleural effusions, and lethargy seen about 7 to 21 days after cardiac surgery; possible viral or autoimmune etiologies)—Antipyretics, diuretics, anti-inflammatory medications

cardiac output, and ventricular function. All lines must be cared for using strict aseptic technique, and patients must be carefully assessed for bleeding at the time of line removal.

Maintaining Respiratory Status. Infants usually require mechanical ventilation in the immediate postoperative period, although early extubation in the operating room or early postoperative period is becoming more common. Children, especially those who did not require cardiopulmonary bypass, may be extubated in the operating room or in the first few postoperative hours. Suctioning is performed only as needed and is performed carefully to avoid vagal stimulation (which can trigger cardiac dysrhythmias) and laryngospasm, especially in infants. Suctioning is intermittent and maintained for no more than 5 seconds at a time to avoid depleting the oxygen supply. Supplemental oxygen is administered with a manual resuscitation bag before and after the procedure to prevent hypoxia. The heart rate is monitored after suctioning to detect changes in rhythm or rate, especially bradycardia. The child should always be positioned facing the nurse to permit assessment of the child's colour and tolerance of the procedure.

! NURSING ALERT

During suctioning, observe for signs and symptoms of respiratory distress, such as tachypnea, use of accessory muscles for breathing, and restlessness.

When weaning and extubation are completed, humidified oxygen is delivered by mask, hood, or nasal cannula to prevent drying of mucosa. The child should be encouraged to turn and deep breathe at least hourly. Incentive spirometer use should be encouraged. Measures are used to enhance ventilation and decrease pain, such as splinting the operative site and providing analgesics. Chest tubes are inserted into the pleural or mediastinal space during surgery or in the immediate postoperative period to remove secretions and air to allow re-expansion of the lung. Drainage should be checked hourly for colour and quantity. Immediately after surgery the drainage may be bright red, but afterward it should be serous. The largest volume of drainage occurs in the first 12 to 24 hours and is greater in extensive heart surgery.

! NURSING ALERT

Chest tube drainage greater than 3 mL/kg/hr for more than 3 consecutive hours or 5 to 10 mL/kg in any 1 hour is excessive and may indicate postoperative hemorrhage. The surgeon should be notified immediately because cardiac tamponade can develop rapidly and is life-threatening.

Chest tubes are usually removed on the first to third postoperative day. Removal of chest tubes can be a painful, frightening experience. Analgesics such as morphine sulphate, often combined with midazolam (Versed), should be given before the procedure. Older children should be forewarned that they will feel a sharp, momentary pain. After the suture is cut, the tubes are quickly pulled out at the end of a full inspiration to prevent the intake of air into the pleural cavity. In the intubated patient, the tubes are pulled out on inspiration because the lungs are stented open with positive pressure ventilation. A purse-string suture (placed when the tubes were inserted) is pulled tight to close the opening. A petrolatum-covered gauze dressing is immediately applied over the wound and securely taped on all four sides to the skin so that an airtight seal is formed. It is left on for 1 or 2 days. Breath sounds need to be checked to assess for a pneumothorax, a possible complication of chest tube removal. A chest X-ray is usually obtained after removal to evaluate for possible pneumothorax or pleural effusion.

Monitoring Fluids. Intake and output of all fluids must be accurately calculated. Intake is primarily IV fluids; however, a record of fluid used to flush the arterial and CVP lines or to dilute medications is also kept. Output includes hourly recordings of urine (usually a Foley catheter is inserted and attached to a closed collecting device), drainage from chest and nasogastric tubes, and blood drawn for analysis. Urine should be analyzed for specific gravity to assess the concentrating ability of the kidneys and the body's approximate degree of hydration. Renal failure is a potential risk from a transient period of low cardiac output.

! NURSING ALERT

The signs of renal failure are decreased urinary output (less than 1 mL/kg/hr) and elevated levels of blood urea nitrogen and serum creatinine.

Fluids are restricted during the immediate postoperative period to prevent hypervolemia, which places additional demands on the myocardium, predisposing the patient to cardiac failure. If the child is to be extubated within the first 24 to 48 hours, fluids are provided primarily intravenously. If the child is to be intubated longer, fluids may be given via a nasogastric or nasojejunal tube to optimize nutrition and gut motility. Approximately 4 hours after extubation, enteral fluids may be reinitiated in the setting of a stable hemodynamic and respiratory status. To monitor fluid retention, the child is weighed daily, and the same scale is used at approximately the same time each day to avoid errors in measurement. Fluid restriction may be imposed even when oral fluids are given. The nurse calculates the distribution over a 24-hour period based on the child's preoperative weight and drinking habits. The distribution should allow for most fluid to be given during the child's most wakeful and active periods.

Providing Rest and Progressive Activity. After heart surgery, rest should be provided to decrease the workload of the heart and promote healing. The simplest way to ensure individualized, efficient, high-quality care is to plan at the beginning of the shift the nursing procedures to be done, with periods of rest identified. The schedule should be shared with parents and they should be encouraged to visit at the most advantageous times, such as after a rest period when no special treatments are anticipated.

A progressive schedule of ambulation and activity is planned, based on the child's preoperative activity patterns and postoperative cardiovascular and pulmonary function. Ambulation is initiated early, usually by the second postoperative day, when chest tubes, arterial lines, and assisted ventilatory equipment may be removed. Activity progresses from sitting on the edge of the bed and dangling the legs to standing up and sitting in a chair. Heart rate and respirations need to be carefully monitored to assess the degree of cardiac demand imposed by each activity. Tachycardia, dyspnea, cyanosis, desaturation, progressive fatigue, or dysrhythmias indicate the need to limit further energy expenditure.

Providing Comfort and Emotional Support. Heart surgery is both painful and frightening for children, and comfort is a primary nursing concern. Several incisions may be used for heart surgery. A median sternotomy is most common, following the sternum down the centre of the chest. A ministernotomy opens the lower sternum. A thoracotomy incision is most uncomfortable because it goes through muscle tissue. It allows access to the side of the chest through an incision from under the arm around the back to the scapula.

Most patients need IV analgesics for pain control during the immediate postoperative period. Patient-controlled analgesia may be used with children old enough to understand the concept. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as ketorolac (Toradol) may be used intravenously. Paralyzing agents may also be used with the analgesics for children who are hemodynamically unstable.

After extubation and the removal of lines and tubes, pain can be controlled satisfactorily with oral medications such as ibuprofen, acetaminophen, or opioids. Acetaminophen alone provides adequate pain relief for most children at discharge. Sternotomy incisions are usually well tolerated, with some discomfort when walking and coughing. Thoracotomy incisions are usually more painful because the incision is through muscle; a more aggressive pain management plan with around-the-clock medications for several days is often necessary to allow for adequate rest, ambulation, and pulmonary hygiene.

In addition to pharmacological pain control, every effort should be made to minimize the discomfort of procedures, such as using a firm pillow or favourite stuffed animal placed against the chest incision during movement and when performing treatments *after* pain medication is given, preferably at a time that coincides with the medication's peak effect. Nonpharmacological measures can be used to lessen the perception of pain, and parents should be encouraged to comfort their child as much as possible (see also Pain Assessment; Pain Management, Chapter 34).

Children may become depressed after surgery. This is thought to be caused by preoperative anxiety, postoperative psychological and physiological stress, and sensory overstimulation. Typically, the child's disposition improves on leaving the CCU.

Children may also be angry and unwilling to assist in any way after surgery as a response to the physical pain and the loss of control imposed by the surgery and treatments. They need an opportunity to express their feelings, either verbally or through activity. Children often regress in their behaviour during the stress of surgery and hospitalization. They also may express feelings of anger or rejection toward their parents. The nurse can support the parents by being available for information and explaining all of the procedures to them. The first few postoperative days are particularly difficult because parents see their child in pain and realize the potential risks from surgery. They often are overwhelmed by the physical environment of the CCU and feel unable to help because they can do so little for their child. The nurse can minimize such feelings by including parents in caregiving activities and in comfort and play activities, providing information about the child's condition, and being sensitive to the parents' emotional and physical needs. The importance of their presence in making the child feel more secure should be stressed, even if they do not provide physical care.

Planning for Discharge and Home Care

Ideally, discharge planning begins on admission for cardiac surgery and includes an assessment of the parents' adjustment to the child's altered state of health. Newborns may need additional screening tests (such as newborn metabolic screen and hearing tests) and may need immunizations before discharge. The family needs both verbal and written instructions on medication, nutrition, activity restrictions, subacute bacterial endocarditis, return to school, wound care, signs and symptoms of infection or complications, and long-term follow-up of growth and physical and cognitive development (see Family-Centred Care box: Topics to Include in Discharge Teaching After Cardiac Surgery). Referrals to community agencies may be warranted to assist parents in the transition from hospital to home and to reinforce the teaching.

FAMILY-CENTRED CARE

Topics to Include in Discharge Teaching After Cardiac Surgery

- Medication teaching
- Activity restrictions
- Diet and nutrition
- Wound care (including dressings, if any; suture removal; bathing)
- Infective endocarditis prophylaxis (see Box 47.9)
- Follow-up appointments (cardiologist, primary care provider)
- Community agencies as needed (visiting nurse service, early developmental intervention)
- When to call the primary care provider; signs and symptoms of postoperative complications
- Review of cardiac defect and surgical repair
- Cardiopulmonary resuscitation (CPR) for caregivers

The parents also need clear instructions on when to seek medical care for complications and how to contact the health care provider. Follow-up with the cardiologist and primary care provider should be arranged before discharge. Parents should have a summary, including their child's medical condition, medications, and health care providers, available for emergencies. Appropriate identification, such as a MedicAlert device, is indicated for children with a pacemaker or heart transplant and for those receiving anticoagulation therapy or antidysrhythmic medication.

Although surgical correction of heart defects has improved dramatically, it is still not possible to completely repair many of the complex anomalies. For many children, repeat procedures are required to replace conduits or grafts or to manage complications such as restenosis. Consequently, the long-term prognosis is uncertain, and full recovery is not always possible. For these families, medical follow-up and continued emotional support are essential. The nurse can often serve as an important primary health care provider and as a resource for referrals when needed.

ACQUIRED CARDIOVASCULAR DISORDERS

Infective (Bacterial) Endocarditis

Infective endocarditis (IE), previously referred to as *bacterial endocarditis (BE)*, or *subacute bacterial endocarditis (SBE)*, is an infection of the inner lining of the heart (*endocardium*), generally involving the valves, which can potentially damage or destroy the heart valves. Though rare in children, there is a high rate of morbidity and mortality for patients who are affected (Murray & Baltimore, 2020). It is most often a sequela of bacteremia in children with acquired or congenital anomalies of the heart or great vessels, particularly those with valvular abnormalities, prosthetic valves, shunts, recent cardiac surgery with invasive lines, and rheumatic heart disease (RHD) with valve involvement. There is an increased incidence of IE in children without cardiac abnormalities, likely related to the increased use of in-dwelling central lines to treat other serious diseases.

Pathophysiology. Organisms may enter the bloodstream from any site of localized infection. Endocarditis may occur from routine exposure to bacteremia associated with usual daily activities such as brushing teeth, although it can also occur after procedures such as dental work; invasive procedures involving the gastrointestinal and genitourinary tracts; cardiac surgery, especially if synthetic material is used (valves, patches, conduits); or from long-term

BOX 47.9 Clinical Manifestations of Infective Endocarditis

Onset usually insidious
Unexplained fever (low grade and intermittent)
Anorexia
Malaise
Weight loss
Characteristic findings caused by extracardiac emboli formation:
- Splinter hemorrhages (thin black lines) under the nails
- Osler nodes (red, painful intradermal nodes found on pads of phalanges)
- Janeway lesions (painless hemorrhagic areas on palms and soles)
- Petechiae on oral mucous membranes

May be present:
- Heart failure
- Cardiac dysrhythmias
- New murmur or change in previously existing one

BOX 47.10 Patients at High Risk for Endocarditis

- Prosthetic cardiac valves
- Previous episode of infective endocarditis
- Congenital heart disease (CHD), including only
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, during the first 6 months after the procedure
  - Repaired CHD with residual defects at the site of or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

Adapted from Allen, U. D., & Canadian Paediatric Society. (2010). Infective endocarditis: Updated guidelines. *Paediatrics & Child Health, 15*(4), 205–208. Reaffirmed 2018. https://doi.org/10.1093/pch/15.4.205.

in-dwelling catheters. The most common causative agents are *Staphylococcus aureus* and *Streptococcus viridans;* other causative agents include Gram-negative bacteria and fungi such as *Candida albicans*. The microorganisms grow on the endocardium, forming vegetations (verrucae), deposits of fibrin, and platelet thrombi. The lesion may invade adjacent tissues, such as aortic and mitral valves, and may break off and embolize elsewhere, especially in the spleen, kidney, and central nervous system.

Diagnostic Evaluation. The diagnosis of IE is suspected on the basis of clinical manifestations (Box 47.9). Definitive diagnosis rests on growth and identification of the causative agent in the blood. At least three blood cultures are drawn at different times to aid in diagnosis. Vegetations on the valve and abnormal valve function can often be visualized by echocardiography. A diagnosis of culture-negative IE is made when the patient has echocardiographic or clinical evidence of IE but no organism can be cultured. Several laboratory findings may suggest IE, including anemia, elevated erythrocyte sedimentation rate (ESR), leukocytosis, and microscopic hematuria.

Therapeutic Management. Treatment should be instituted immediately and consists of administration of high doses of appropriate antibiotics intravenously for 2 to 8 weeks. Blood cultures are taken periodically to evaluate response to antibiotic therapy. Cardiac function is monitored by echocardiograms. Heart surgery to repair or replace the affected valve may be necessary.

Prevention involves administration of prophylactic antibiotic therapy 30 to 60 minutes before procedures known to increase the risk of entry of organisms. This prophylaxis can also be administered up to 2 hours after a procedure. Recent guidelines recommend prophylaxis only in patients with the highest risk for poor outcome if they develop endocarditis (Box 47.10). Medications of choice for prophylaxis include amoxicillin, ampicillin, clindamycin, cephalexin, cefadroxil, azithromycin, and clarithromycin.

Procedures that require prophylaxis include the following (Allen & Canadian Paediatric Society [CPS], Infectious Diseases and Immunization Committee, 2010/2018):

- All dental procedures that involve the manipulation of gingival tissue, the periapical region of teeth, or the perforation of the oral mucosa
- Invasive procedures of the respiratory tract
- Gastrointestinal or genitourinary tract procedures (high-risk patients only)
- Procedures on infected skin, skin structure, or musculoskeletal tissue

Nursing Care. Nurses should teach parents of high-risk children the signs and symptoms of endocarditis and the need for prophylactic antibiotic therapy before occurrence of any recommended procedures. The family's dentist should be advised of the child's cardiac diagnosis as an added precaution to ensure preventive treatment. It is important that all children with congenital or acquired heart disease maintain the highest level of oral health to reduce the chance of bacteremia from oral infections.

Parents should also have a high index of suspicion regarding potential infections. Without unduly alarming them, the nurse can stress that any unexplained fever, weight loss, or change in behaviour (lethargy, malaise, anorexia) must be brought to the primary care provider's attention. Early diagnosis and treatment are important in preventing further cardiac damage, embolic complications, and growth of resistant organisms.

Treatment of endocarditis requires long-term parenteral medication therapy. In many cases, IV antibiotics may be administered at home with nursing supervision for part of the treatment course. Nursing goals during this period are (1) preparation of the child for IV infusion, usually with an intermittent-infusion device, and several venipunctures for blood cultures; (2) observation for adverse effects of antibiotics, especially inflammation along venipuncture sites; (3) observation for complications, including embolism and HF; and (4) education regarding the importance of follow-up visits for cardiac evaluation, echocardiographic monitoring, and blood cultures. Some children may need preparation for surgery and postoperative care.

Acute Rheumatic Fever and Rheumatic Heart Disease

Acute rheumatic fever (ARF) is a result of an abnormal immune response to a group A streptococcal (GAS) infection, usually pharyngitis, in a genetically susceptible host (Shulman & Reuter, 2020). It occurs most often in late school-age children and adolescents and is rare in adults. ARF is a self-limited illness that involves the joints, skin, brain, and heart, but cardiac valve damage, which is referred to as *rheumatic heart disease (RHD),* the most significant complication of ARF, occurs in more than one half of cases. The mitral valve is most often affected. ARF and resulting RHD is the leading cause of HF in young people.

In developed countries, such as Canada, ARF and RHD have become uncommon and incidence rates are low. However, there is a higher incidence of ARF in the Indigenous population of Canada, likely because of overcrowded living conditions and poor access to medical

care. Researchers identified that in the First Nations population in northern Ontario, there was an incidence rate of 21.3 per 100 000, which is 75 times greater than the overall Canadian estimated incidence. The average patient age was 9.4 years. Most of these patients lived in inadequate and crowded housing (Gordon et al., 2015).

Etiology. Strong evidence supports a relationship between upper respiratory tract infection with GAS and subsequent development of ARF (usually within 2 to 6 weeks). Prevention or treatment of GAS infection prevents ARF. If the GAS infection is left untreated, antibodies are produced to fight the infection, which can also act against the heart valves, causing damage. If children have one strep infection, they are at greater risk for repeated infections, and recurrent infections cause the cumulative valve damage of RHD.

Diagnostic Evaluation. Diagnosis is based on a set of guidelines and later revisions, known as the *modified Jones criteria*. The updated Jones criteria suggest that the presence of two major manifestations or one major and two minor manifestations, with supportive evidence of recent GAS infection, indicates a high probability of ARF (Bach, 2015) (Box 47.11).

Children suspected of having ARF are tested for streptococcal antibodies. The most reliable and best standardized test is an elevated or rising antistreptolysin O (ASO or ASLO) titre, which occurs in 80% of children with ARF. Additional antistreptococcal antibody titres may be sent if ASO titres are negative. Acute-phase reactants, ESR, and C-reactive protein (CRP) are usually elevated as well. Echocardiography plays an important role in diagnosis of RHD and in monitoring deteriorating valve function.

Therapeutic Management. Primary prevention involves prompt diagnosis and treatment of strep throat infections so that ARF does not occur. Penicillin is the medication of choice, or an alternative in penicillin-sensitive children (Shulman & Reuter, 2020).

Children with ARF are given antibiotics to treat the GAS infection, and salicylates are used to control the inflammatory process, especially in the joints, and reduce the fever and discomfort. Supportive care involves bed rest initially and then quiet activities as symptoms subside. Good nutrition is important.

BOX 47.11 Modified Jones Criteria

Rheumatic fever is diagnosed with the presence of two major criteria, or one major and two minor criteria, plus a history of streptococcal infection.

Major Criteria

- Carditis
- Polyarthritis
- Erythema marginatum
- Chorea
- Subcutaneous nodules

Minor Criteria

- Fever
- Arthralgia
- Previous history of rheumatic heart disease
- Elevated erythrocyte sedimentation rate
- Leukocytosis
- Abnormal electrocardiogram (altered P-R interval)
- Positive test for C-reactive protein

Children who have had ARF are susceptible to recurrent infections that are likely to result in RHD and further damage to the heart valves. Prophylactic treatment against recurrence of ARF (secondary prevention) is started after the acute therapy. The treatment of choice is intramuscular injections of benzathine penicillin G every 28 days because it is most effective. Alternative therapy includes oral doses of penicillin or erythromycin twice a day, or one daily dose of sulfadiazine. The duration of secondary prophylaxis is based on the presence of residual heart disease. If ARF occurs without carditis, then prophylaxis is recommended for 5 years or until 21 years of age, whichever is longer. In patients with carditis, 10 years is recommended or until 21 years of age. In patients with RHD, prophylaxis can continue until 40 years of age and may be indicated indefinitely depending on the individual's risk (Shulman & Reuter, 2020).

Management of RHD may require surgical valve repair or replacement. Valve replacement with a mechanical valve requires lifelong anticoagulation with warfarin.

Nursing Care. The objective of nursing care is, first, prevention. Nurses play an important role in prevention by educating parents about the complications of strep infections and working with patients and families to ensure follow-up with antibiotic prophylaxis. Because adherence is a major concern in long-term medication therapy, every effort is made to encourage the patient's adherence to the therapeutic plan. When adherence is poor, monthly injections may be substituted for daily oral administration of antibiotics and children need preparation for this often-dreaded procedure.

For the child with ARF, the nurse needs to (1) encourage adherence to medication regimens, (2) facilitate recovery from the illness, and (3) provide emotional support. Interventions for ARF are primarily concerned with providing rest and adequate nutrition and managing cardiac symptoms or chorea. Usually, after the febrile stage is over, children can resume moderate activity, and their appetite improves. If carditis is present, the family must be aware of any activity restrictions and may need help in choosing less strenuous activities for the child. One of the most disturbing manifestations of ARF is chorea. The onset is gradual and may occur weeks to months after the illness. Sometimes mistaken for nervousness, clumsiness, or inattentiveness, it is usually a source of great frustration to the child because the movements, incoordination, and weakness severely limit physical ability. It is important that parents and teachers are aware of the involuntary, sudden nature of the movements and that the movements are transitory and will eventually disappear.

Children with RHD will need lifelong follow-up, education, and management of HF and monitoring for progressive valve disease. If surgery is required, preparation for the procedure is provided. An important aspect of postoperative care is education about anticoagulation medications and follow-up.

Hyperlipidemia/Hypercholesterolemia

Hyperlipidemia is a general term for excessive lipids (fat and fatlike substances); *hypercholesterolemia* refers to excessive cholesterol in the blood. *Dyslipidemia* is a term used to describe all abnormalities in lipid metabolism, including low levels of high-density lipoprotein, or "good" cholesterol. High lipid or cholesterol levels play an important role in producing *atherosclerosis* (fatty plaque on the arteries), which eventually can lead to coronary artery disease, a primary cause of morbidity and mortality in the adult population. A presymptomatic phase of atherosclerosis can begin in childhood or adolescence, providing the template for later clinical disease. Preventive cardiology focuses on the identification of high-risk patients and management of lipid levels in children and adolescents.

Cholesterol is part of the lipoprotein complex in plasma that is essential for cellular metabolism. *Triglycerides*, natural fats synthesized from carbohydrates, are used for energy. Both are major lipids transported on *lipoproteins*, a combination of lipids and proteins, which include the following:

- **Low-density lipoproteins (LDLs)**—These contain low concentrations of triglycerides, high levels of cholesterol, and moderate levels of protein. LDL is the major carrier of cholesterol to the cells. Cells use cholesterol for synthesis of membranes and steroid production. Elevated circulating LDL is a strong risk factor in cardiovascular disease. In addition, particle size and density of LDL may affect overall risk, with small, dense particles associated with increased atherosclerosis.
- **High-density lipoproteins (HDLs)**—These contain very low concentrations of triglycerides, relatively little cholesterol, and high levels of protein. They transport free cholesterol to the liver for excretion in the bile. High levels of HDL are thought to be protective against cardiovascular disease.
- **Very-low-density lipoproteins (VLDLs)**—These contain high concentrations of triglycerides, some cholesterol, and a little protein. Triglycerides are the main storage form of fuel or energy for the body.

Diagnostic Evaluation. Hyperlipidemia is diagnosed on the basis of analysis of blood for a full lipid profile, drawn after a 12-hour fast. Hyperlipidemia can have a genetic basis or a lifestyle component or can be caused by secondary conditions, such as hypothyroidism. In children with elevated cholesterol levels, a screening thyroid-stimulating hormone (TSH) is useful to rule out hypothyroidism as a cause of secondary hypercholesterolemia. Additional blood work is individualized on the basis of other risk factors. Lipid values may be affected by recent high fevers; therefore, cholesterol values should not be drawn if a child has had a fever within the past 3 weeks. Diagnostic values for acceptable, borderline, and high total cholesterol and LDL cholesterol levels are listed in Table 47.5.

TABLE 47.5 Classification of Cholesterol Levels in Children

Category	Normal mmol/L (mg/dL)	Borderline High mmol/L (mg/dL)	Elevated mmol/L (mg/dL)
Triglycerides	<4.39 (170)	4.40–5.16 (170–199)	≥5.1 (200)
Low-density lipoprotein (LDL)	<2.8 (110)	2.8–6.67 (110–120)	≥3.4 (130)
Non–high-density lipoprotein (HDL)	<6.67 (120)	6.67–7.99 (120-144)	≥145 (8.05)
High-density lipoprotein (HDL)*	>45 (2.50)	N/A	N/A

N/A, Not applicable.
*Borderline low HDL 40–45; Low HDL <40.
Data adapted from the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, Daniels, S. R., Benuck, I., et al. (2012). *Expert panel on integrated guidelines for cardiovascular health and risk reduction in children and adolescents: Summary report.* US Department of Health and Human Services, National Heart, Lung, and Blood Institute, National Institutes of Health.

Familial hypercholesterolemia (FH) is a major factor in the likelihood that children will develop atherosclerotic cardiovascular disease in the future. This atherosclerotic condition is a genetic disorder that causes premature atherosclerotic cardiovascular disease characterized by very high plasma levels of low-density lipoprotein cholesterol (LDL-C) (Brunham et al., 2018). The risk for children with diagnosed FH of developing hypercholesterolemia is 10 to 20 times that for individuals with normal lipid profiles.

The Canadian Cardiovascular Society recommends that cascade screening (lipid profile) protocols be implemented and offered to first-degree relatives of patients with FH (Brunham et al., 2018). Diagnosis and early treatment of FH can normalize life expectancy.

In addition to abnormal cholesterol levels, known risk factors that correlate with the development of coronary artery disease include the following:

- Positive family history of elevated cholesterol and/or early heart disease
- Sedentary lifestyle
- Nutritional factors
- Older age
- Male gender
- Hypertension
- Type 1 or type 2 diabetes

Therapeutic Management. The first step in the treatment of high cholesterol is oriented toward lifestyle modification. The recommendation is that all children with a presumptive diagnosis of FH first undergo at least 12 months of lifestyle changes, including diet, exercise, and a tobacco-free environment (Genest et al., 2014). Children with known elevated cholesterol should have individual nutritional counselling by a dietitian with expertise in pediatric lipids.

Research continues to support the benefit of diets low in saturated fats and trans fats and higher in monounsaturated fats (found in olive and canola oil). Current thinking favours a "Mediterranean"-type diet. Whole grains, fruits, and vegetables form the foundation of this diet along with monounsaturated fats such as olive oil, canola oil, nuts, avocados, and fish, which have beneficial effects on HDL cholesterol values. Patients with elevated triglycerides, particularly those with an elevated body mass index (BMI), should receive targeted counselling aimed at adopting a low-glycemic diet. Daily aerobic exercise of at least 60 minutes a day is also recommended for children with high cholesterol levels (see Chapter 35 for recommended activity levels).

In addition, patients and parents should be counselled regarding the negative effects of tobacco, vaping, and cannabis smoking (both first-hand and secondhand). Secondhand tobacco smoke exposure during childhood is detrimental to arterial function and structure resulting in premature atherosclerosis and can have cardiovascular consequences of impaired cardiac autonomic function and changes in heart rate variability (Raghuveer et al., 2016). Emerging evidence shows an increased risk for heart disease and stroke from the effects of cannabis and vaping on blood pressure, inflammation of the blood vessels, and cardiac arrhythmias (Heart and Stroke, 2020).

For children with severe hypercholesterolemia who fail to respond to dietary modifications (after a 6- to 12-month trial) medication therapy may be necessary. Pharmacological therapy is recommended for children with LDL cholesterol over 4.9 mmol/L with a positive history of early heart disease and over 4.1 L mmol/L in patients with a positive family history for atherosclerotic cardiovascular disease. In most situations, medication is reserved for children aged 8 to 10 years of age (Brunham et al., 2018).

The most recent findings on lipid abnormalities in children recommend treatment with statins if pharmacological therapy is indicated,

using the previously outlined guidelines for treatment (Brunham et al., 2018). Statins are much more effective at lowering LDL cholesterol and triglycerides and raising HDL cholesterol. They work by inhibiting the enzyme necessary for cholesterol synthesis, are most effective when taken in the evening, and are started at the lowest possible dose in young people. Blood work should be followed closely in children and adolescents and usually includes a fasting lipid profile, liver function tests, and creatinine kinase repeated 1 month or so after initiation, and then twice yearly, as well as with any dosage changes.

Patients beginning therapy with a statin should be counselled regarding rare but potentially serious adverse effects (e.g., rhabdomyolysis) as well as more minor potential adverse effects. Patients should discontinue their medication and contact their health care provider if they develop dark urine or new muscle aches. Statin medications are not safe during pregnancy; therefore, sexually active adolescents need to take adequate birth control measures.

Ezetimibe is sometimes given in combination with statins to further reduce LDL cholesterol, which it accomplishes by decreasing reabsorption of cholesterol from the gut. This medication is currently approved for children older than 10 years of age with extremely severe hyperlipidemia. Several large clinical trials are currently in process to determine the effectiveness of this medication (Maliachova & Stabouli, 2018).

Nursing Care. Nurses play an important role in the screening, education, and support of children with lipid abnormalities and their families. When a child is referred to a preventative cardiology clinic, it is essential that the family be adequately prepared for the first visit. Generally, the parents are asked to keep a dietary history of the child before this visit. Sometimes they need to complete a questionnaire regarding the child's normal dietary habits. Families should be instructed to keep their child fasting for at least 12 hours before lab work is performed. Parents should also be aware that lipids should not be drawn within 3 weeks of a febrile illness because doing so can affect cholesterol values. The blood test should be scheduled early in the morning and nourishment provided immediately thereafter. At the visit a full family history should be taken, including the health of both parents and all first-degree relatives. Specific questions should be asked regarding early heart disease, hypertension, strokes (CVAs), sudden death, hyperlipidemia, diabetes, and endocrine abnormalities.

Patients and parents should be educated about cholesterol and lipid abnormalities. This should include a brief introduction of the different lipoprotein categories, including an explanation of the components of the lipid profile. Also, lifestyle risk factors for heart disease, such as smoking and exercise, should be reviewed. For management to be effective, parents and patients need to understand that the rationale for dietary or pharmacological intervention is prevention of future cardiovascular disease and is part of any treatment plan for lipid abnormalities.

A child with a lipid disorder should not be viewed as having a disease, and stringent dietary guidelines may become an issue of control and a source of stress for many families. Rather, the positive aspects of healthy eating, regularly exercising, and avoiding smoking should be emphasized. Basic dietary changes should be encouraged for the whole family so that the affected child is not singled out. Cultural differences must be considered and recommendations individualized. Substitution rather than elimination needs to be emphasized. Visual aids (e.g., test tubes depicting the amount of fat in a hot dog or the number or packs of sugar in a glass of juice) are often helpful, especially for children. Diets should be flexible and individually tailored by a dietitian who is experienced in lipid disorders. Dietary recommendations need to meet the nutritional demands of growing children while providing benefit to the overall profile. Parents and patients should be encouraged to participate in dietary and educational sessions, ask questions, and share their ideas and experiences.

Parents often feel guilty about the hereditary component of hyperlipidemia. Many also believe they have failed if the diet alone is not making a significant difference in their child's lipid profile. They need to be reassured that a dietary approach alone is often not sufficient, especially for children with significantly elevated values.

Parents of children who require pharmacological therapy need to understand the purpose, dosage, and possible adverse effects of the various medications. Medication schedules should remain flexible and should not interfere with the child's daily activities. Follow-up phone calls by the nurse between visits can give parents the chance to discuss their concerns and ask any questions that have arisen.

Cardiac Dysrhythmias

Dysrhythmias, or abnormal heart rhythms, can occur in children with structurally normal hearts, as features of some congenital heart defects, and in patients after surgical repair of congenital heart defects. They are also seen in patients with cardiomyopathy and cardiac tumours and can occur secondary to metabolic and electrolyte imbalances. They can be classified in several ways, including by heart rate characteristics (bradycardia and tachycardia) and by the origin of the dysrhythmia in the atria or ventricles. Some dysrhythmias are well tolerated and self-limited. Others may cause decreased cardiac output with associated symptoms, and some can cause sudden death. Treatment depends on the cause of the dysrhythmia and its severity.

Many advances have been made in the diagnosis and treatment of pediatric dysrhythmias. Improvements in technology have allowed better diagnosis, the development of ablation techniques, and the expansion of pacemaker capabilities. New antidysrhythmic medications have proved to be safe and effective in children. Radiofrequency ablation has offered a cure for some dysrhythmias. Pediatric electrophysiology has become a highly specialized field; the reader should consult more detailed sources for an in-depth discussion.

The next sections address diagnostic studies and provide a general discussion of the most common tachycardia (supraventricular tachycardia) and the most common bradycardia (complete heart block) that require treatment in the pediatric population.

Diagnostic Evaluation. Nurses must be familiar with the standards of normal heart rate for the particular age group (see Appendix C). An initial nursing responsibility is recognition of a heartbeat that is abnormal in either rate or rhythm. When a dysrhythmia is suspected, the apical rate is counted for a full minute and compared with the radial rate, which may be lower because not all of the apical beats are felt. Consistently high or low heart rates should be regarded as suspicious. The patient should be placed on a cardiac monitor with recording capabilities. A 12-lead ECG yields more information than the monitor recording and should be done as soon as possible.

The basic diagnostic procedure is the ECG, including 24-hour Holter monitoring. Electrophysiological cardiac catheterization allows for identification of the conduction disturbance and immediate investigation of medications that may control the dysrhythmia. Another procedure that may be used is transesophageal recording. An electrode catheter is passed to the lower esophagus and, when in position at a point proximal to the heart, is used to stimulate and record dysrhythmias.

Dysrhythmias can be classified according to various criteria, such as effect on heart rate and rhythm, as follows:

Bradydysrhythmias—Abnormally slow rate
Tachydysrhythmias—Abnormally rapid rate
Conduction disturbances—Irregular heart rate

Bradydysrhythmias. *Sinus bradycardia* (slower than normal rate) in children can be caused by the influence of the autonomic nervous system, as with hypervagal tone, or in response to hypoxia and hypotension. Sinus bradycardias are also known to develop after some complex cardiac surgical repairs involving extensive atrial suture lines, such as atrial baffle repairs (Mustard and Senning repairs) and the Fontan procedure.

Complete atrioventricular (AV) block is also referred to as *complete heart block*. This can be either congenital (occurring in children with structurally normal hearts) or acquired after surgery to repair cardiac defects. AV blocks are most often related to edema around the conduction system and resolve without treatment. Temporary epicardial wires are placed in most patients at surgery; if a rhythm disturbance occurs, temporary pacing can be used. Several days after surgery, the health care provider removes the wires by pulling slowly and deliberately down on them from the site of insertion.

Some children may need a permanent pacemaker. The pacemaker takes over or assists in the heart's conduction function. The implantation of a pacemaker, in the operating room or possibly the catheterization laboratory, is usually a low-risk procedure. The pacemaker is made up of two basic parts: the pulse generator and the lead. The pulse generator is composed of the battery and the electronic circuitry. The lead is an insulated, flexible wire that conducts the electrical impulse from the pulse generator to the heart. Two types of leads are available: transvenous and epicardial. After the lead has been attached to the heart, a small incision is made, and a pocket is formed under the muscle to house and protect the generator. Continuous ECG monitoring is necessary during the recovery phase to assess pacemaker function. The nurse should be aware of the programmed rate and expected individual generator variations. The pacemaker insertion site should be monitored for signs of infection. Analgesics can be given for pain.

Pacemaker functions have become more sophisticated, and some models can adjust heart rate to activity demands or be programmed for overdrive pacing or cardioversion.

Discharge teaching includes information about the signs and symptoms of infection, general wound care, and activity restrictions. Parents and patients, if they are old enough, should be taught to take a pulse and know the settings of the pacemaker. If the patient's low rate is set at 80 bpm and the heart rate is only 68 bpm, there is a possible problem with the pacemaker that needs to be investigated. Instructions for telephone transmission of ECG readings are also given. Telephone transmission can be used to transmit ECG strips and also to monitor battery life and pacemaker function. The pacemaker generator will have to be replaced periodically because of battery depletion. Children with pacemakers should wear a medical alert device, and their parents should have a paper identification card with specific pacer data in case of an emergency. **Cardiopulmonary resuscitation (CPR)** instruction is suggested for parents.

Tachydysrhythmias. *Sinus tachycardia* (abnormally fast heart rate) secondary to fever, anxiety, pain, anemia, dehydration, hypovolemia, hypoxia, shock, pulmonary edema, medication, or any other etiological factor requiring increased cardiac output should be ruled out before diagnosing an increased heart rate as pathological. Supraventricular tachycardia (SVT) is the most common tachydysrhythmia found in children and refers to a rapid regular heart rate of 200 to 300 bpm. The onset of SVT is often sudden, the duration is variable, and the rhythm may end abruptly and convert back to a normal sinus rhythm. Clinical signs in infants and young children are poor feeding, extreme irritability, and pallor. Children may experience palpitations, dizziness, chest pain, and diaphoresis. If SVT is sustained, signs of HF may be seen.

The treatment of SVT depends on the degree of compromise imposed by the dysrhythmia (see Clinical Reasoning Case Study: Supraventricular Tachycardia). In some cases vagal manoeuvres, such as applying ice to the face, massaging the carotid artery (on one side of the neck only), or having an older child perform a Valsalva manoeuvre (e.g., exhaling against a closed glottis, blowing on a thumb as if it were a trumpet for 30 to 60 seconds), have terminated SVT. If vagal manoeuvres fail or the child is hemodynamically unstable, adenosine (a medication that impairs AV conduction) may be used. Adenosine is given by rapid IV push with a saline bolus given immediately after the medication because of its very short half-life. If this is unsuccessful or cardiac output is compromised, esophageal overdrive pacing or synchronized cardioversion (delivering an electrical shock to the heart) can be used in the critical care setting. Sedation is needed for both procedures. Cardioversion should never be done in a conscious patient. More long-term pharmacological treatment includes digoxin or possibly propranolol (Inderal) or amiodarone for severe or recurrent SVT.

CLINICAL REASONING CASE STUDY

Supraventricular Tachycardia

A nurse is working in the emergency department when a father comes through the doors, crying, carrying his 1-month-old infant. The infant is awake and very irritable. The father reports that the infant has not been feeding well for the past 6 hours, and the father has noticed sweating (diaphoresis) with attempted feeds. No history of fever is noted. Further assessment reveals a diaphoretic, crying infant with a respiratory rate of 60 breaths/min, blood pressure of 60/40 mm Hg, and heart rate that is too fast to count by auscultation. When the infant is attached to the cardiorespiratory monitor, the heart rate is 220 beats/min, nonvariable, with an oxygen saturation of 97%. Capillary refill time is slightly prolonged at 3 seconds, and femoral pulses are palpable but weak.

Questions

1. What evidence should the nurse consider regarding this condition?
2. What symptoms are associated with heart failure?
3. Why might the infant be having difficulties with feeding?
4. How are tachyarrhythmias treated?
5. What priorities for nursing care should be established?

A primary focus of nursing care is education of the family regarding the symptoms of SVT and its treatment. SVT may occur again despite therapy. Parents should be taught to take a radial pulse for a full minute. If medication is prescribed, instructions in accurate dosage should be given, and the importance of administering the correct dose at specified intervals should be stressed.

Radiofrequency ablation has become first-line therapy for some types of SVT. The procedure is done in the cardiac catheterization laboratory and begins with mapping of the conduction system to identify the dysrhythmia focus. A catheter delivering radiofrequency current is directed at the site, and the area is heated to destroy the tissue in the area. These are lengthy procedures, often 6 to 8 hours, and sedation or general anaesthesia is required. Preparation is similar to that for cardiac catheterization.

Another procedure, cryoablation, is also used in treatment of SVT. Liquid nitrous oxide is used to cool a catheter to subfreezing temperatures, which then destroys the target tissue by freezing. This procedure is performed in the cardiac electrophysiology catheterization laboratory (Dalal & Van Hare, 2020).

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) is a disease of the entire pulmonary circulation. The pulmonary arteries are described as having vascular narrowing due to decreased vascular growth and surface area, as well as structure remodelling of the vessel wall. This leads to an

increase in pulmonary vascular resistance and right-sided HF (Bernstein & Feinstein, 2020). These disorders are poorly understood, and until recently, there was no treatment beyond supportive care. PAH is a progressive, eventually fatal disease for which there is no known cure. PAH can be difficult to diagnose in the early stages. Often when patients become symptomatic and a diagnosis is made, their disease is rapidly progressing, treatment is unsuccessful, and death occurs within several years. Significant new information about the disease process, genetic links, diagnosis, and treatment has been learned that may improve treatments and outcomes for these patients.

There are many possible causes of PAH. Cardiac causes occur primarily in patients with a large left-to-right shunt producing increased pulmonary blood flow. If these defects are not repaired early, the high pulmonary flow will cause changes in the pulmonary artery vessels and the vessels will lose their elasticity. Other causes of PAH include hypoxic lung diseases, thromboembolic diseases causing pulmonary vascular obstruction, collagen vascular diseases, and exposure to toxic substances. Many patients with PAH have no identifiable cause for it and have primary or idiopathic PAH.

Clinical Manifestations. The clinical manifestations include dyspnea with exercise, chest pain, and syncope. Dyspnea is the most common symptom and is caused by impaired oxygen delivery. Chest pain is the result of coronary ischemia in the right ventricle from severe hypertrophy. Syncope reflects a limited cardiac output leading to decreased cerebral blood flow. Right-sided heart dysfunction is steadily progressive; when symptoms of venous congestion and edema are present, the prognosis is poor.

Therapeutic Management. Although no cure is known, several therapies have shown promise in slowing the progression of the disease and improving quality of life. In general, situations that may exacerbate the disease and cause hypoxia, such as exercise and high altitudes, are to be avoided. Supplemental oxygen, especially at night while sleeping, is commonly used to relieve hypoxia. Patients are at risk for thromboembolic events leading to pulmonary **emboli**; thus anticoagulation with warfarin (Coumadin) is often prescribed. A number of new medication therapies have been used in this patient population and have promise in improving quality of life and survival. Several studies and newer approaches in treatment emphasize combined therapy that targets each of the major pathways of the disease process, rather than monotherapy approaches.

Vasodilator therapy (which relaxes vascular smooth muscle and reduces pulmonary artery pressure) can prolong survival of patients with PAH. Oral calcium channel blockers, such as nifedipine, have been successful in some children. Continuous IV infusion of the arachidonic acid metabolite prostacyclin (epoprostenol) provides relief as long as the infusion is continued. Despite the success of prostacyclin in reducing symptoms and improving quality of life, it only slows, not stop, progression of the disease. Treprostinil, a prostacyclin analogue with a longer half-life has also been shown to be effective (Bernstein & Feinstein, 2020).

Lung transplantation may be another treatment option for patients with severe disease. Patients with pulmonary hypertension have had a higher mortality rate after lung transplantation than that of other lung transplant patients.

The management of PAH continues to evolve as new information is learned and new combination therapies are tested and evaluated.

Cardiomyopathy

Cardiomyopathy refers to abnormalities of the myocardium in which the cardiac muscles' ability to contract is impaired. Cardiomyopathies are relatively rare in children. Possible etiological factors include familial or genetic causes, infection, deficiency states, metabolic abnormalities, and collagen vascular diseases. Most cardiomyopathies in children are considered primary or idiopathic, in which the cause is unknown and the cardiac dysfunction is not associated with systemic disease. Some of the known causes of secondary cardiomyopathy are anthracycline toxicity (the antineoplastic agents doxorubicin [Adriamycin] and daunomycin), hemochromatosis (from excessive iron storage), Duchenne muscular dystrophy, Kawasaki disease (KD), collagen diseases, and thyroid dysfunction.

Cardiomyopathies can be divided into three broad clinical categories according to the type of abnormal structure and dysfunction present: (1) dilated cardiomyopathy, (2) hypertrophic cardiomyopathy, and (3) restrictive cardiomyopathy.

Dilated cardiomyopathy is characterized by ventricular dilation and greatly decreased contractility, resulting in symptoms of HF. This is the most common type of cardiomyopathy in children. Its cause is often unknown. The clinical findings are HF with tachycardia, dyspnea, hepatosplenomegaly, fatigue, and poor growth. Dysrhythmias may be present and may be more difficult to control with worsening HF.

Hypertrophic cardiomyopathy is characterized by an increase in heart muscle mass without an increase in cavity size, usually occurring in the left ventricle and associated with abnormal diastolic filling. It is a familial autosomal dominant genetic abnormality in most cases and is probably the most common genetically transmitted cardiovascular disease. The expression of clinical disease varies greatly among patients. Clinical symptoms usually appear in the school-age period or adolescence and may include anginal chest pain, dysrhythmias, and syncope. Sudden death is possible. In one study, children under 18 years of age with known hypertrophic cardiomyopathy and unexplained syncope had a 60% cumulative risk of sudden death within 5 years of the syncopal event (Spirito et al., 2009). Presentation in infancy includes signs of HF and has a poor prognosis. The ECG demonstrates left ventricular hypertrophy, often with ST-T changes. The echocardiogram is most helpful and demonstrates asymmetrical septal hypertrophy and an increase in left ventricular wall thickness with a small left ventricle cavity.

Restrictive cardiomyopathy, rare in children, involves a restriction to ventricular filling caused by endocardial or myocardial disease or both. It is characterized by diastolic dysfunction and absence of ventricular dilation or hypertrophy. Symptoms are similar to those of HF (see Box 47.6).

Therapeutic Management. Treatment of cardiomyopathy is directed toward correcting the underlying cause whenever feasible. However, in most affected children this is not possible, and treatment is aimed at managing HF and dysrhythmias. Digoxin, diuretics, and aggressive use of afterload reduction agents have been found to be helpful in managing symptoms in those with dilated cardiomyopathy. Practice guidelines for the management of HF in children have been outlined and provide an in-depth review of available therapies (Kantor et al., 2013). Digoxin and inotropic agents are usually not helpful in treating the other forms of cardiomyopathy because increasing the force of contraction may exacerbate the muscular obstruction and actually impair ventricular ejection. Beta blockers such as propranolol or calcium channel blockers such as verapamil have been used to reduce left ventricular outflow obstruction and improve diastolic filling in patients with hypertrophic cardiomyopathy.

Careful monitoring and treatment of dysrhythmias are essential. The placement of an implantable defibrillator (AICD) should be considered for patients at high risk of sudden death from ventricular dysrhythmias. Anticoagulants may be given to reduce the risk of

thromboemboli, a complication of the sluggish circulation through the heart. For worsening HF and signs of poor perfusion, IV inotropic or vasodilating medications may be needed. Severely ill children may require mechanical ventilation, oxygen administration, and IV medications. Heart transplantation may be a treatment option for patients with worsening symptoms despite maximum medical therapy.

Nursing Care. Because of the poor prognosis in many children with cardiomyopathy, nursing care is consistent with that for any child with a life-threatening disorder (see Chapter 41). One of the most difficult adjustments for the child (especially the normally active youngster with hypertrophic cardiomyopathy) may be the realization of failing health and the need for restricted activity. The child should be included in decisions regarding activity and allowed to discuss their feelings, particularly if the disease follows a progressively fatal course. After symptoms of HF or dysrhythmias develop, the same nursing interventions are implemented. If heart transplantation is considered, the child and family require thorough psychological preparation and postoperative care. The nurse plays an important role in assessing the family's understanding of the procedure and its long-term consequences. Children of school age and older should be fully informed about the procedure in order for them to give their assent to it being carried out (see Informed Consent, Chapter 44).

HEART TRANSPLANTATION

Heart transplantation has become a treatment option for infants and children with worsening HF and a limited life expectancy despite maximum medical and surgical management. Indications for heart transplantation in children are cardiomyopathy and end-stage CHD. It is also an option for patients with some forms of complex congenital cardiac defects, such as HLHS, for whom conventional surgical approaches have a high mortality rate.

The heart transplant procedure may be orthotopic or heterotopic. *Orthotopic heart transplantation* refers to removing the recipient's own heart and implanting a new heart from a donor who has had neurological determination of death but has a healthy heart. The donor and recipient are matched by weight and blood type. *Heterotopic heart transplantation* refers to leaving the recipient's own heart in place and implanting a new heart to act as an additional pump, or "piggyback" heart; this type of transplant is rarely done in children.

Before transplantation, potential recipients undergo a careful cardiac evaluation to determine whether any other medical or surgical options are available to improve the patient's cardiac status. Other organ systems are assessed to identify issues that might increase the risk of or preclude transplantation. A psychosocial evaluation of the patient and family is done to assess family function, support systems, and ability to adhere to the complex medical regimen after the transplant. Support services to help the family successfully care for their child are provided when possible. Parents and older adolescents need extensive education about the risks and benefits of transplantation so they can make an informed decision.

According to data from the International Society for Heart and Lung Transplantation (ISHLT) registry, which keeps data on most transplants worldwide, the number of heart transplants in pediatric patients has increased over time, with 442 reported in 2004, 586 in 2014, and 684 in 2015 (Dipchand, 2018). Infants are the largest group of pediatric transplant recipients and account for about one fourth of all procedures. CHD is the underlying diagnosis leading to transplant in the majority of infants (55%), whereas cardiomyopathy was the most common diagnosis among adolescents (age 11 to 17 years at transplant) (Rossano et al., 2017).

Survival rates post-transplant are affected by the age at transplant, with a median survival of 22.3 years for those under 1 year of age at transplantation, 18.4 years for those aged 1 to 5 years, 14.4 years for those aged 6 to 10 years, and 13.1 years for those over 11 years of age. These numbers are improving almost annually. The 1-year survival rate for children under 10 years is 83% (Dipchand, 2018). Surviving pediatric patients have excellent functional recovery; most children who survive at least 1 year post-transplant have an excellent functional status with few limitations to daily life (Dipchand, 2018).

Waiting-list mortality remains high, particularly in the smallest children. Efforts are ongoing to increase donor organ supply, including organ donor awareness, country-specific legislation around organ donation, optimization of donor management, and assessment of the heart for transplantation (Dipchand, 2018). High-risk children waiting for transplants could benefit from emerging cardiac assist devices, such as extracorporeal membrane oxygenation and ventricular assist devices, as a bridge to transplantation in order to improve survival rates.

The post-transplant course is complex. Graft failure, rejection, infection, and cardiac allograft vasculopathy (CAV) continue to be the major causes of death within the first 5 years post-transplant (Dipchand, 2018). CAV causing graft failure has continued to be a major hindrance to long-term survival for many transplant recipients, although 67% of patients were free from CAV 10 years after transplantation (Rossano et al., 2017).

Although heart function is greatly improved or normal after transplantation, the risk of rejection is serious. Rejection of the heart is diagnosed primarily by endomyocardial biopsy in older children. Serial echocardiograms are often used in infants and young children to reduce the need for invasive biopsies. Immunosuppressants must be taken for life and have many systemic adverse effects. Triple-drug therapy for immunosuppression with a calcineurin inhibitor (cyclosporine or tacrolimus), steroids, and mycophenolate mofetil or azathioprine is most commonly used in pediatric patients. Steroids are weaned in the first year and may be discontinued in some patients; many pediatric centres are avoiding long-term use of steroids by utilizing induction therapy protocols of high-dose steroids and thymoglobulin at the time of transplant (Rossano et al., 2017).

Infection is always a risk. The pediatric patient undergoing an organ transplant is at risk of acquiring various infectious diseases from three possible sources: the endogenous reactivation of latent pathogens (e.g., herpes viruses), transmission from the donated organ or tissue, and transmission from within the community or health care setting. The pretransplant period should be used to improve a patient's overall health and well-being, including maximizing vaccination status and identifying any infections that are present (Allen & CPS, Infectious Disease and Immunization Committee, 2013/2018). The likelihood of an adequate immune response improves when vaccines are administered before the onset of immune suppression. Parents need guidance from the transplant team on their child's vaccination schedule.

Potential long-term conditions that may limit survival include chronic rejection, causing coronary artery disease; renal dysfunction and hypertension resulting from cyclosporine administration; lymphoma; and infection. In the short term, after successful transplantation, children are able to return to full participation in age-appropriate activities and appear to adapt well to their new lifestyle. Transplantation is not considered a cure because patients must live with the lifetime consequences of chronic immunosuppression.

Nursing Care

Successful care of a child after they have undergone a heart transplant requires the expertise and dedication of many members of the health

care team. Nurses play vital roles in assessment, coordination of care, psychosocial support, and patient and family education. The heart transplant recipient must be carefully monitored for signs of rejection, infection, and the adverse effects of immunosuppressant medications. The patient's and family's psychosocial well-being also needs to be assessed to identify issues such as increased family stress, depression, substance use, and school issues, as these patients are at risk for behavioural and psychological consequences. Nonadherence to an intense medication regimen, especially during adolescence, can lead to serious medical issues and can be fatal. Care of the immunosuppressed child is reviewed in Chapter 48. Psychosocial concerns and appropriate interventions for the child with a life-threatening disorder are presented in Chapter 41.

The first 6 months to 1 year after the transplant are most intense because the risk of complications is greatest and the patient and family are adjusting to a new lifestyle. Patients need to be monitored closely by the health care team, with frequent clinic visits and laboratory tests. Care is usually shared between local health care providers and the transplant centre. Many patients are able to return to school and other age-appropriate activities within 2 to 3 months after the transplant.

VASCULAR DYSFUNCTION

Systemic Hypertension

Hypertension is defined as the consistent elevation of BP beyond values considered to be the upper limits of what is healthy. The two major categories are *essential hypertension* (no identifiable cause) and *secondary hypertension* (subsequent to an identifiable cause). In recent years, there has been increasing incidence in this disorder in adolescents and children. The prevalence of hypertension in children is approximately 2% in Canada and is closely related to childhood obesity and sedentary activity patterns in children (Nerenberg et al., 2018). Recent data suggest that the prevalence of obesity is stabilizing and that the prevalence of elevated BP in children is decreasing (Nerenberg et al., 2018).

Children can be diagnosed as hypertensive if their systolic or diastolic BP is at the ninety-fifth percentile for age, sex, and height (Nerenberg et al., 2018). This group is further delineated as follows:

- *Stage 1 hypertension* includes patients with BP readings between the ninety-fifth and ninety-ninth percentiles plus 5 mm Hg.
- *Stage 2 hypertension* describes patients with BP readings over the ninety-ninth percentile plus 5 mm Hg.

Etiology. Most instances of hypertension observed in young children occur secondary to a structural abnormality or an underlying pathological process, although this association is being challenged by screening programs of relatively healthy children. The most common cause of secondary hypertension is renal disease, followed by cardiovascular, endocrine, and some neurological disorders. As a rule, the younger the child and the more severe the hypertension, the more likely it is to be secondary.

While the causes of essential hypertension are undetermined, evidence indicates that both genetic and environmental factors play a role. The incidence of hypertension has been shown to be higher in children whose parents are hypertensive. Environmental factors that contribute to the risk of developing hypertension include obesity, poor diet, lack of exercise, smoking, and stress.

Diagnostic Evaluation. BP assessment should be a routine part of annual assessment in healthy children older than 3 years of age. BP may be measured with a mercury sphygmomanometer, aneroid sphygmomanometer, or oscillometric device. Abnormal oscillometric values should be confirmed with auscultation (Nerenberg et al., 2018).

Appendix C provides BP values that require further investigation. These values represent the lower limits for abnormal BP ranges, according to age and gender. Any BP readings equal to or greater than these values should be further evaluated (Nerenberg et al., 2018). Before a diagnosis is made, BP should be measured on at least three separate occasions. Routine BP screening is not recommended in children less than 3 years of age. Behavioural symptoms that may indicate hypertension in children include frequent headaches, dizziness, changes in vision, and chest or abdominal pain.

A careful medical and family history should be obtained to screen for other relatives with hypertension or other cardiovascular risk factors. In children with suspected hypertension, initial laboratory data include a urinalysis, renal function studies such as creatinine and blood urea nitrogen, a lipid profile, complete blood count, blood glucose, albumin-to-creatinine ratio (first-morning determination), and electrolytes. Depending on the severity of hypertension, additional testing may be indicated. Testing may include a retinal examination, renal ultrasonography to measure kidney size and Doppler flow to detect the possibility of a renal cause, and an ECG and echocardiogram to evaluate the presence of end-organ involvement such as left ventricular hypertrophy. Further testing for a secondary cause may be indicated on the basis of individual circumstances, especially in children with significant hypertension and normal initial screening test findings.

Therapeutic Management. Therapy for secondary hypertension involves diagnosis and treatment of the underlying cause. Children or adolescents with consistently elevated BP readings from no known cause or those with secondary hypertension not amenable to surgical correction may be treated with a combination of nonpharmacological and pharmacological interventions. Dietary practices and lifestyle changes are important in the control of hypertension for both children and adults. BMI readings should be determined for all children at routine health visits. Achieving a healthy body weight (BMI percentile less than 85%) is recommended for nonhypertensive children to prevent hypertension and for hypertensive children to reduce BP (Nerenberg et al., 2018). Nonpharmacological measures, such as weight control in overweight patients, increased exercise, limited salt intake (such as recommended in the Dietary Approaches to Stop Hypertension [DASH] diet), and avoidance of stress and smoking, carry no risk and should be instituted as first-line therapy except in severe cases in which pharmacological therapy may be indicated as well.

Medication therapy is instituted with caution in children with significant elevations of BP despite lifestyle modification. The treatment should begin with one medication, with additional medication added if control is not obtained. The classes of oral antihypertensive drugs used in children include the beta blockers, ACE inhibitors, calcium channel blockers, angiotensin-receptor blockers, and diuretics. The decision to initiate pharmacological treatment depends on many factors, including the presence of symptoms of hypertension, level of BP elevation, presence of end-organ damage, response to nonpharmacological therapy, and presence of comorbid conditions that confer increased cardiovascular risks (Nerenberg et al., 2018). ACE inhibitors and angiotensin-receptor blockers are not recommended as first-line agents in Black patients, and beta blockers are not recommended as first-line agents in children with asthma or diabetes (type 1 or type 2) or in high-performance athletes (Nerenberg et al., 2018). The goal is to achieve a normotensive state throughout the day without accompanying medication adverse effects.

Nursing Care. BP measurement should always be a part of routine assessment of children over 3 years old. To obtain an accurate reading, it is important to quiet the child or relax the adolescent while the

measurement is recorded, to avoid false readings caused by excitement. BP should be measured in the sitting position with the arm at the level of the heart. The chief cause of falsely elevated BP readings is the use of improperly fitting, narrow cuffs. Thus attention to correct measurement technique is essential (see Blood Pressure, Chapter 33).

Home BP measurements can facilitate surveillance in children with chronic hypertension and can document effectiveness of therapy. A family member can be instructed in how to take and record accurate BP measurements, thus decreasing the number of trips to a health care facility. The child's BP needs to have parameters above which the primary health care provider should be contacted.

The nurse plays an important role in assessing individual families and providing targeted information about nonpharmacological modes of intervention, such as diet, weight loss, smoking cessation, and exercise programs. A DASH diet—low in sodium, red meats, and sugar, and high in fruits, vegetables, whole grains, beans, nuts, low-fat dairy, fish, and poultry—is recommended for children and adolescents with elevated BP or hypertension. The child should be referred to a dietitian with expertise in working with children and adolescents with hypertension. Exercise regimens should be individualized but should emphasize the benefits of regular aerobic exercise (ideally 60 minutes per day of moderate aerobic exercise). School-age children and young adolescents generally prefer team sports rather than individual training, which they may view as a burden rather than an enjoyable activity. If peers and family members can be encouraged to participate in any of the management strategies, the child's adherence to treatment is likely to be greater.

Hypertensive adolescents should avoid using oral contraceptives because of their pressor effects. Other options need to be presented before this form of birth control is discontinued.

If medication therapy is prescribed, the nurse needs to provide information to the patient and family regarding the reasons for it, how the medication works, and possible adverse effects. General instructions for antihypertensive medications include the following:

- Rise slowly from a horizontal position and avoid sudden position changes.
- Take medication as prescribed.
- Maintain adequate hydration.
- Notify the health care provider if adverse effects occur, but do not discontinue medication.
- Avoid using alcohol and follow the DASH diet.

The need for follow-up should be stressed, especially because antihypertensive therapy can sometimes be safely discontinued if BP remains under control over time.

Kawasaki Disease

Kawasaki disease (KD) is an acute systemic vasculitis of unknown cause. The acute disease is self-limited; however, without treatment, approximately 20 to 25% of children develop coronary artery dilation or aneurysm formation. Approximately 75% of cases occur in children younger than the age of 5 years, with peak incidence in the toddler age group. Currently, the incidence per year of KD in Canada is estimated to be approximately 30 per 100 000 children under the age of 5. There is a higher incidence in boys than in girls. KD is now the most common cause of acquired heart disease in children in developed countries (McCrindle et al., 2017). Infants younger than 1 year of age are most seriously affected by KD and are at greatest risk for heart involvement.

The etiology of KD is unknown. The illness is not spread by person-to-person contact; however, several factors support an infectious etiological trigger, possible in a genetically susceptible host. It is often seen in geographic and seasonal outbreaks, with an increased incidence reported in the late winter and early spring (McCrindle et al., 2017).

Pathophysiology. The principal area of concern in KD is the cardiovascular system. During the initial stage of the illness, extensive inflammation of the arterioles, venules, and capillaries occurs. In addition, segmental damage to the medium-size muscular arteries, mainly the coronary arteries, can occur, causing the formation of coronary artery aneurysms in some children. When death occurs (in less than 1% of cases), it is usually the result of myocardial ischemia from coronary thrombosis or, over time, severe scar formation and stenosis in coronary aneurysms (McCrindle et al., 2017; Son & Newburger, 2020).

Clinical Manifestations. Because no specific diagnostic test exists for KD, the diagnosis is established on the basis of clinical findings and associated laboratory results (Box 47.12). These criteria should be used as guidelines. It is important to note that many children with KD do not fulfill standard diagnostic criteria and infants often have an incomplete presentation. Thus it is important to consider KD as a possible diagnosis in any infant or child with prolonged elevated temperature that is unresponsive to antibiotics and not attributable to another cause.

KD manifests in three phases: acute, subacute, and convalescent. The *acute phase* begins with the abrupt onset of high fever that is unresponsive to antibiotics and antipyretics. The remaining diagnostic symptoms evolve over the next week or so. Symptoms may come and go and do not need to be present simultaneously for diagnosis, although the fever is generally persistent throughout. During this stage, the child is typically very irritable. The *subacute phase* begins with resolution of the fever and lasts until all clinical signs of KD have disappeared. During this phase, coronary artery aneurysms may be noticed or previously dilated vessels may continue to increase in size. Irritability persists during this phase. In the *convalescent phase*, all the clinical signs of KD have resolved, but the laboratory values have not returned to normal. This phase is complete when all blood values are normal (6 to 8 weeks after onset). At the end of this stage the child has regained their usual temperament, energy, and appetite.

Cardiac involvement. Long-term complications of KD include the development of coronary artery aneurysms, potentially disrupting blood flow. Children with large (giant) aneurysms have the potential for myocardial infarction, which can result from thrombotic occlusion of a coronary aneurysm or late stenosis of the same vessel.

Affected coronary arteries dilate progressively, reaching their maximal diameter approximately 1 month from the onset of fever. Over time, as the damaged vessel tries to heal, stenosis of the aneurysm may develop and may lead to myocardial ischemia. Most of the morbidity and mortality occur in children affected with the largest

BOX 47.12 Diagnostic Criteria for Kawasaki Disease

The child must have had fever for more than 5 days along with four of five clinical criteria (diagnosis may be made on day 4 by an experienced clinician if child has all the clinical criteria):

1. Changes in the extremities: in the acute phase, edema and erythema of the palms and soles, and in the subacute phase, periungual desquamation (peeling) of the hands and feet
2. Bilateral conjunctival injection (inflammation) without exudation
3. Changes in the oral mucous membranes, such as erythema of the lips, oropharyngeal reddening, or "strawberry tongue" (large papillae are exposed)
4. Polymorphous rash
5. Cervical lymphadenopathy (one lymph node larger than 1.5 cm)

Note: Kawasaki disease can be diagnosed with fewer clinical criteria when coronary artery changes are noted.

aneurysms (giant aneurysms greater than 8 mm or *z*-score greater than 10). Symptoms of acute myocardial infarction in young children can be confusing and may include abdominal pain, vomiting, restlessness, inconsolable crying, pallor, and shock, as well as chest pain or pressure (noted more in older children). In the initial phase of the illness, children with KD may have signs or symptoms related to inflammation of the myocardium, including myocarditis, valvulitis, or arrhythmias.

Echocardiograms are accurate in assessing coronary artery dilation and are used to monitor coronary artery dimensions, myocardial function, and valvar function. A baseline echocardiogram should be obtained at the time of diagnosis and is used for comparison with future studies, which are obtained at 1 week after the initial diagnosis and again at 4 to 6 weeks later. Additional echocardiograms should be done (often as frequently as twice per week) in situations where a child has coronary artery dilation or obvious aneurysm formation or when response to treatment is incomplete.

Therapeutic Management. The current treatment of KD includes high-dose intravenous immunoglobulin (IVIG) along with salicylate therapy. IVIG has been demonstrated to be effective at reducing the incidence of coronary artery abnormalities when given within the first 10 days of the illness and ideally in the first 7 days of illness. A single large infusion of 2 g/kg over 10 to 12 hours is recommended. Retreatment with IVIG and/or other anti-inflammatory medications may be given to patients with an incomplete response to the initial IVIG (continued or recrudescent fever) or those with coronary artery dilation.

Aspirin is used in an anti-inflammatory dose (80 to 100 mg/kg/day in divided doses every 6 hours) to control fever and symptoms of inflammation. After fever has subsided, aspirin can be reduced to an antiplatelet dose (3 to 5 mg/kg/day). Low-dose aspirin is continued in patients without echocardiographic evidence of coronary abnormalities until the platelet count has returned to normal (6 to 8 weeks). If the child develops coronary abnormalities, salicylate therapy is continued indefinitely. Additional anticoagulation (e.g., clopidogrel [Plavix], enoxaparin [Lovenox], or warfarin) may be indicated in children who have medium-sized or giant coronary artery aneurysms.

Prognosis. Most children with KD recover fully after treatment. However, when cardiovascular complications occur, serious morbidity may result. The prognosis for patients is strongly related to the extent of coronary damage; patients with giant aneurysms are at highest risk for complications, and those with normal coronary dimensions have an excellent long-term prognosis.

Nursing Care. In the initial phase the nurse must monitor the child's cardiac status carefully. Intake and output and daily weight measurements are recorded. Although the child may be reluctant to eat and therefore may be partially dehydrated, fluids need to be administered with care because of the usual finding of myocarditis. The child should be assessed frequently for signs of HF, including decreased urinary output, gallop rhythm (an additional heart sound), tachycardia, and respiratory distress.

Administration of IVIG should follow the same guidelines as for any blood product, with frequent monitoring of vital signs. Patients must be watched for allergic reactions. Cardiac status must be monitored because of the large volume being administered to patients with myocarditis and diminished left ventricular function.

Most nursing care in the hospital focuses on symptomatic relief. To minimize skin discomfort, cool cloths, unscented lotions, and soft, loose clothing are helpful. During the acute phase, mouth care, including lubricating ointment to the lips, is important for mucosal inflammation. Clear liquids and soft foods can be offered.

Patient irritability is perhaps the most challenging situation. These children need a quiet environment that promotes adequate rest. Their parents need to be supported in their efforts to comfort an often inconsolable child. They may need time away from their child, and nurses can often provide respite care for the family. Parents need to understand that irritability is a hallmark of KD and that they need not feel guilty or embarrassed about their child's behaviour.

Discharge teaching. Parents need accurate information about the progression of KD, including the importance of follow-up monitoring and when they should contact their health care provider. Irritability is likely to persist for up to 2 months after the onset of symptoms. Periungual desquamation (peeling of the hands and feet) begins in the second and third weeks (Figure 47.11). Usually the fingertips peel first, followed by the feet. The peeling is painless, but the new skin may be tender. Arthritis is always temporary but may involve the larger weight-bearing joints and may persist for several weeks. Affected children are typically most stiff in the mornings, during cold weather, and after naps. Passive range-of-motion exercises in the bathtub are often helpful for increasing flexibility. Any live immunizations (e.g., measles-mumps-rubella, varicella) should be deferred for 11 months after the administration of IVIG because the body might not produce the appropriate amount of antibodies to provide lifelong immunity. The decision to give the varicella (chicken pox) vaccine while the child is receiving Aspirin therapy is made individually by the health care provider. Daily temperatures should be recorded in the first week or two after discharge, and the occurrence of fever should be communicated to the health care provider.

At discharge, the ultimate cardiac sequelae are generally not fully known yet because vessels may be evolving. Parents of children with large aneurysms should be educated about the unlikely but real possibility of myocardial infarction, as well as the signs and symptoms of cardiac ischemia in a child. CPR should be taught to parents of children with severe coronary artery aneurysms.

Long-Term Follow-Up. The frequency and type of follow-up for children with KD are based on the presence or absence of coronary damage. The long-term outlook for children without aneurysms is excellent. Increased incidence of early heart disease in this population has not been observed with over 40 years of follow-up. In order to keep the coronary arteries as healthy as possible, it is recommended that these children follow the national guidelines, which recommend screening for the presence of coronary risk factors as they grow older. They should have a cholesterol screen performed at routine physical

Fig. 47.11 Peeling of the fingertips. The appearance of fingertip or toe tip peeling is characteristic of the subacute phase of Kawasaki disease. (From Zitelli, B. J., McIntire, S., & Nowalk, A. [2018]. *Zitelli and Davis' atlas of pediatric physical diagnosis* [7th ed.]. Elsevier.).

examinations; routine BP monitoring; and education recommending a heart-healthy lifestyle, including exercise, a heart-healthy diet, and avoidance of smoking.

In patients with aneurysms, follow-up focuses on the prevention and early detection of coronary ischemia. Noninvasive modalities of coronary imaging (e.g., echocardiography, ECGs, and stress testing to assess for reversible ischemia) are used as much as possible with other forms of imaging such as cardiac computed tomography angiography, MRI, and cardiac catheterization, recommended on the basis of the individual situation.

In addition to regular monitoring, patients with coronary aneurysms may require long-term antiplatelet or anticoagulation and possibly beta-blocker therapy or other therapies, depending on the severity of coronary involvement.

Shock

Shock, or *circulatory failure*, is a complex clinical syndrome characterized by inadequate tissue perfusion to meet the metabolic demands of the body, resulting in cellular dysfunction and eventual organ failure. Although the causes are different, the physiological consequences are the same: hypotension, tissue hypoxia, and metabolic acidosis. Circulatory failure in children is a result of hypovolemia, altered peripheral vascular resistance, or pump failure. Types of shock are listed in Table 47.6.

Pathophysiology. A healthy child's circulatory system is able to transport oxygen and metabolic substrates to body tissues, which require a constant source for these essential needs. The cardiac output and distribution to the various body tissues can change rapidly in response to intrinsic (myocardial and intravascular) or extrinsic (neuronal) control mechanisms. In shock states these mechanisms are altered or challenged.

Reduced blood flow, as in hypovolemic shock, causes diminished venous return to the heart, low CVP, low cardiac output, and hypotension. Vasomotor centres in the medulla are signalled, causing a compensatory increase in the force and rate of cardiac contraction and constriction of arterioles and veins, thereby increasing peripheral vascular resistance. Simultaneously, the lowered blood volume leads to the release of large amounts of catecholamines, antidiuretic hormone, adrenocorticosteroids, and aldosterone in an effort to conserve body fluids. This causes reduced blood flow to the skin, kidneys, muscles, and viscera to shunt the available blood to the brain and heart. Consequently, the skin feels cold and clammy, there is poor capillary filling, and the glomerular filtration rate and urinary output are significantly reduced.

As a result of impaired perfusion, oxygen is depleted in the tissue cells, causing them to revert to anaerobic metabolism, producing lactic acidosis. The acidosis places an extra burden on the lungs as they attempt to compensate for the metabolic acidosis by increasing respiratory rate to remove excess carbon dioxide. Prolonged vasoconstriction results in fatigue and atony of the peripheral arterioles, which leads to vessel dilation. Venules, less sensitive to vasodilator substances, remain constricted for a time, causing massive pooling in the capillary and venular beds, which further depletes blood volume.

Complications of shock create further hazards. Central nervous system hypoperfusion may eventually lead to cerebral edema, cortical infarction, or intraventricular hemorrhage. Renal hypoperfusion causes renal ischemia with possible tubular or glomerular necrosis and renal vein thrombosis. Reduced blood flow to the lungs can interfere with surfactant secretion and result in acute respiratory distress syndrome (ARDS), characterized by sudden pulmonary congestion and atelectasis with formation of a hyaline membrane. Gastrointestinal tract bleeding and perforation are always a possibility after splanchnic ischemia and necrosis of intestinal mucosa. Metabolic complications of shock may include hypoglycemia, hypocalcemia, and other electrolyte disturbances.

TABLE 47.6 Types of Shock

Characteristics	Most Frequent Causes
Hypovolemic	
Reduction in size of vascular compartment Falling blood pressure Poor capillary filling Low central venous pressure	Blood loss (hemorrhagic shock)—Trauma, gastrointestinal bleeding, intracranial hemorrhage Plasma loss—Increased capillary permeability associated with sepsis and acidosis, hypoproteinemia, burns, peritonitis Extracellular fluid loss—Vomiting, diarrhea, glycosuric diuresis, sunstroke
Distributive	
Reduction in peripheral vascular resistance Profound inadequacies in tissue perfusion Increased venous capacity and pooling Acute reduction in return blood flow to the heart Diminished cardiac output	Anaphylaxis (anaphylactic shock)—Extreme allergy or hypersensitivity to a foreign substance Sepsis (septic shock, bacteremic shock, endotoxic shock)—Overwhelming sepsis and circulating bacterial toxins Loss of neuronal control (neurogenic shock)—Interruption of neuronal transmission (spinal cord injury) Myocardial depression and peripheral dilation—Exposure to anaesthesia or ingestion of barbiturates, tranquilizers, opioids, antihypertensive agents, or ganglionic blocking agents
Cardiogenic	
Decreased cardiac output	After surgery for congenital heart disease Primary pump failure—Myocarditis, myocardial trauma, biochemical derangements, heart failure Dysrhythmias—Supraventricular tachycardia, atrioventricular block, and ventricular dysrhythmias; secondary to myocarditis or biochemical abnormalities (occasionally)

Diagnostic Evaluation. The etiology of shock can be discerned from the history and physical examination. The severity of the shock is determined by measurements of vital signs, including CVP and capillary filling (Box 47.13). Shock can be regarded as a form of compensation for circulatory failure. Because of its progressive nature, it can be divided into the following three stages or phases:

- **Compensated shock**—Vital organ function is maintained by intrinsic compensatory mechanisms; blood flow is usually normal or increased but generally uneven or maldistributed in the microcirculation.
- **Decompensated shock**—Efficiency of the cardiovascular system gradually diminishes until perfusion in the microcirculation becomes marginal despite compensatory adjustments. The outcomes of circulatory failure that progress beyond the limits of compensation are tissue hypoxia, metabolic acidosis, and eventual dysfunction of all organ systems.

BOX 47.13 Clinical Manifestations of Shock

Compensated
Apprehensiveness
Irritability
Unexplained tachycardia
Normal blood pressure
Narrowing pulse pressure
Thirst
Pallor
Diminished urinary output
Reduced perfusion of extremities

Decompensated
Confusion and somnolence
Tachypnea
Moderate metabolic acidosis
Oliguria
Cool, pale extremities
Decreased skin turgor
Poor capillary filling

Irreversible
Thready, weak pulse
Hypotension
Periodic breathing or apnea
Anuria
Stupor or coma

- **Irreversible, or terminal, shock**—Damage to vital organs, such as the heart or brain, is of such magnitude that the entire organism will be disrupted regardless of therapeutic intervention. Death occurs even if cardiovascular measurements return to normal levels with therapy.

At all stages the principal differentiating signs are observed in the (1) degree of tachycardia and perfusion to extremities, (2) level of consciousness, and (3) BP. Additional signs or modifications of these more universal signs may be present, depending on the type and cause of the shock. Initially the child's ability to compensate is effective; thus early signs are subtle. As the shock state advances, signs are more obvious and indicate early decompensation.

Additional signs may be present, depending on the type and cause of the shock. In early septic shock there are chills, fever, and vasodilation, with increased cardiac output that results in warm, flushed skin (hyperdynamic, or "hot," shock). A later and ominous development is disseminated intravascular coagulation (DIC) (see Chapter 48), the major hematological complication of septic shock. Anaphylactic shock is frequently accompanied by urticaria and angioneurotic edema, which is life-threatening when it involves the respiratory passages (see Anaphylaxis later in this chapter).

Laboratory tests that assist in assessment are blood gas measurements, pH, and sometimes liver function tests. Coagulation tests are evaluated when there is evidence of bleeding, such as oozing from a venipuncture site, bleeding from any orifice, or petechiae. Cultures of blood and other sites are indicated when there is a high suspicion of sepsis. Renal function tests are performed when impaired renal function is evident.

Therapeutic Management. Treatment of shock consists of three major interventions: (1) ventilation, (2) fluid administration, and (3) improvement of the pumping action of the heart (vasopressor support). The first priority is to establish an airway and administer oxygen. After the airway is ensured, circulatory stabilization is the major concern. Establishment of adequate IV access, ideally with multilumen central lines, is essential to deliver fluids and medications.

Ventilatory support. The lung is the organ most sensitive to shock. Decreased distribution or redistribution of blood flow to respiratory muscles plus the increased work of breathing can rapidly lead to respiratory failure. Critically ill patients are unable to maintain an adequate airway. To place the lung at rest and improve ventilation, tracheal intubation is initiated early with positive-pressure ventilation. Supplemental oxygen is always given as soon as possible. Blood gases and pH are monitored frequently.

Increased extravascular lung water caused by edema contributes to the development of respiratory complications. Therapy is directed toward maintaining normal arterial blood gas measurements, normal acid–base balance, and circulation. Efforts are made to remove fluid and prevent its accumulation with the use of diuretics.

Cardiovascular support. In most cases rapid restoration of blood volume is all that is needed for resuscitation of the child in shock. An isotonic crystalloid solution (normal saline or Ringer's lactate) is the fluid of choice; colloids such as albumin are also used. Successful resuscitation is reflected by an increase in BP and a reduction in heart rate; increased cardiac output results in improved capillary circulation and skin colour. CVP measurements of right atrial pressure help guide fluid therapy, and urinary output measurement is an important indicator of adequacy of circulation. Correction of acidosis, hypoxemia, hypoglycemia, hypothermia, and any metabolic derangements is mandatory.

Temporary pharmacological support may be required to enhance myocardial contractility, reverse metabolic or respiratory acidosis, maintain arterial pressure, or do all of these. The principal agents used to improve cardiac output and circulation are catecholamines, such as dopamine or epinephrine (Adrenalin). Vasodilators that are sometimes used include nitroprusside or milrinone.

Nursing Care. The child who is in shock requires intensive observation and care in a CCU. The *initial action is to ensure adequate tissue oxygenation*. The nurse should be prepared to administer oxygen by the appropriate route and assist with any intubation and ventilatory procedures indicated. Other procedures and activities that require immediate attention are establishing an IV line, weighing the child, obtaining baseline vital signs, placing an in-dwelling catheter, obtaining blood gases and other measurements, and administering medications as indicated. The child is best positioned flat with the legs elevated.

! NURSING ALERT

Early clinical signs of shock include apprehension, irritability, normal BP, narrowing pulse pressure (difference between diastolic and systolic BP), thirst, pallor, diminished urinary output, unexplained mild tachycardia, and decreased perfusion of the hands and feet.

The nurse's responsibilities are to monitor the IV infusion, intake and output, vital signs (including CVP), and general systems assessments on a routine basis. IV medications are titrated according to patient responses, and vital signs are taken every 15 minutes during the critical periods and thereafter as needed. Urinary output

is measured hourly; blood gases, hematocrit, pH, and electrolytes are monitored frequently to assess the child's status and the efficacy of therapy. An apnea and cardiac monitor is attached and monitored continuously. In the initial stages of acute shock, more than one nurse is often needed to manage all the necessary activities that must be carried out simultaneously (see Emergency box: Shock).

Throughout the intense activity, support for the family must not be overlooked. A health care provider should contact family members at frequent intervals to inform them about what is being done and whether there is any progress. Ideally, someone should remain with the parents to serve as a liaison between them and the critical care team. However, this is not always feasible in such a critical situation. As soon as possible, the family should be allowed to see the child. A member of the clergy or a social worker may be called to help provide comfort and support.

EMERGENCY

Shock

Ventilation

Establish airway; be prepared for intubation.
Administer oxygen, usually 100% by mask.

Fluid Administration

Obtain vascular access (preferably intravenous [IV]; intraosseous in emergency).
Restore fluid volume as ordered.

Cardiovascular Support

Administer vasopressors, especially IV epinephrine (dose: 0.01 mg/kg = 0.1 mL/kg of 1:10 000 solution).
This may be repeated every 3 to 5 minutes for patients in cardiac arrest.

General Support

Provide continuous electrocardiographic monitoring.
Monitor pulse oximetry.
Keep child flat with legs raised above level of heart.
Keep child warm and calm.

In Addition

Septic shock—Administer broad-spectrum antibiotics intravenously.
Anaphylaxis—Remove allergen if possible; provide intramuscular epinephrine and corticosteroids as ordered.

Anaphylaxis

Anaphylaxis is the acute clinical syndrome resulting from the interaction of an allergen and a patient who is hypersensitive to that allergen. When the **antigen** enters the circulatory system, a generalized reaction rapidly takes place. Vasoactive amines (principally histamine or a histamine-like substance) are released and cause vasodilation, bronchoconstriction, and increased capillary permeability.

Severe reactions are immediate in onset, are often life-threatening, and frequently involve multiple systems, primarily the cardiovascular, respiratory, gastrointestinal, and integumentary systems. Exposure to the antigen can be by ingestion, inhalation, skin contact, or injection. Examples of common allergens associated with anaphylaxis include medications (e.g., antibiotics, chemotherapeutic agents, radiological contrast media), latex, foods, venom from bees or snakes, and biological agents (antisera, enzymes, hormones, blood products).

NURSING ALERT

Penicillin allergy is associated with immediate (within an hour of administration) or accelerated (1 to 72 hours after administration) onset of skin eruption, especially an urticarial rash, or more serious symptoms such as laryngeal edema or anaphylactic shock.

Clinical Manifestations. The onset of clinical symptoms usually occurs within seconds or minutes of exposure to the antigen, and the rapidity of the reaction is directly related to its intensity: the earlier the onset, the more severe the reaction. The reaction may be preceded by symptoms of uneasiness, restlessness, irritability, severe anxiety, headache, dizziness, paresthesia, and disorientation. The patient may lose consciousness. Cutaneous signs of flushing and urticaria are common early signs, followed by angioedema, most notable in the eyelids, lips, tongue, hands, feet, and genitalia.

Bronchiolar constriction may follow, causing narrowing of the airway; pulmonary edema and hemorrhage also may occur. Laryngeal edema with severe acute upper airway obstruction may be life-threatening and requires rapid intervention. Shock occurs as a result of mediator-induced vasodilation, which causes capillary permeability and loss of intravascular fluid into the interstitial space. Sudden hypotension and impaired cardiac output with poor perfusion are seen.

Therapeutic Management. A successful outcome of anaphylactic reactions depends on rapid recognition of the reaction and institution of treatment. The goals of treatment are to provide ventilation, restore adequate circulation, and prevent further exposure by identifying and removing the cause when possible.

A mild reaction with no evidence of respiratory distress or cardiovascular compromise can be managed with subcutaneous administration of antihistamines, such as diphenhydramine (Benadryl) and epinephrine.

Moderate or severe distress presents a potentially life-threatening emergency. Establishing an airway is the first concern, as with all shock states. Epinephrine is given subcutaneously or intravenously as an antihistamine and to support the cardiovascular system and increase BP. Other routes for giving epinephrine are intramuscular and via the airway, either nebulized or injected through an endotracheal tube. In severe anaphylaxis, epinephrine by any route is better than none. Fluids are given to restore blood volume. Additional vasopressors may be given to improve cardiac output.

Prevention of a reaction is preferable. Preventing exposure is more easily accomplished in children known to be at risk, including those with (1) a history of previous allergic reaction to a specific antigen; (2) a history of atopy; (3) a history of severe reactions in immediate family members; and (4) a reaction to a skin test, although skin tests are not available for all allergens. Desensitization may be recommended in certain cases.

Nursing Care. When an anaphylactic reaction is suspected, both immediate intervention and preparation for medical therapy are nursing responsibilities. Ventilation is ensured by placing the child in a head-elevated position, unless contraindicated by hypotension, to facilitate breathing and administer oxygen. If the child is not breathing, CPR is initiated and emergency medical services are summoned.

If the cause can be determined, measures need to be implemented to slow the spread of the offending substance. An IV infusion should be established immediately. Emergency medications should be given intravenously whenever possible; however, epinephrine may be given subcutaneously (see Emergency box: Shock). Vital signs and urinary

output should be monitored frequently. Medications need to be administered as prescribed, with regular assessment to monitor effectiveness and detect signs of adverse effects of medication and fluid overload.

To prevent an anaphylactic reaction, parents should always be asked about possible allergic responses to foods, latex, medications, and environmental conditions. These need to be displayed prominently on the patient's chart. The specific allergen should be noted, as well as the type and severity of the reaction. Parents are excellent historians, especially when the child has displayed a pronounced reaction to a substance. Medications, including related medications (e.g., penicillin, nafcillin), and other items such as latex that have produced a reaction previously should never be used in or touch the child. If the child is allergic to insect venom, the family should be instructed to purchase an emergency kit to be kept with them at all times. If the child is old enough, both the family and the child need to be taught how to use the equipment. The patient should carry medical identification at all times.

Septic Shock

Sepsis and septic shock are caused by an infectious organism. Normally an infection triggers an inflammatory response in a local area, which results in vasodilation, increased capillary permeability, and eventually elimination of the infectious agent. The widespread activation and systemic release of inflammatory mediators is called the *systemic inflammatory response syndrome (SIRS)*. Box 47.14 provides the exact definitions for SIRS, infection, sepsis, and severe sepsis. SIRS can occur in response to both infectious and noninfectious (e.g., trauma, burns) causes. When caused by infection, it is called *sepsis*. *Septic shock* is defined as sepsis with organ dysfunction and hypotension.

Most of the physiological effects of shock occur because the exaggerated immune response triggers more than 30 different mediators that result in diffuse vasodilation, increased capillary permeability, and maldistribution of blood flow. This impairs oxygen and nutrient delivery to the cells, resulting in cellular dysfunction. If the process continues, multiple organ dysfunction occurs and may result in death. Table 47.7 includes the age-specific vital signs and laboratory values reflective of septic shock in children.

In septic shock, mortality rates are as low as 3% in previously healthy children and 6 to 9% in children with chronic illness (compared with 25 to 30% in adults). With early recognition and therapy, the mortality rate for pediatric shock continues to improve, but shock and

BOX 47.14 Definitions of Systemic Inflammatory Response Syndrome, Infection, Sepsis, and Severe Sepsis

Systemic inflammatory response syndrome (SIRS)—The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

1. Core temperature of more than 38.5°C (101.3°F) or less than 36°C (96.8°F)
2. Tachycardia, defined as a mean heart rate more than 2 standard deviations above normal for age in the absence of external stimulus, chronic medication use, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hour period; or, for children less than 1 year old: bradycardia, defined as a mean heart rate less than the tenth percentile for age in the absence of external vagal stimulus, beta blockers, or congenital heart disease; or otherwise unexplained persistent depression over a 30-minute period
3. Mean respiratory rate more than 2 standard deviations above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anaesthesia
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or more than 10% immature neutrophils

Infection—A suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen; or a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans)

Sepsis—SIRS in the presence or as a result of suspected or proven infection

Severe sepsis—Sepsis plus cardiovascular organ dysfunction or acute respiratory distress syndrome (ARDS); or two or more other organ dysfunctions

Septic shock—Sepsis plus cardiovascular organ dysfunction as defined above

Multiple-organ dysfunction syndrome (MODS)—Presence of altered organ function such that homeostasis cannot be maintained without medical intervention

From Turner, D.A. & Chiefetz, I. (2020). Shock. In R. M. Kliegman, J. St. Geme, N. J. Blum, et al. (Eds.), *Nelson textbook of pediatrics* (21st ed.). Elsevier.

TABLE 47.7 Age-Specific Vital Signs and Laboratory Variables in Septic Shock*

Age Group	HEART RATE (BEATS/MIN)		Respiratory Rate (breaths/min)	Leukocyte Count (leukocytes × 10^9/L)	Systolic Blood Pressure (mm Hg)
	Tachycardia	Bradycardia			
0 days–1 wk	>180	<100	>60	>34	<65
1 wk–1 mo	>180	<100	>40	>19.5 or <5	<75
1 mo–1 yr	>180	<90	>34	>17.5 or <5	<100
2–5 yr	>140	N/A	>22	>15.5 or <6	<94
6–12 yr	>130	N/A	>8	>13.50 or <4.5	<105
13–<18 yr	>110	N/A	>4	>11 or <4.5	<117

N/A, Not applicable.

*Lower values for heart rate, leukocyte count, and systolic blood pressure are for fifth percentile, and upper values for heart rate, respiratory rate, or leukocyte count are for ninety-fifth percentile.

multiple-organ dysfunction syndrome (MODS) remain one of the leading causes of death in infants and children. The risk of death involves a complex interaction of factors, including the underlying etiology, presence of chronic illness, host immune response, and timing of recognition and therapy (Turner & Cheifetz, 2020).

Three stages have been identified in septic shock. In early septic shock the patient has chills, fever, and vasodilation with increased cardiac output, which results in warm, flushed skin that reflects vascular tone abnormalities and hyperdynamic, warm, or hyperdynamic-compensated responses. BP and urinary output are normal. The patient has the best chance for survival in this stage. The second stage—the normodynamic, cool, or hyperdynamic-decompensated stage—lasts only a few hours. The skin is cool, but pulses and BP are still normal. Urinary output diminishes, and the mental state becomes depressed. With advancing disease, certain signs of circulatory decompensation that deteriorate to signs of circulatory collapse are indistinguishable from late shock of any cause. In the hypodynamic, or cold, stage of shock, cardiovascular function progressively deteriorates, even with aggressive therapy. The patient has hypothermia, cold extremities, weak pulses, hypotension, and oliguria or anuria. Patients are severely lethargic or comatose. Multiorgan failure is common. This is the most dangerous stage of shock.

Management of septic shock involves measures to provide hemodynamic stability and adequate oxygenation to the tissues and the use of antimicrobials to treat the infectious organism. As with other forms of shock, hemodynamic stability is achieved with fluid volume resuscitation and inotropic agents as needed. Providing adequate oxygenation often requires intubation and mechanical ventilation, supplemental oxygen, sedation, and paralysis to decrease the work of breathing. Septic shock involves activation of complement proteins that promote clumping of the granulocytes in the lung. The granulocytes can release chemicals that can cause direct lung injury to the pulmonary capillary endothelium. This causes a fluid leak into the alveoli, which causes stiff, noncompliant lungs. DIC and MODS may also occur and require prompt assessment and management. Newer therapies are being developed to modify the host immune response by attempting to block various mediators, thereby interrupting the inflammatory cascade.

Early identification of the symptoms of septic shock is critical to patient survival. A high index of suspicion is required in all critically ill patients, who are at greater risk for sepsis because of multiple invasive lines and devices, poor nutrition, and impaired immune function. Subtle alterations in tissue perfusion and unexplained tachypnea and tachycardia often are early warning signs. Identification of the infectious agent and prompt treatment are also critical to patient survival. Broad-spectrum antibiotics should be given, and the site of infection should be removed if possible (e.g., drain abscesses, remove in-dwelling lines). Patients should be managed in a CCU in which continuous monitoring and sophisticated cardiac and respiratory support are available. Interprofessional collaboration is essential in managing these critically ill patients.

Toxic Shock Syndrome

Toxic shock syndrome (TSS) is a relatively rare condition caused by the toxins produced by the *Staphylococcus* or group A *streptococcal* bacteria. First described in 1978, TSS can cause acute multisystem organ failure and a clinical picture that resembles septic shock. TSS became well known in 1980 because of the striking relationship between the disease and tampon use. An aggressive health education campaign about the dangers of prolonged tampon use and a change in the chemical composition of tampons have markedly reduced the incidence of TSS in menstruating persons. Cases of TSS have also been reported in men, older women, and children.

BOX 47.15 Criteria for Diagnosis of Toxic Shock Syndrome

- Streptococcal toxic strep syndrome characterized by hypotension (systolic blood pressure of 90 mmHg or less in adults, or less than the fifth percentile for age in children) AND at least two of the following signs:
- Renal impairment (creatinine level of at least 2 × the upper limit normal for age or 2 × the patient's baseline)
- Coagulopathy (platelet count of 100 × 10^9/L or lower, or disseminated intravascular coagulation)
- Liver function abnormality (levels of aspartate aminotransferase, alanine aminotransferase, or total bilirubin greater than 2 × the upper limit normal for age)
- Acute respiratory distress syndrome
- Generalized erythematous macular rash that may later desquamate

Adapted from Moore, D. L., Upton, D. A., Mailman, T., et al. (2019). Invasive group A streptococcal disease: Management and chemoprophylaxis. *Paediatrics & Child Health, 24*(2), 128.

Diagnostic Evaluation. TSS has a wide spectrum of clinical presentation, from patients with evolving TSS who do not yet meet full criteria, to severe life-threatening disease with multisystem involvement. Patients with suspected or evolving TSS should receive urgent empiric therapy. A history of tampon use contributes to the diagnosis. Additional laboratory tests include cultures from blood, the vagina, the cervix, and any discharge. Streptococcal TSS is clinically indistinguishable from staphylococcal TSS. Other laboratory tests are those that facilitate the management of shock. The criteria used to diagnose the condition are listed in Box 47.15.

Therapeutic Management. The management of patients with TSS is the same as management of shock of any cause and may range from supportive care in mild cases to hospitalization and critical care in severe cases. Appropriate parenteral antibiotics are usually administered after cultures are obtained.

Nursing Care Management. Because the disease is relatively rare, the major efforts of nursing are directed toward prevention. The association between the disease and the use of tampons provides some direction for education. Avoiding the use of tampons offers the most certain preventive measure, although this approach is probably unacceptable to most adolescents, who prefer the freedom, comfort, and inconspicuousness that tampons afford.

Adolescents who use tampons can be taught general hygiene measures, such as good hand washing and careful insertion to avoid vaginal abrasion. It is wise to modify their use, alternating with sanitary napkins—perhaps using the napkins during the night, when at home during the day, and when flow is slight. Young teens are advised not to use super-absorbent tampons and not to leave any tampon in the body for more than 4 to 6 hours.

KEY POINTS

- Congenital heart disease (CHD) is the most common form of cardiac disease in children.
- Major categories to investigate in the cardiac history are poor weight gain, poor feeding habits, and fatigue during feeding; frequent respiratory tract infections and difficulties; and evidence of exercise intolerance.
- The most common procedures used in assessing cardiac function are X-rays, ECG, echocardiography, and cardiac catheterization.

- Cardiac catheterization procedures can be divided into three groups: (1) diagnostic procedures, including angiography, that measure pressures and saturations to establish cardiac diagnosis; (2) interventional procedures, in which catheters or balloon devices are used to correct cardiac defects; and (3) electrophysiology studies, in which catheters with electrodes are used to evaluate dysrhythmias.
- Several prenatal factors may predispose children to CHD: exposure to rubella and other infections during pregnancy, alcohol consumption by the pregnant parent, type 1 diabetes in the pregnant parent, and exposure to some environmental toxins.
- Congenital heart defects can be divided into four main groups, as determined by hemodynamic patterns: (1) defects that result in increased pulmonary blood flow, (2) obstructive defects, (3) defects that result in decreased pulmonary blood flow, and (4) mixed defects.
- Clinical consequences of congenital heart defects include HF and hypoxemia. A child can have both hypoxemia and HF, although usually they occur independently.
- Clinical manifestations of HF are impaired myocardial function (tachycardia, cardiomegaly), pulmonary congestion (dyspnea, tachypnea, orthopnea, cyanosis), and systemic congestion (hepatosplenomegaly, edema, distended veins).
- Nursing measures in the care of a child with HF are to assist in improving cardiac function, decrease cardiac demands, reduce respiratory distress, maintain nutritional status, promote fluid loss, and provide family support.
- Clinical manifestations of hypoxemia are cyanosis, polycythemia, clubbing, and delayed growth and development. The child is at increased risk for hypercyanotic spells, CVAs, brain abscess, and infective endocarditis.
- Caring for the child with CHD and the family requires helping them to adjust to the disorder and cope with the effects of the anomaly, as well as fostering growth and promoting family relationships.
- Preoperative care of the child with a congenital heart defect involves introducing the child and family to the hospital and preparing them for preoperative and postoperative procedures.
- Providing postoperative care includes observing vital signs and arterial and venous pressures, maintaining respiratory status, allowing maximum rest, providing comfort, monitoring fluids, planning for progressive activities, giving emotional support, observing for complications of surgery, and planning for discharge and home care.
- Acquired cardiovascular disorders include infective endocarditis, acute rheumatic fever, hyperlipidemia (hypercholesterolemia), and cardiac dysrhythmias.
- Prevention of infectious endocarditis in certain children with CHD involves administration of prophylactic antibiotics when specific procedures are performed.
- Acute rheumatic fever is a systemic inflammatory disease that can damage the cardiac valves and is associated with previous group A *streptococcus* infection.
- Children with known risk factors for hyperlipidemia are screened and treated as needed. The influence of childhood cholesterol levels on later development of coronary artery disease is under investigation.
- Common dysrhythmias in children include slow (bradycardias, heart block) and fast (sinus tachycardia, SVT) rhythms.
- Heart transplantation is a treatment for infants and children with cardiomyopathy and complex congenital heart defects involving ventricular dysfunction, such as hypoplastic left heart syndrome.
- Education of the child with hypertension and the family focuses on lifestyle modifications including weight reduction, nutrition counselling, and age-appropriate exercise, as well as medication therapy as necessary.
- Kawasaki disease is an extensive inflammation of small vessels and capillaries that may progress to involve the coronary arteries, causing aneurysm formation. The administration of immunoglobulin is an important aspect of treatment.
- Emergency treatment for shock includes ensuring ventilation; administering vasopressors, fluids, blood, and antibiotics as needed; and providing supportive measures, such as correct positioning, warmth, and psychological reassurance to the child and family.
- Persons at risk for anaphylaxis may be identified by a history of previous allergic reaction, history of atopy, history of severe reactions in family, and positive skin test to the allergen.

Hematological or Immunological Conditions

Katherine Bertoni

Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Distinguish between the various categories of anemia.
2. Describe the prevention of iron-deficiency anemia and the care of the child with iron-deficiency anemia.
3. Compare sickle cell anemia and beta thalassemia major in relation to pathophysiology and nursing care.
4. Describe the mechanisms of inheritance and nursing care of the child with hemophilia.
5. Distinguish between the pathophysiology and nursing care of immune thrombocytopenia (ITP) and disseminated intravascular coagulation (DIC).
6. Relate the pathophysiology and clinical manifestations of aplastic anemia, leukemia, and lymphoma.
7. Demonstrate an understanding of the rationale of therapies for neoplastic disease.
8. Outline a plan of care for the child with neoplastic disease and the family.
9. Contrast the pathophysiology and management of the immunodeficiency disorders.
10. Describe nursing precautions and responsibilities required during blood transfusion.
11. Describe the types of hematopoietic stem cell transplants.

HEMATOLOGICAL AND IMMUNOLOGICAL DISORDERS

Several tests can be performed to assess hematological function, including additional procedures to identify the cause of the dysfunction. The following discussion is limited to a description of the complete blood cell count (CBC). The CBC is the most common and one of the more valuable tests used. Other procedures, such as those related to iron, coagulation, and immune status, are discussed throughout the chapter as appropriate. The nurse should be familiar with the significance of the findings from the CBC (Table 48.1) and be aware of normal values for all ages, which are listed in Appendix B.

As with any disorder, the health history and physical examination are essential to identify hematological dysfunction, and the nurse is often the first person to suspect an issue based on information from these sources. Comments by the parent(s) regarding the child's lack of energy, food diary of poor sources of iron, frequent infections, and bleeding that is difficult to control offer clues to the more common disorders affecting the blood. A careful physical appraisal, especially of the skin, can reveal findings (e.g., pallor, petechiae, bruising) that may indicate minor or serious hematological conditions. Nurses need to be aware of the clinical manifestations of blood diseases in order to assist in recognizing symptoms and establishing a diagnosis.

! NURSING ALERT

A common term used in describing an abnormal complete blood count (CBC) is *shift to the left,* which refers to the presence of immature neutrophils in the peripheral blood from hyperfunction of the bone marrow, as seen during a bacterial infection.

RED BLOOD CELL DISORDERS

Anemia

The term *anemia* describes a condition in which the number of red blood cells (RBCs) or the hemoglobin (Hgb or Hb) concentration is reduced below normal values for gender and age. This diminishes the oxygen-carrying capacity of the blood, causing a reduction in the oxygen available to the tissues. The anemias are the most common hematological disorder of infancy and childhood and are not diseases but an indication or manifestation of an underlying pathological process.

Classification. Anemias are classified in relation to (1) *etiology* or *physiology*, manifested by erythrocyte or Hgb depletion, and (2) *morphology*, the characteristic changes in RBC size, shape, or colour (Box 48.1). Although the morphological classification is more useful

TABLE 48.1 Tests Performed as Part of the Complete Blood Cell Count

Test (Average Value)	Description and Comments
RBC count (4.5 to 5.5 × 10^{12}/L)	Number of RBCs per 10^{12} cells/L of blood RBCs carry oxygen from the lungs to the rest of the body Indirectly estimates Hgb content of blood Reflects function of bone marrow
Hgb determination (11.5 to 15.5 g/L)	Amount of Hgb g/L of whole blood Total blood Hgb primarily dependent on number of circulating RBCs but also on amount of Hgb in each cell
Hct (0.35 to 0.45)	Percent volume of packed RBCs in whole blood Indirectly measures Hgb content
RBC indices	
MCV (77 to 95 fL)	Average or mean volume (size) of a single RBC
MCH (25 to 33 pg)	Average or mean quantity (weight) of Hgb in a single RBC MCV and MCH depend on accurate counts of RBCs, whereas MCHC does not; thus MCHC is often more reliable All indexes depend on average cell measurements and do not show individual RBC variations (anisocytosis)
MCHC (31 to 37 g/dL)	Average concentration of Hgb in a single RBC
RBC volume distribution width	Average size of RBCs Differentiates some types of anemia
Reticulocyte count (0.5 to 2% of total number of RBCs)	Percent reticulocytes in RBCs Index of production of mature RBCs by bone marrow • Decreased count indicates depressed bone marrow function. • Increased count indicates erythrogenesis in response to some stimulus. When reticulocyte count is extremely high, other forms of immature RBCs (normoblasts, even erythroblasts) may be present Indirectly estimates hypochromic anemia Usually elevated in patients with chronic hemolytic anemia
WBC count (5.0 to 10.0 × 10^9/L)	Number of WBCs × 10^9/L of blood • Increased with infection or inflammation, trauma, tissue necrosis, hemorrhage, or leukemia • Decreased with viral infection, hypersplenism, bone marrow, depression Total number of WBCs less important than differential count
Differential WBC count	Inspection and quantification of WBC types present in peripheral blood Values are expressed as percentages; to obtain absolute number of any type of WBC, multiply its respective percentage by total number of WBCs
Neutrophils (polys) (2.5 to 8.0 × 10^9/L)	Primary defence in bacterial infection; capable of phagocytizing and killing bacteria
Bands	Immature neutrophil Increased numbers in bacterial infection Also capable of phagocytosis and killing
Eosinophils (0.0 to 0.5 × 10^9/L)	Named for their staining characteristics with eosin dye Increased in allergic disorders, parasitic diseases, certain neoplasms, and other diseases
Basophils (0.02 to 0.05 × 10^9/L)	Named for their characteristic basophilic stippling Contain histamine, heparin, and serotonin; believed to cause increased blood flow to injured tissues while preventing excessive clotting. Can increase in cases of leukemia, during inflammatory processes, or viral infections
Lymphocytes (1 to 4 × 10^9/L)	Involved in development of antibody and delayed hypersensitivity
Monocytes (0.1 to 0.7 × 10^9/L)	Large phagocytic cells that are involved in early stage of inflammatory reaction
Absolute neutrophil count (ANC)	Percent neutrophils/bands × WBC count Indicates capability of body to handle bacterial infections
Platelet count (150 to 400 × 10^9/L)	Cellular fragments that are necessary for clotting to occur
Stained peripheral blood smear	Visual estimation of amount of Hgb in RBCs and overall size, shape, and structure of RBCs Various staining properties of RBC structures may be evidence of immature forms of erythrocytes Shows variation in size and shape of RBCs: microcytic, macrocytic, poikilocytic (variable shapes)

ANC, Absolute neutrophil count; *Hct,* hematocrit; *Hgb,* hemoglobin; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *WBC,* white blood cell.

in terms of laboratory evaluation of anemia, the etiological approach provides direction for planning nursing care. For example, anemia with reduced Hgb concentration may be caused by a dietary depletion of iron, and the principal intervention is replenishing iron stores. The classification of anemias is found in Figure 48.1.

Consequences of Anemia. The basic physiological defect caused by anemia is a decrease in the oxygen-carrying capacity of blood and consequently a reduction in the amount of oxygen available to the cells. When the anemia has developed slowly, the child usually adapts to the declining Hgb level.

BOX 48.1 Red Blood Cell Morphology

Size (Cell Size)
Variation in red blood cell (RBC) sizes (anisocytosis)
- Normocytes (normal cell size)
- Microcytes (smaller than normal cell size)
- Macrocytes (larger than normal cell size)

Shape (Cell Shape)
Variation in RBC shapes (poikilocytosis)
- Spherocytes (globular cells)
- Drepanocytes (sickle-shaped cells)
- Numerous other irregularly shaped cells

Colour (Cell Staining Characteristics)
Variation in hemoglobin concentration in the RBCs
- Normochromic (sufficient or normal amount of hemoglobin per RBC)
- Hypochromic (reduced amount of hemoglobin per RBC)
- Hyperchromic (increased amount of hemoglobin per RBC)

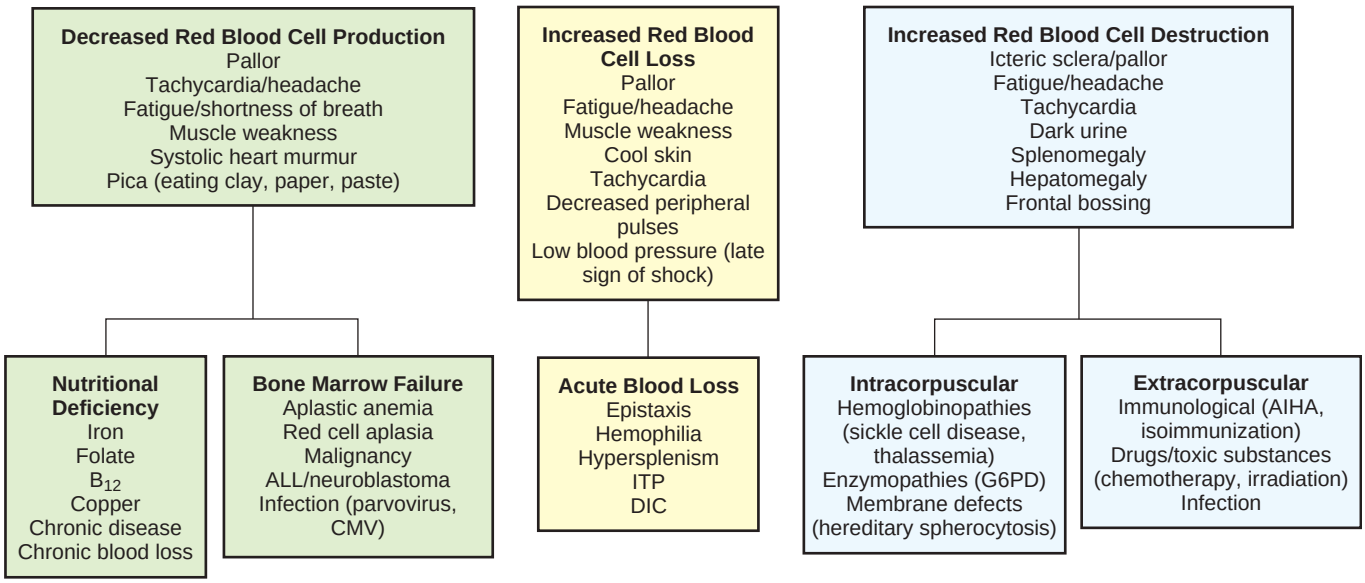

Fig. 48.1 Classifications of anemias. *AIHA*, Autoimmune hemolytic anemia; *ALL*, acute lymphoid leukemia; *CMV*, cytomegalovirus; *DIC*, disseminated intravascular coagulation; *G6PD*, glucose-6-phosphate dehydrogenase; *ITP*, immune thrombocytopenic purpura.

The effects of anemia on the circulatory system can be profound. Because the viscosity of blood depends almost entirely on the concentration of RBCs, the resulting hemodilution of severe anemia decreases peripheral resistance, causing greater quantities of blood to return to the heart. The increased circulation and turbulence within the heart may produce a murmur. Because the cardiac workload is greatly increased, especially during exercise, infection, or emotional stress, cardiac failure may ensue.

Children seem to have a remarkable ability to function well despite low levels of Hgb. *Cyanosis* (the result of the quantity of deoxygenated Hgb in arterial blood) is typically not evident. Growth restriction, resulting from decreased cellular metabolism and coexisting anorexia, is a common finding in chronic severe anemia and is frequently accompanied by delayed sexual maturation in the older child.

Diagnostic Evaluation. In general, anemia may be suspected on the basis of findings in the health history and physical examination, such as lack of energy, easy fatigability, and pallor; however, unless the anemia is severe, the first clue to the disorder may be alterations in the CBC, such as decreased RBCs and decreased Hgb and hematocrit (Hct) levels (Figure 48.2). Although anemia is sometimes defined as a Hgb level below 100 or 110 g/L, this arbitrary cutoff is inappropriate for all children, because Hgb levels normally vary with age and comorbid conditions (Table 48.1).

Other tests specific to a particular type of anemia are used to determine the underlying cause of anemia. These are discussed in relation to the particular disorder.

Therapeutic Management. The objective of medical management is to reverse the anemia by treating the underlying cause. In nutritional anemias, the specific deficiency is replaced. In blood loss from acute hemorrhage, RBC transfusion may be given. In patients with severe anemia, supportive medical care may include oxygen therapy, bed rest, and replacement of intravascular volume with intravenous (IV) fluids. In addition to these general measures, the nurse may implement more specific interventions, depending on the cause.

Nursing Care. The assessment of anemia includes the basic techniques that are applicable to any condition. The age of the infant or child provides some clues regarding the possible etiology of the anemia. For example, iron-deficiency anemia occurs more frequently in infants and children between 6 and 36 months of age and during the growth spurt of adolescence.

Ethnic background is also significant. For example, the anemias related to abnormal Hgb levels are found in Indigenous populations, Southeast Asians, and persons of African or Mediterranean descent. These same groups may be genetically predisposed to be deficient in the enzyme lactase after the period of infancy. Affected individuals

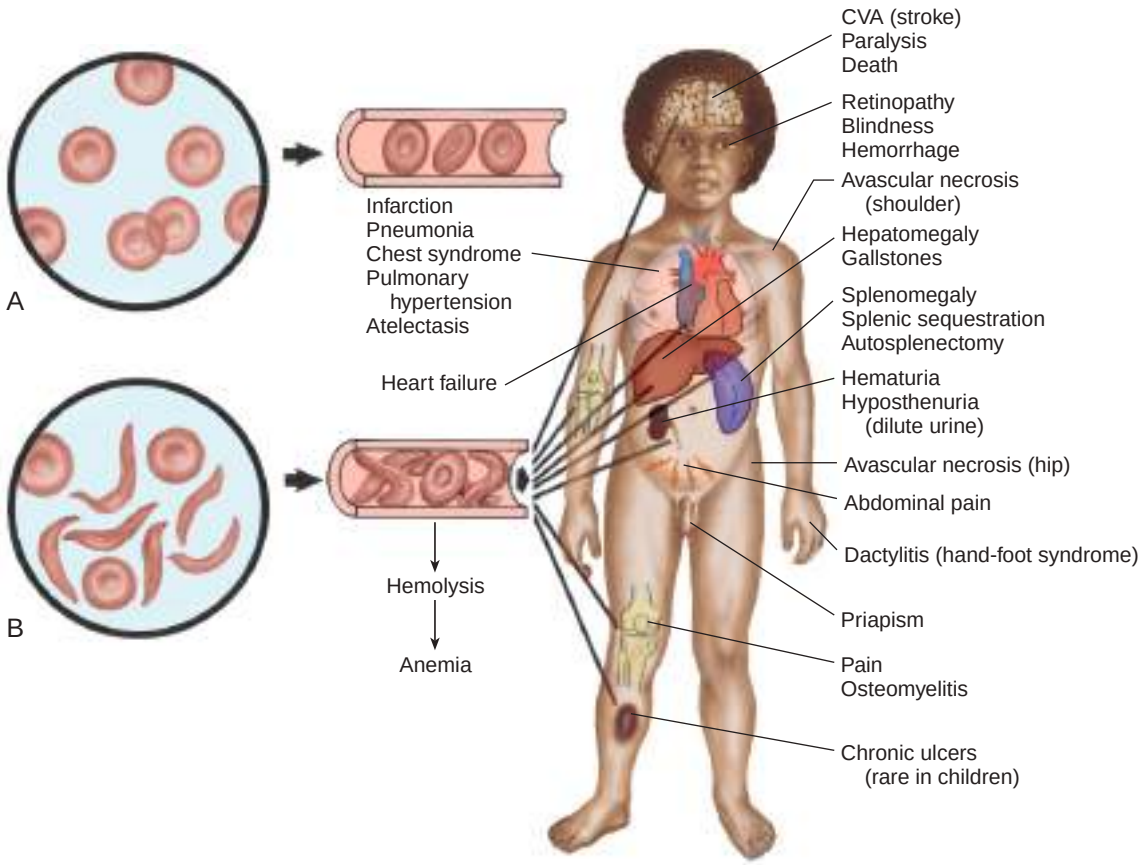

Fig. 48.2 Differences between effects on circulation of normal **(A)** and sickled **(B)** red blood cells with related complications. *CVA,* Cerebrovascular accident.

are unable to tolerate lactose in the diet, with consequent intestinal irritation and chronic blood loss.

Special emphasis should be placed on a careful history to elicit any information that might help identify the cause of the anemia. For example, a statement such as "My child drinks lots of milk" is a frequent finding in toddlers with iron-deficiency anemia. An episode of diarrhea may have precipitated temporary lactose intolerance in a young child.

Stool examination for occult (microscopic) blood (Hemoccult test) can identify chronic intestinal bleeding that results from a primary or secondary lactase deficiency. It is also important to understand the significance of various blood tests.

Preparing the child and family for laboratory tests. Usually several blood tests are ordered; because they are generally done sequentially rather than at one time, the child is subjected to multiple finger or heel punctures or venipunctures. Repeated punctures can be quite traumatic, especially to a young child. However, these invasive procedures need not be as painful with the appropriate preparation (see Blood Specimens, Chapter 44). For example, the topical application of a eutectic mix of lidocaine and prilocaine (EMLA) before needle punctures can significantly reduce pain (see Pain Management, Chapter 34). The nurse is responsible for preparing the child and family for the tests by doing the following:

- Explaining the significance of each test, particularly why the tests are not all done at one time
- Encouraging parents or another supportive person to be with the child during the procedure
- Allowing the child to play with the equipment on a doll or participate in the actual procedure (e.g., by holding the Band-Aid)

Older children may appreciate the opportunity to observe the blood cells under a microscope or in photographs. This experience is especially important if a serious blood disorder, such as leukemia, is suspected, because it serves as a foundation for explaining the pathophysiology of the disorder.

Bone marrow aspiration is not a routine hematological test but is essential for definitive diagnosis of certain anemias such as aplastic anemia.

! NURSING ALERT

The following are suggested explanations for teaching children about blood components:

Red blood cells (RBCs)—Carry the oxygen you breathe from your lungs to all parts of your body

White blood cells (WBCs)—Help keep germs from causing infection

Platelets—Small parts of cells that help make bleeding stop by forming a clot (scab) over the hurt area

Plasma—The liquid portion of blood, which has clotting factors that help make bleeding stop

Decreasing tissue oxygen needs. Because the basic pathological process in anemia is a decrease in oxygen-carrying capacity, an important nursing responsibility is to minimize tissue oxygen needs by continual assessment of the child's energy level. The child's level of tolerance for activities of daily living and play needs to be assessed and adjustments made to allow as much self-care as possible without undue exertion. During periods of rest, the nurse can take vital signs and observe behaviour to establish a baseline of nonexertion energy

expenditure. During periods of activity, the nurse should repeat these measurements and observations to compare them with resting values.

! NURSING ALERT

Signs of exertion include tachycardia, palpitations, tachypnea, dyspnea, hyperpnea, dizziness, lightheadedness, diaphoresis, and change in skin colour. The child looks fatigued (sagging, limp posture; slow, strained movements; inability to tolerate additional activity; difficulty sucking in infants).

Preventing complications. Children who are so severely anemic that they are hospitalized may require oxygen to prevent or reduce tissue hypoxia. Because these children are susceptible to infection, every effort should be made to prevent exposure to infectious agents. All the usual precautions need to be taken to prevent infection, such as practising thorough hand hygiene, selecting an appropriate room in a non-infectious area, restricting visitors or hospital personnel with active infection, and maintaining adequate nutrition. The nurse also needs to observe for signs of infection, particularly temperature elevation and leukocytosis. However, an elevated white blood cell (WBC) count sometimes occurs in anemia without the presence of systemic or local infection.

Iron-Deficiency Anemia

While the rate of iron-deficiency anemia in Canada is presumed to be quite low, the current prevalence in Canadian infants and young children is unknown (Unger et al., 2019/2021). Canadian Indigenous infants and children have a prevalence of iron-deficiency anemia that is 36% in infants 4 to 18 months old to 58% in infants 9 to 14 months old. This high prevalence is in part due to poverty, which can result in food insecurity. Diminishing access to traditional iron-rich foods and increasing access to low-iron "convenience" foods contribute to reduced iron intake and bioavailability (Unger et al., 2019/2021). Other risk factors include living with chronic illness, suboptimal intake of iron-rich foods, and prolonged bottle feeding (Unger et al., 2019/2021).

Low birth weight infants are especially at risk. Iron supplementation is recommended for low birth weight infants (less than 2.5 kg) who are predominantly breastfed (greater than 50% of intake). Infants with a birth weight of 2.0 kg to 2.5 kg, should receive an iron supplement of 1–2 mg/kg/day for the first 6 months of age. Infants with a birth weight less than 2.0 kg, should receive an iron supplement of 2–3 mg/kg/day for the first year of age. Elemental iron supplementation is not needed when the formula used is high in iron.

Preterm infants are at risk because of their reduced fetal iron supply. Noninvasive monitoring for tests such as carbon dioxide and bilirubin and clustering blood samples will minimize the amount of blood being taken in preterm infants (Lemyre et al., 2015/2021).

Adolescents are at risk for iron-deficiency anemia because of their rapid growth rate combined with possible poor eating habits or menses.

Pathophysiology. Iron-deficiency anemia can be caused by any number of factors that decrease the supply of iron, impair its absorption, increase the body's need for iron, or affect the synthesis of Hgb. Although the clinical manifestations and diagnostic evaluations are similar regardless of the cause, the therapeutic and nursing care management depends on the specific reason for the iron deficiency. The following discussion is limited to iron-deficiency anemia resulting from inadequate iron in the diet.

During the last trimester of pregnancy, iron is transferred from pregnant person to fetus. Most of the iron is stored in the circulating erythrocytes of the fetus, with the remainder stored in the fetal liver, spleen, and bone marrow. These iron stores are usually adequate for the first 6 months in a full-term infant but for only 2 to 3 months in preterm infants or multiple births. If dietary iron is not supplied to meet the infant's growth demands after the fetal iron stores are depleted, iron-deficiency anemia results. Delayed clamping of the umbilical cord by 1 to 3 minutes can improve iron status and reduce the risk of iron deficiency, whereas early clamping (before 30 seconds) puts the infant at risk for iron deficiency (Rothman, 2020; Unger et al., 2019). Physiological anemia should not be confused with iron-deficiency anemia resulting from nutritional causes.

Although most infants with iron-deficiency anemia are underweight, many infants are overweight because of excessive milk ingestion (known as *milk babies*). These children become anemic because milk is a poor source of iron and is given almost to the exclusion of solid foods.

Therapeutic Management. After the diagnosis of iron-deficiency anemia is made, therapeutic management focuses on increasing the amount of supplemental iron the child receives. This is usually done through dietary counselling and the administration of oral iron supplements.

In formula-fed infants, the most convenient and best sources of supplemental iron are formula containing 6.5 mg/L to 13 mg/L of iron (which is the typical concentration in standard cow's milk–based formulas in Canada) for the first 9 to 12 months with the addition of iron-rich foods after 6 months of age (Unger et al., 2019/2021). Iron-fortified formula provides a relatively constant and predictable amount of iron and is not associated with an increased incidence of gastrointestinal (GI) symptoms, such as colic, diarrhea, or constipation. Infants younger than 9 to 12 months of age should not be given fresh cow's milk because it may increase the risk of GI blood loss occurring from allergy to the milk protein or from GI mucosal damage resulting from a lack of cytochrome iron (**heme** protein) (Abdullah et al., 2011). If GI bleeding is suspected, the child's stool should be tested on at least four or five occasions to identify any intermittent blood loss.

Dietary addition of iron-rich foods is usually inadequate as the sole treatment of iron-deficiency anemia, since the iron is poorly absorbed and thus provides insufficient supplemental quantities. If dietary sources of iron cannot replace body stores, oral iron supplements are prescribed. Ferrous iron, more readily absorbed than ferric iron, results in higher Hgb levels. Ascorbic acid (vitamin C) appears to facilitate the absorption of iron and may be given as vitamin C–enriched foods and juices with the iron preparation.

If the Hgb level fails to rise after 1 month of oral therapy, it is important to assess for persistent bleeding, iron malabsorption, not taking the medication, improper iron administration, or other causes for the anemia. Parenteral (IV or intramuscular [IM]) iron administration is safe and effective but painful, expensive, and occasionally associated with regional **lymphadenopathy**, transient arthralgias, or allergic reaction (Rothman, 2020). Thus parenteral iron is reserved for children who have iron malabsorption, chronic hemoglobinuria, or intolerance to oral preparations. Transfusions are indicated for the most severe anemia and in cases of serious infection, cardiac dysfunction, or surgical emergency when anaesthesia is required. Packed RBCs (2 to 3 mL/kg), not whole blood, are used to minimize the chance of circulatory overload. Supplemental oxygen is administered when tissue hypoxia is severe.

Prognosis. The prognosis for a child with this condition is very good. However, there is some evidence that iron-deficiency anemia is also associated with later, possibly irreversible, cognitive impairments. Although there is support for iron deficiency with or without anemia causing these effects, it has not been established unequivocally. Some

studies suggest an increased risk of seizures, strokes, breath-holding spells in children, and exacerbations of restless legs syndrome in adults (Rothman, 2020).

Nursing Care. Given the potential for adverse neurodevelopmental outcomes, minimizing the incidence of iron deficiency is an important goal. It is also important to assess for iron-deficiency anemia based on the signs and symptoms described by caregivers.

Once the diagnosis is made an essential nursing responsibility is instructing parents in the administration of iron. Oral iron should be given as prescribed in two divided doses between meals, when the presence of free hydrochloric acid is greatest, since more iron is absorbed in the acidic environment of the upper GI tract. Citrus fruit or juice taken with the medication aids in absorption.

! NURSING ALERT

Cow's milk contains substances that bind the iron and interfere with absorption. Iron supplements should not be administered with milk or milk products.

An adequate dosage of oral iron turns the stools a tarry green colour. The nurse needs to advise parents of this normally expected change and inquire about its occurrence on follow-up visits. Absence of the greenish black stool may be a clue to lack of administration of iron, in either schedule or dosage. If there are concerns with the ability to give the medication, changing the schedule to more convenient times may enhance the administration. Vomiting or diarrhea can occur with iron therapy. If the parents report these symptoms, the iron can be given with meals and the dosage reduced and then gradually increased until tolerated.

Liquid preparations of iron may temporarily stain the teeth. If possible, the medication should be taken through a straw or given through a syringe or medicine dropper placed toward the back of the mouth. Brushing the teeth after administration of the medication lessens the discoloration.

If parenteral iron preparations are prescribed, iron dextran must be injected deeply into a large muscle mass using the Z-track method. The injection site is *not* massaged after injection, to minimize skin staining and irritation. Because no more than 1 mL should be given in one injection site, the IV route should be considered to avoid multiple injections. Careful observation with IV iron administration is required because of the risk for anaphylaxis, so a test dose is recommended before use.

! NURSING ALERT

Because iron ingestion in excessive quantities is toxic or even fatal, parents should be instructed to keep no more than 1 month's supply in the home and store it safely away from the reach of children.

Diet. A primary nursing objective is to prevent nutritional anemia through family education. Exclusively breastfed infants as well as formula-fed infants should be fed solid foods that are iron-rich, in the form of meat, meat alternatives such as fish, eggs, and legumes, or iron-fortified cereals as first foods between 6 and 12 months of age (Critch & Canadian Paediatric Society [CPS], Nutrition and Gastroenterology Committee, 2013/2018; Health Canada et al., 2015) (see Chapter 35, Selection of Solid Foods). Preterm infants fed human milk should begin iron supplements between 2 and 6 weeks of age (Unger et al., 2019/2021).

A difficulty encountered in discouraging the parents from feeding milk to the exclusion of other foods is dispelling the popular myth that milk is a "perfect food." Many parents believe that milk is best for the infant and equate the weight gain with a "healthy child" and "good parenting." The nurse can also stress that being overweight is not synonymous with good health.

Diet education of teenagers can be difficult, especially because teenage girls are prone to following weight-reduction diets. Emphasizing the effect of anemia on appearance (pallor) and energy level (difficulty maintaining popular activities) may be useful.

Sickle Cell Anemia

Sickle cell anemia (SCA) is one of a group of diseases collectively termed *hemoglobinopathies*, in which normal adult Hgb (Hgb A [HbA]) is partly or completely replaced by abnormal sickle HgbS (HbS). Sickle cell disease (SCD) includes all the hereditary disorders with clinical, hematological, and pathological features that are related to the presence of HgbS. Even though the term *SCD* is sometimes used to refer to SCA, this use is incorrect. Other correct terms for SCA are *HgbSS disease* and *homozygous sickle cell disease*.

The following are the most common forms of SCD:

- **SCA**—the homozygous form of the disease (HgbSS or SS), in which valine, an amino acid, is substituted for glutamic acid at the sixth position of the beta chain
- **Sickle cell–C disease**—a heterozygous variant of SCD (HgbSC), including both HgbS and HgbC (SC), in which lysine is substituted for glutamic acid at the sixth position of the beta chain
- **Sickle thalassemia disease**—a combination of sickle cell trait and beta thalassemia trait (Sβ-thal). In the β^+ (beta plus) form, some normal HbA can be produced. In the β^0 (beta zero) form, there is no ability to produce HbA.

Of the SCDs, SCA is the most common form found in Blacks, followed by sickle cell–C disease and sickle thalassemia. Numerous other sickle syndromes exist when the HbS is paired with other mutant globin.

SCA is found in 1 in 396 births of Blacks and 1 in 36 000 births of Latin Americans, with lower incidences in other ethnic groups (Smith-Whitley & Kwiatkowski, 2020). The incidence of the disease varies in different geographic locations. In Canada, there are about 2000 people living with sickle cell disease (Canadian Institute of Child Health, 2021).

The gene that determines the production of HgbS is situated on an autosome and, when present, is always detectable and therefore dominant. Heterozygous persons who have both normal HgbA and abnormal HgbS are said to have the *sickle cell trait*. Persons who are homozygous have predominantly HgbS and have SCA. The inheritance pattern is essentially that of an autosomal recessive disorder. Therefore, when both parents have the sickle cell trait, there is a 25% chance with each pregnancy of producing an offspring with SCA. Among Blacks, the incidence of the sickle cell trait is about 9%. In West Africa, the incidence is reported to be as high as 40% among native Africans. The high incidence of the sickle cell trait in West Africans is believed to be the result of selective protection afforded trait carriers against one type of malaria.

Although the defect is inherited, the sickling phenomenon is usually not apparent until later in infancy because of the presence of fetal Hgb (HgbF). As long as the child has predominantly HgbF, sickling does not occur because there is less HgbS. The newborn with SCA is generally asymptomatic because of the protective effect of HgbF (60 to 80% HgbF), but this rapidly decreases during the first year; thus the child is at risk for sickle cell–related complications (Smith-Whitley & Kwiatkowski, 2020).

Pathophysiology. The clinical features of SCA are primarily the result of (1) obstruction caused by the sickled RBCs, (2) vascular

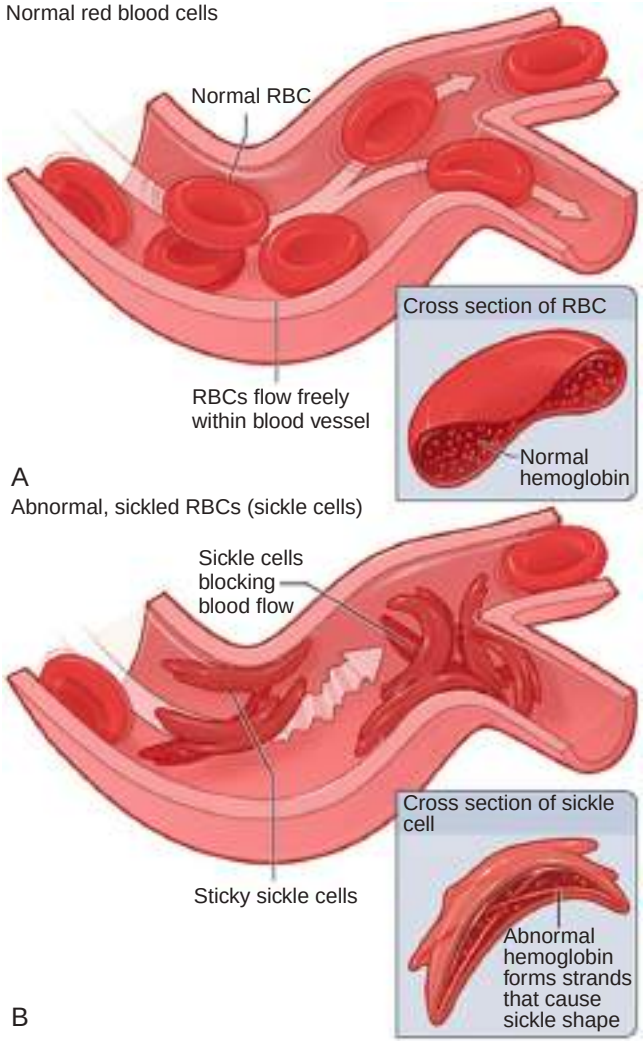

Fig. 48.3 **A,** Normal red blood cells (RBCs) flowing freely in a blood vessel. The inset shows a cross-section of a normal RBC with normal hemoglobin. **B,** Abnormal, sickled RBCs clumping and blocking blood flow in a blood vessel. (Other cells also may play a role in this clumping process.) The inset shows a cross-section of a sickle cell with abnormal hemoglobin. (From National Heart, Lung, and Blood Institute. [2008]. *What is sickle cell anemia?*)

inflammation, and (3) increased RBC destruction (Figure 48.3). The abnormal adhesion, entanglement, and enmeshing of rigid sickle-shaped cells accompanied by the inflammatory process intermittently block the microcirculation, causing vaso-occlusion (see Figure 48.2). The resultant absence of blood flow to adjacent tissues causes local hypoxia, leading to tissue ischemia and infarction (cellular death). Most of the complications seen in SCA can be traced to this process and its impact on various organs of the body. The effect of sickling and infarction on organ structures occurs in the following sequence (Box 48.2):

1. Stasis with enlargement
2. Infarction with ischemia and repeated destruction
3. Replacement with fibrous tissue (scarring)

Clinical Manifestations. The clinical manifestations of SCA vary greatly in severity and frequency. The most acute symptoms of the disease occur during periods of exacerbation called *crises*. There are several types of episodic crises: vaso-occlusive, acute splenic sequestration, aplastic, hyperhemolytic, cerebrovascular accident (CVA) (stroke), chest syndrome, and infection. The crises may occur individually or concomitantly with one or more other crises. The *vaso-occlusive crisis* (VOC), preferably called a "painful episode," is characterized by ischemia causing mild to severe pain that may last from minutes to days. *Sequestration crisis* is a pooling of a large amount of blood—usually in the spleen and infrequently in the liver—that causes a decreased blood volume and ultimately shock. *Aplastic crisis* is diminished RBC production usually caused by viral infection that may result in profound anemia. *Hyperhemolytic crisis* is an accelerated rate of RBC destruction characterized by anemia, jaundice, and reticulocytosis.

Another serious complication is acute chest syndrome (ACS), which is clinically similar to pneumonia. It involves the presence of a new pulmonary infiltrate and is associated with chest pain, fever, cough, tachypnea, wheezing, and hypoxia.

A CVA (stroke) is a sudden and severe complication, often with no related illnesses. Sickled cells block the major blood vessels in the brain, resulting in cerebral infarction, which causes variable degrees of neurological impairment. The current treatment for children with SCA who have experienced a stroke is chronic transfusion therapy. Despite regular blood transfusion therapy, approximately 20% of patients will have a second stroke and 30% of this group will have a third stroke (Smith-Whitley & Kwiatkowski, 2020).

Diagnostic Evaluation. Currently, British Columbia, Ontario, and the Yukon are the only provinces that offer universal newborn screening programs for SCD. Manitoba offers screening to select populations or by request, and in Nova Scotia and Quebec testing is required or offered universally but not yet implemented (Canadian Institute of Child Health, 2021). The screening provides early identification of these children before complications develop. At birth, infants have up to 80% of HbF, which does not carry the defect. Because levels of HbS are low at birth, Hgb electrophoresis or other tests that measure Hgb concentrations are indicated. Early diagnosis (before 3 months of age) enables initiation of appropriate interventions to minimize complications. The family is taught to administer prophylactic antibiotics and identify early signs of infection to seek medical therapy as soon as possible.

If SCA is not diagnosed in early infancy, it is likely to manifest symptoms during the toddler and preschool years. SCA is occasionally first diagnosed during a crisis that follows an acute respiratory tract or GI infection.

There are several specific tests used to detect the presence of the abnormal Hgb in the heterozygous or the homozygous form of SCD. For screening purposes, the sickle-turbidity test (Sickledex) is used because it can be performed on blood from a finger or heel stick and yields accurate results in 3 minutes. If the test result is positive, however, Hgb electrophoresis is necessary to distinguish between children with the trait and those with the disease. *Hemoglobin electrophoresis* (referred to as "fingerprinting" of the protein) is a specially prepared blood test that separates various hemoglobins by high voltage. The blood test is accurate, rapid, and specific for detecting the homozygous and heterozygous forms of the disease, as well as the percentages of the various types of Hgb.

Therapeutic Management. The aims of therapy are to prevent the sickling phenomena, which are responsible for the pathological sequelae, and effectively treat the medical emergencies of sickle cell crisis. The successful achievement of these aims depends on prompt nursing interventions, medical therapies, patient and family preventive measures, and use of innovative treatments.

BOX 48.2 Clinical Manifestations of Sickle Cell Anemia

General
Possible growth restriction
Chronic anemia (hemoglobin level of 60 to 90 g/L)
Possible delayed sexual maturation
Marked susceptibility to sepsis

Vaso-Occlusive Crisis
Pain in area(s) of involvement
Manifestations related to ischemia of involved areas
Extremities—Painful swelling of hands and feet (sickle cell dactylitis, or hand–foot syndrome), painful joints
Abdomen—Severe pain resembling acute surgical condition
Cerebrum—Stroke, visual disturbances
Chest—Symptoms resembling pneumonia, protracted episodes of pulmonary disease
Liver—Obstructive jaundice, hepatic coma
Kidney—Hematuria
Genitalia—Priapism (painful, constant penile erection)

Sequestration Crisis
Pooling of large amounts of blood
- Hepatomegaly
- Splenomegaly
- Circulatory collapse

Effects of Chronic Vaso-Occlusive Phenomena
Heart—Cardiomegaly, systolic murmurs
Lungs—Altered pulmonary function, susceptibility to infections, pulmonary insufficiency
Kidneys—Inability to concentrate urine, enuresis, progressive renal failure
Liver—Hepatomegaly, cirrhosis, intrahepatic cholestasis
Spleen—Splenomegaly, susceptibility to infection, functional reduction in splenic activity progressing to autosplenectomy
Eyes—Intraocular abnormalities with visual disturbances; sometimes progressive retinal detachment and blindness
Extremities—Avascular necrosis of hip or shoulder; skeletal deformities, especially lordosis and kyphosis; chronic leg ulcers; susceptibility to osteomyelitis
Central nervous system—Hemiparesis, seizures

Medical management of a crisis is usually directed by an interprofessional care team that provides supportive, symptomatic, and specific treatments. The main objectives are to provide (1) rest to minimize energy expenditure and oxygen use, (2) hydration through oral and IV therapy, (3) electrolyte replacement because hypoxia results in metabolic acidosis, which also promotes sickling, (4) analgesics for the severe pain from vaso-occlusion, (5) blood replacement to treat anemia and reduce the viscosity of the sickled blood, and (6) antibiotics to treat any existing infection.

Administration of pneumococcal, meningococcal, and *Haemophilus influenzae* type b conjugate vaccines is recommended for these children because of their susceptibility to infection as a result of a functional asplenia. In addition to routine immunizations, the child with SCA should receive an annual influenza vaccination, as well as hepatitis A and B vaccination for those who receive repeat blood transfusions. Oral penicillin prophylaxis is also recommended by 2 months of age in order to reduce the chance of pneumococcal infections in children with SCA younger than 5 years (HealthLink BC, 2020; Rankine-Mullings & Owusu-Ofori, 2017). Parents and children with SCA should be instructed in the importance of taking the prophylactic penicillin twice daily and seeking medical attention immediately for acute illness, especially if the temperature exceeds 38.5°C (101.3°F), regardless of the use of prophylaxis. Rates of pneumococcal infection were found to be relatively low in children over the age of 5 years (Rankine-Mullings & Owusu-Ofori, 2017).

Oxygen therapy may be administered during episodes of crisis to provide comfort and to decrease the incidence of respiratory complications. Severe hypoxia must be prevented because it causes massive systemic sickling that can be fatal. Oxygen administration is usually not effective in reversing sickling or reducing pain because the oxygen is unable to reach the enmeshed sickled erythrocytes in clogged vessels. Patients admitted for a febrile or vaso-occlusive episode should be carefully assessed and have continuous oxygen saturation monitoring. High-flow oxygen is administered to maintain an oxygen saturation of equal to or over 95% for early detection of clinical symptoms and/or changes in oxygenation (Canadian Haemoglobinopathy Association [CHA], 2015/2018).

Another important component of care is the use of blood transfusions. Exchange RBC transfusion (erythrocytapheresis) is the replacement of sickle cells with normal RBCs. Typically, short-term transfusions are used to prevent progression of acute complications such as ACS, aplastic crisis, splenic sequestration, and acute stroke, as well as to prevent surgery-related ACS. Exchange transfusion is a successful, rapid method of reducing the number of circulating sickle cells and therefore slowing down the vicious circle of hypoxia, thrombosis, tissue ischemia, and injury. However, multiple transfusions carry the risk of transmission of viral infection, hyperviscosity, transfusion reactions, alloimmunization, and iron overload. Packed RBC transfusions may be used for treatment of splenic sequestration and stroke and preoperatively for surgical procedures in the child with SCA. Unless the child has heart failure, dyspnea, hypotension, or marked fatigue, a blood transfusion is avoided unless the hemoglobin has decreased to less than 50 to 60 g/L (CHA, 2015/2018). The child with SCA should be transfused with phenotypically matched RBCs to reduce the risk of alloimmunization and hemolytic transfusion reactions (CHA, 2015/2018). To reduce iron overload from chronic transfusion therapy, chelation therapy may be started (see Chapter 46, Chelation Therapy).

In children with recurrent life-threatening splenic sequestration, splenectomy may be a lifesaving measure. However, the spleen usually atrophies on its own through progressive fibrotic changes (functional asplenia) by 6 years of age in children with SCA. Prophylactic penicillin postsplenectomy and pneumococcal vaccines have decreased the incidence of pneumococcal sepsis.

The most common and debilitating symptom experienced by patients with SCA is vaso-occlusive pain. The chronic nature of this pain can greatly affect the child's development. An interprofessional approach is best for vaso-occlusive pain management, which includes pharmacological treatment, hydration, physiotherapy, and complementary treatment (e.g., prayer, spiritual healing, massage, heat, herbs, relaxation, acupuncture, and biofeedback) (Brandow et al., 2011). See Chapter 34 for more information on pain control.

For mild to moderate pain, nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen, ketorolac) or acetaminophen (Tylenol) is used initially. If these medications are not effective alone, opioids can be added. The dosages of both medications are titrated (adjusted) to a therapeutic level.

Opioids such as immediate- and sustained-release morphine, oxycodone, hydromorphone (Dilaudid), and methadone are administered intravenously or orally for severe pain and given around the clock.

Patient-controlled analgesia (PCA) has been used successfully for sickle cell–related pain. PCA reinforces the patient's role and responsibility in managing the pain and provides flexibility in dealing with pain, which may vary in severity over time (see Pain in Children with Sickle Cell Disease, Chapter 34). Opioid dependency in children with SCD is rare and should never be used as a reason to withhold pain medication. However, patients with multiple painful episodes requiring hospitalization within 1 year or with pain episodes that require hospitalization for greater than 7 days should be evaluated for comorbidities and environmental stressors that are contributing to the frequency or duration of pain (Smith-Whitley & Kwiatkowski, 2020).

Hydroxyurea is a medication that increases the production of HgbF—fetal Hgb that decreases endothelial adhesion of sickle cells, improves the sickle cell hydration, increases nitric oxide production (a vasodilator), and reduces leukocyte and reticulocyte counts (Smith-Whitley & Kwiatkowski, 2020). Hydroxyurea is a *Health Canada Food and Drug Act*–approved medication. Long-term follow-up of patients taking hydroxyurea alone revealed a 40% reduction in mortality and decreased frequency of VOC, ACS, hospital admissions, and need for transfusions, thus making SCA crises milder (CHA, 2015/2018; SickKids, 2021; Smith-Whitley & Kwiatkowski, 2020).

Prognosis. The prognosis varies, but most patients with SCA live into the fifth decade. Most of the time, children are without symptoms and participate in normal activities without restrictions, but they may become fatigued more quickly than their counterparts. The greatest risk is usually in children younger than 5 years of age, and the majority of deaths in these children are caused by overwhelming infection. Consequently, SCA is a chronic illness with a potentially terminal outcome. Physical and sexual maturation are delayed in adolescents with SCA. Although adults achieve normal height, weight, and sexual function, the delay may present challenges for the adolescent.

HLA-typing and storage of umbilical cord blood may be considered for siblings of children with SCA. HLA typing may be coordinated with prenatal diagnostic techniques (such as chorionic villus sampling, amniocentesis, or preimplantation genetic diagnosis) to determine if the fetus is affected with SCA (CHA, 2015/2018).

Hematopoietic stem cell transplantation (HSCT) offers the only cure for some children. Transplants are from a sibling or unrelated donor. Sibling-matched stem cell transplantation has a lower risk for graft-versus-host disease than unrelated donors. Younger children may have lower morbidity and mortality from HSCT (Smith-Whitley & Kwiatkowski, 2020).

Nursing Care

Educating the family and child. Family education begins with an explanation of the disease and its consequences. After this explanation, the most important issues to teach the family are to (1) seek early intervention for conditions such as fever of 38.0°C (100.4°F) oral or greater, (2) give penicillin as ordered, (3) recognize signs and symptoms of splenic sequestration and respiratory difficulties that can lead to hypoxia, and (4) provide the same childhood experiences offered to any other child who is without illness or disease. The nurse needs to convey to the family that the child is a person like any other child but can get sick in ways that other children cannot.

The nurse should emphasize the importance of adequate hydration to prevent sickling and to delay the adhesion–stasis–thrombosis–ischemia cycle in a crisis. It is not sufficient to advise parents to "force fluids" or "encourage drinking." They need specific instructions on how many daily glasses or bottles of fluid are required. Many foods are also a source of fluid, particularly soups, flavoured ice pops, ice cream, sherbet, gelatin, and puddings.

! NURSING ALERT

One simple yet graphic way to demonstrate the effect of sickling is to roll rounded objects, such as marbles or beads, through a tube to simulate normal circulation and then roll pointed objects, such as screws or jacks, through the tube. The effect of sickling and clumping of the pointed objects is especially noticeable at a bend or slight narrowing of the tube.

Increased fluids combined with impaired kidney function can result in enuresis. Parents who are unaware of this fact frequently use the usual measures to discourage bed-wetting, such as limiting fluids at night, and may resort to punishment and shame to force bladder control. The nurse should discuss this issue with the parents, stressing that the child's ability to concentrate urine is impaired. Reminding the child to urinate frequently during the day and prior to bedtime may be helpful, and waking the child during the night may help if the child's sleep pattern is not disturbed. Enuresis is treated as a complication of the disease, such as joint pain or some other symptom, to alleviate parental pressure on the child.

! NURSING ALERT

Advise parents to be particularly alert to situations such as hot weather, in which dehydration may be a possibility, and to recognize early signs of reduced intake, such as decreased urinary output (e.g., fewer wet diapers) and increased thirst.

Promoting supportive therapies during crises. Management of pain is an especially difficult challenge and often involves experimenting with various analgesics, including opioids, and schedules before relief is achieved. Unfortunately, these children tend to be undermedicated, resulting in "clock watching" and demands for additional doses sooner than might be expected. Often this incorrectly raises suspicions of drug addiction, when in fact the issue is one of improper dosage (see Family-Centred Care box: Fear of Addiction). In choosing and scheduling analgesics, the goal should be *prevention* of pain. See Chapter 34, Pain in Children with Sickle Cell Disease.

FAMILY-CENTRED CARE

Fear of Addiction

Although the pain during a sickle cell crisis is usually severe and opioids are needed, many families fear that their child will become addicted to the opioid. Unfortunately, misinformed health care providers may foster this unfounded fear, which results in a child's needless suffering. Very few children who receive opioids for severe pain become behaviourally addicted to the drug (Lynch & Fischer, 2011). Families and older children, especially adolescents, need to be reassured that opioids are medically indicated, high doses may be needed, and children rarely become addicted.

Any pain program should be combined with psychological support to help the child manage the depression, anxiety, and fear that may accompany the disease. This includes regular visits with the child to discuss any concerns during the hospitalization and positive reinforcement of coping skills, such as successful methods of dealing with pain and adherence to treatment prescriptions. To reduce the negative connotation associated with the term sickle cell *crisis*, it is best to say *pain episode*.

Frequently, heat to the affected area is soothing. Cold compresses should not be applied because this enhances sickling and **vasoconstriction**. Bed rest is usually well tolerated during a crisis, although actual rest depends greatly on pain alleviation and organized schedules of

nursing care. Some activity, particularly passive range-of-motion exercises, is beneficial to promote circulation. Usually the best course of action is to let children dictate their tolerance of activity.

If blood transfusions or exchange transfusions are given, the nurse has the responsibility of observing for signs of transfusion reaction (see Table 48.3, later in the chapter). Because hypervolemia from too-rapid transfusion can increase the workload of the heart, the nurse also needs to be alert to signs of cardiac failure.

In splenic sequestration the size of the spleen is gently measured by abdominal palpation (see Abdomen, Chapter 33). The nurse should be aware of spleen size because increasing splenomegaly is an ominous sign. A decreasing spleen size denotes response to therapy. Vital signs and blood pressure are also closely monitored for impending shock. Anemia is typically not a presenting complication in VOC, but it is a critical concern in other types of crises. The nurse needs to monitor for evidence of increasing anemia and institute appropriate nursing interventions (see earlier in this chapter). Oxygen saturation level needs to be monitored carefully, and high-flow oxygen is to given if the oxygen saturation level drops below 95% (CHA, 2015/2018).

Intake, especially of IV fluids, and output need to be recorded. The child's weight should be taken on admission to serve as a baseline for evaluating hydration. Because diuresis can result in electrolyte loss, the nurse also should observe for signs of hypokalemia and be familiar with normal serum electrolyte values to report changes.

Recognizing other complications. Nurses also need to be aware of the signs of ACS and CVA, both potentially fatal complications. It is essential to educate parents about these symptoms.

! NURSING ALERT

Report signs of the following immediately:

Acute Chest Syndrome (ACS)
- Severe chest, back, or abdominal pain
- Fever of 38.5°C (101.3°F) or higher
- Cough
- Dyspnea, tachypnea
- Retractions
- Declining oxygen saturation (oximetry)

Cerebrovascular Accident (CVA)
- Severe, unrelieved headaches
- Severe vomiting
- Jerking or twitching of the face, legs, or arms
- Seizures
- Strange, abnormal behaviour
- Inability to move an arm or leg
- Stagger or an unsteady walk
- Stutter or slurred speech
- Weakness in the hands, feet, or legs
- Changes in vision

Supporting the family. Families need the opportunity to discuss their feelings about genetically transmitting a potentially fatal, chronic illness to their child. Because of the widely publicized prognosis for children with SCA, many parents express their prevalent fear of the child's death. Three manifestations of SCA that may appear in the first 2 years of life—dactylitis or painful episode, severe anemia (less than 70 g/L), and elevated WBC count—can be predictors of disease severity (Smith-Whitley & Kwiatkowski, 2020). However, nursing care for the family should be the same as for any family with a child with a life-threatening illness. The siblings' reactions, the stress on the parent's relationship, and the child-rearing attitudes displayed toward the child should be given particular emphasis (see Chapter 41).

The nurse needs to advise parents to inform all treating personnel of the child's condition. The use of medical identification, such as a bracelet, is another way of ensuring awareness of the disease.

If family members have the SCD trait or SCA, genetic counselling is necessary. A primary consideration in genetic counselling is informing parents of the 25% chance with each pregnancy of having a child with the disease when both parents carry the trait.

Beta Thalassemia (Cooley Anemia)

Worldwide, thalassemia is a common genetic disorder with an estimate of approximately 60 000 symptomatic individuals born annually (Hassan et al., 2016). The term *thalassemia*, derived from the Greek word *thalassa*, meaning "sea," is applied to a variety of inherited blood disorders characterized by deficiencies in the rate of production of specific globin chains in Hgb. The name appropriately refers to people living near the Mediterranean Sea, namely Italians, Greeks, Syrians, Asians, Africans, and their descendants. Evidence suggests that the high incidence of the disorders among these groups is a result of the selective advantage the trait confers in relation to malaria, as is postulated in SCA. However, the disorder has a wide geographic distribution, probably as a result of genetic migration through population migration, intermarriage, or possibly as a result of spontaneous mutation.

Beta thalassemia is the most common of the thalassemias and occurs in four forms:
- Two heterozygous forms: *thalassemia minor*, an asymptomatic silent carrier; and *thalassemia trait*, which produces a mild microcytic anemia
- *Thalassemia intermedia*, which may involve either homozygous or heterozygous abnormalities and is manifested as splenomegaly and moderate to severe anemia
- A homozygous form, *thalassemia major* (also known as *Cooley anemia*), which results in a severe anemia that would lead to hepatosplenomegaly, growth restrictions, bone deformities, cardiac failure, and death in early childhood without transfusion support.

Pathophysiology. Normal postnatal Hgb is composed of two alpha- and two beta-polypeptide chains. In beta thalassemia there is a partial or complete deficiency in the synthesis of the beta chain of the Hgb molecule. Consequently, there is a compensatory increase in the synthesis of alpha chains, and gamma-chain production remains activated, resulting in defective Hgb formation. This unbalanced polypeptide unit is very unstable; when it disintegrates, it damages RBCs, causing severe anemia.

To compensate for the hemolytic process, an overabundance of erythrocytes is formed unless the bone marrow is suppressed by transfusion therapy. Excess iron from **hemolysis** of supplemental RBCs in transfusions and from the rapid destruction of defective cells is stored in various organs (*hemosiderosis*).

Diagnostic Evaluation. The onset of thalassemia major may be insidious and not recognized until the latter half of infancy. The clinical effects of thalassemia major are primarily attributable to (1) defective synthesis of HgbA, (2) structurally impaired RBCs, and (3) the shortened lifespan of erythrocytes (Box 48.3).

Hematological studies reveal the characteristic changes in RBCs (i.e., microcytosis, hypochromia, anisocytosis, poikilocytosis, target cells, and basophilic stippling of various stages). Low Hgb and Hct levels are seen in severe anemia, although they are typically lower than the reduction in RBC count because of the proliferation of immature

BOX 48.3 Clinical Manifestations of Beta Thalassemia

Anemia (Before Diagnosis)
Pallor
Unexplained fever
Poor feeding
Enlarged spleen or liver

Progressive Anemia
Signs of chronic hypoxia
- Headache
- Precordial and bone pain
- Decreased exercise tolerance
- Listlessness
- Anorexia

Other Features
Small stature
Delayed sexual maturation
Bronzed, freckled complexion (if not receiving chelation therapy)

Bone Changes (Older Children if Untreated)
Enlarged head
Prominent frontal and parietal bosses
Prominent malar eminences
Flat or depressed bridge of the nose
Enlarged maxilla
Protrusion of the lip and upper central incisors and eventual malocclusion
Generalized osteoporosis

erythrocytes. Hgb electrophoresis confirms the diagnosis and is helpful in distinguishing the type of thalassemia because it analyzes the quantity and kind of hemoglobin variants found in the blood. Radiographs of involved bones reveal characteristic findings.

Newborn screening is available to detect several thalassemia syndromes in Ontario, Quebec, British Columbia, Nova Scotia, New Brunswick, Yukon, and Nunavut. With an increase in immigration to Canada, testing should be offered to all new patients with a clinical suspicion of thalassemia (CHA, 2018).

Therapeutic Management. The objective of supportive therapy is to maintain sufficient Hgb levels to prevent bone marrow expansion and the resulting bony deformities and to provide sufficient RBCs to support normal growth and normal physical activity. Transfusions are the foundation of medical management with the goal of maintaining the Hgb level at 90–100 g/L, an aim that may require transfusions as often as every 3 to 5 weeks (CHA, 2018; Tubman et al., 2015). The advantages of this therapy include (1) improved physical and psychological well-being because of the ability to participate in normal activities, (2) decreased cardiomegaly and **hepatosplenomegaly**, (3) fewer bone changes, (4) normal or near-normal growth and development until puberty, and (5) fewer infections. Folic acid supplements may also be given to assist the body in producing red blood cells.

One of the potential complications of frequent blood transfusions is iron overload (*hemosiderosis*). Because the body has no effective means of eliminating the excess iron, the mineral is deposited in body tissues. To minimize the development of hemosiderosis, the oral iron chelators deferasirox (Exjade) or deferiprone (Ferriprox) have been shown to be equivalent to deferoxamine (Desferal), a parenteral iron-chelating agent, and more tolerable by patients and families (CHA, 2018). The most commonly reported combination regimen utilizes oral deferiprone with parenteral deferoxamine. Deferoxamine is given intravenously or subcutaneously at home via a portable infusion pump over a period of 8 to 10 hours (usually during sleep) for 5 to 7 days a week.

In some children with severe splenomegaly who required repeated transfusions, a splenectomy may be necessary to decrease the disabling effects of abdominal pressure and to increase the lifespan of supplemental RBCs. Over time, the spleen may accelerate the rate of RBC destruction and thus increase transfusion requirements. After a splenectomy, children generally require fewer transfusions, although the basic defect in Hgb synthesis remains unaffected. A major postsplenectomy complication is severe and overwhelming infection. Therefore, these children continue to receive prophylactic antibiotics with close medical supervision for many years and should receive the influenza, pneumococcal, and meningococcal vaccines in addition to the regularly scheduled immunizations. Hepatitis A and B vaccinations are also recommended for those who receive repeat blood transfusions.

! NURSING ALERT

Ensure that the family and patient understand the need to notify the health care provider of all fevers of 38.5°C (101.3°F) or greater because of the risk of sepsis in a child with asplenia.

Prognosis. Most children treated with blood transfusion and early chelation therapy survive well into adulthood. The most common cause of death is iron-induced heart disease, multiple-organ failure, postsplenectomy sepsis, liver disease, and malignancy. A curative treatment for some children is HSCT. Children with the least symptoms who are younger than 14 years of age have the best results when undergoing HSCT, with an overall survival rate of 96% and a disease-free survival rate of 86% (CHA, 2018).

Nursing Care. The objectives of nursing care are to (1) promote adherence to transfusion and chelation therapy, (2) assist the child and family in coping with the anxiety-provoking treatments and the effects of the illness, (3) foster the child's and family's adjustment to living with a chronic illness, and (4) observe for complications of multiple blood transfusions. Basic to each of these goals is explaining to parents and older children or adolescents the defect responsible for the disorder, its effect on RBCs, and the potential effects of untreated iron overload (such as diabetes and heart disease). Because the prevalence of this condition is high among families of Mediterranean descent, the nurse also needs to inquire about the family's previous knowledge about thalassemia. All families with a child with thalassemia should be tested for the trait and referred for genetic counselling.

As with any chronic illness, the family's needs must be met for optimal adjustment to the stresses imposed by the disorder (see Chapter 41). Sources of information for the family are included in the Additional Resources at the end of this chapter. Genetic counselling for the parents and fertile offspring is important. If both parents are known to be carriers of beta thalassemia trait, chorionic villus sampling can be done during the first trimester (11 weeks) or by amniocentesis during the second trimester (16 weeks) (see Chapter 13).

Aplastic Anemia

Aplastic anemia (AA) refers to a bone marrow failure condition in which the formed elements of the blood are simultaneously depressed.

BOX 48.4 Common Causes of Acquired Aplastic Anemia

- Human parvovirus infection, hepatitis, Epstein-Barr virus, HIV, cytomegalovirus, or overwhelming infection
- Irradiation
- Immune disorders such as eosinophilic fasciitis and hypoimmunoglobulinemia
- Medications such as certain chemotherapeutic agents, anticonvulsants, and antibiotics
- Industrial and household chemicals, including benzene and its derivatives, which are found in petroleum products, dyes, paint remover, shellac, and lacquers
- Infiltration and replacement of myeloid elements, such as in leukemia or the lymphomas
- Idiopathic (In most cases no identifiable precipitating cause can be found.)

The peripheral blood smear demonstrates **pancytopenia** or the triad of profound anemia, leukopenia, and thrombocytopenia. *Hypoplastic anemia* is characterized by a profound depression of RBCs but normal or slightly decreased WBCs and platelets.

Etiology. AA can be primary (congenital, or present at birth) or secondary (acquired). The best-known congenital disorder of which AA is an outstanding feature is *Fanconi anemia*, a rare hereditary disorder characterized by pancytopenia, hypoplasia of the bone marrow, and patchy brown discoloration of the skin resulting from the deposit of melanin and associated with multiple congenital anomalies of the musculoskeletal and genitourinary systems. *Fanconi anemia* is not to be used synonymously with *Fanconi syndrome*, which is a rare and serious disorder that affects the kidneys. Fanconi anemia appears to be inherited as an autosomal recessive trait with varying penetrance; thus affected siblings may demonstrate several different combinations of defects.

Several etiological factors contribute to the development of acquired hypoplastic anemia. Most of the cases are considered idiopathic (Box 48.4); however, increasing evidence suggests there is an autoimmune component (National Organization for Rare Disorders, 2018). Acquired AA is classified as either severe acquired AA or moderate acquired AA. The following discussion focuses on severe acquired AA, which carries a poorer prognosis and follows a more rapidly fatal course than the primary types.

Diagnostic Evaluation. The onset of clinical manifestations, which include anemia, leukopenia, and decreased platelet count, is usually insidious. Definitive diagnosis is determined from bone marrow aspiration, which demonstrates the conversion of red bone marrow to yellow, fatty bone marrow. *Severe AA* is defined as less than 25% bone marrow cellularity with at least two of the following findings: absolute **granulocyte** count less than 0.5×10^9/L, platelet count less than 20×10^9/L, and absolute **reticulocyte** count less than 25×10^9/L (McKee, 2015). *Moderate AA* is defined as more than 25% bone marrow cellularity with the presence of mild or moderate cytopenia (McKee, 2015).

Therapeutic Management. The objectives of treatment are based on the recognition that the underlying disease process is failure of the bone marrow to carry out its **hematopoietic** functions. Therefore, therapy is directed at restoring function to the marrow and involves two main approaches: (1) immunosuppressive therapy to remove the presumed immunological functions that prolong aplasia or (2) replacement of the bone marrow through transplantation. Bone marrow transplantation is the treatment of choice for severe AA, when a suitable donor exists (see later in chapter).

Antithymocyte globulin (ATG) and cyclosporin are the principal medication treatments used for AA. The rationale for using ATG is based on the theory that AA may be a result of autoimmunity. ATG and cyclosporine suppress T cell–dependent autoimmune responses but do not cause bone marrow suppression. Cyclosporine is administered orally for several weeks to months. ATG usually is administrated intravenously over 12 to 16 hours for 4 days, after a test dose to check for hypersensitivity. A course may be repeated, depending on the reduction in circulating **lymphocytes** and the patient's response. Because of the hypersensitivity response associated with ATG (i.e., fever, chills, myalgias), methylprednisolone is given intravenously to prevent these adverse effects. Colony-stimulating factor (CSF) and granulocyte-macrophage colony–stimulating factor (GM-CSF) given parenterally may be used to enhance bone marrow production. Androgens may be used with ATG to stimulate erythropoiesis if the AA is unresponsive to initial therapies.

HSCT should be considered early in the course of the disease if a compatible donor can be found. Because the outcomes of matched unrelated donor transplant for children with acquired aplastic anemia have improved to probability of survival rates greater than 75%, the use of unrelated donor HSCT upfront without prior immunosuppressive therapy is being considered more frequently; 2-year overall survival can be as high as 96% in upfront, matched unrelated donor recipients (Phelan & Margolis, 2020).

Nursing Care. The care of the child with AA is similar to that of the child with leukemia (see discussion later in chapter) and includes preparing the child and family for the diagnostic and therapeutic procedures, preventing complications from the severe pancytopenia, and providing emotional support in the face of a potentially fatal outcome. Information and support are available from the Aplastic Anemia and Myelodysplasia Association of Canada (see Additional Resources at the end of this chapter).

Because the aspects of nursing care are discussed in the section on leukemia, only the exceptions are presented here. The drug ATG is usually administered by way of a central vein. If not, vigilant care must be directed to the IV infusion to prevent extravasation. Meticulous care of the venous access is essential because of the child's susceptibility to infection. CSFs are usually given by subcutaneous injection over several days. Chemotherapeutic agents have been reported in the treatment of the relapsed patient with AA after ATG and CSF therapy. Many of the adverse effects associated with chemotherapy, such as nausea and vomiting, **alopecia**, and mucositis, are experienced by children receiving treatment for AA. Specialized care is required for children who have HSCT (see discussion later in chapter).

DEFECTS IN HEMOSTASIS

Hemostasis is the process that stops bleeding when a blood vessel is injured. Vascular and plasma clotting factors, as well as platelets, are required. A complex system of clotting, anticlotting, and clot breakdown (*fibrinolysis*) mechanisms exists in equilibrium to ensure clot formation only in the presence of blood vessel injury and to limit the clotting process to the site of vessel wall injury. Dysfunction in these systems leads to bleeding or abnormal clotting. Although the coagulation process is complex, clotting depends on three factors: (1) vascular influence, (2) platelet role, and (3) clotting factors.

Hemophilia

The term *hemophilia* refers to a group of bleeding disorders resulting from congenital deficiency, dysfunction, or absence of specific

coagulation proteins or factors. Although the symptomatology is similar regardless of which clotting factor is deficient, the identification of specific factor deficiencies allows definitive treatment with replacement agents.

In about 80% of all cases of hemophilia, the inheritance pattern is X-linked recessive. The two most common forms of the disorder are factor VIII deficiency (hemophilia A, or classic hemophilia) and factor IX deficiency (hemophilia B, or Christmas disease). Hemophilia A affects less than 1 in 10 000 individuals, whereas hemophilia B affects approximately 1 in 50 000 individuals in Canada (Canadian Hemophilia Society, 2018a). Von Willebrand disease (vWD) is another hereditary bleeding disorder characterized by a deficiency, abnormality, or absence of the protein called *von Willebrand factor* (vWF) and a deficiency of factor VIII (see Chapter 24, von Willebrand disease [vWD]). Unlike hemophilia, which affects many more males than females, vWD affects both males and females equally. Approximately 1% of the world's population is affected by vWD (Canadian Hemophilia Society, 2018b). The following discussion is primarily concerned with factor VIII deficiency, which accounts for 80 to 85% of all hemophilia cases.

Pathophysiology. The basic defect of hemophilia A is a deficiency of factor VIII (antihemophilic factor [AHF]). AHF is produced by the liver and is necessary for the formation of thromboplastin in phase I of blood coagulation (Figure 48.4). The less AHF found in the blood, the more severe the disease. Individuals with hemophilia have two of the three factors required for coagulation: vascular influence and platelets. Therefore, they may bleed for longer periods but not at a faster rate.

Subcutaneous and IM hemorrhages are common. *Hemarthrosis*, which is bleeding into a joint space (knees, elbows, ankles, shoulders, hips, wrists), is the most frequent type of internal bleeding. Bony changes and crippling deformities occur after repeated bleeding episodes over several years. Early signs of hemarthrosis are a feeling of stiffness, tingling, or achiness in the affected joint, followed by decrease in joint movement. Obvious affected joint signs and symptoms are increased warmth, redness, and swelling and severe pain with loss of movement. Bleeding in the neck, mouth, or thorax is serious because the airway can become obstructed. Intracranial hemorrhage can have fatal consequences and is one of the major causes of death. Hemorrhage anywhere along the GI tract can lead to anemia, and bleeding into the retroperitoneal cavity is especially hazardous because of the large space for blood to accumulate. Hematomas in the spinal cord can cause paralysis.

Diagnostic Evaluation. Overt, prolonged hemorrhage is readily apparent; bleeding into tissues is less apparent (Box 48.5). The diagnosis is usually made from a history of bleeding episodes, evidence of X-linked inheritance (only one third of the cases are new mutations), and laboratory findings. The tests specific for hemophilia plasma depend on specific factors for a reaction to occur, such as the partial thromboplastin time (PTT). Specific determination of factor deficiencies requires assay procedures normally performed in specialized laboratories. Carrier detection is possible in classic hemophilia using DNA testing and is an important consideration in families in which female offspring may have inherited the trait.

Therapeutic Management. The primary therapy for hemophilia is replacement of the missing clotting factor. The products available are factor VIII concentrate from pooled plasma or a genetically engineered recombinant, to be reconstituted with sterile water immediately before use. A synthetic form of vasopressin, 1-deamino-8-D-arginine

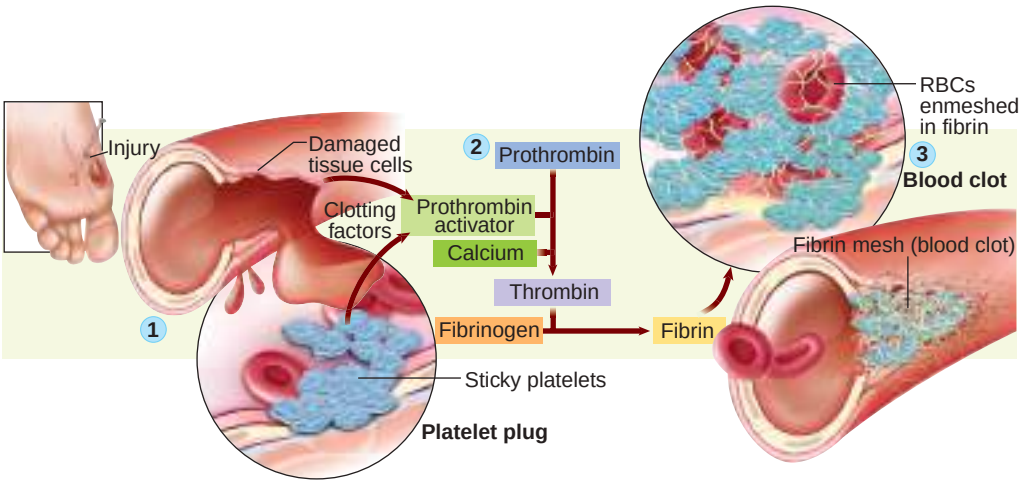

Fig. 48.4 Blood clotting. The extremely complex clotting mechanism can be distilled into three basic steps: (1) release of clotting factors from both injured tissue cells and sticky platelets at the injury site (which form a temporary platelet plug); (2) a series of chemical reactions that eventually result in the formation of thrombin; and (3) formation of fibrin and trapping of red blood cells (RBCs) to form a clot. (From Thibodeau, G. A. [2010]. *The human body in health and disease* [5th ed.]. Mosby.)

BOX 48.5 Clinical Manifestations of Hemophilia

- Prolonged bleeding anywhere from or in the body
- Hemorrhage from any trauma—loss of deciduous teeth, circumcision, cuts, epistaxis, injections
- Excessive bruising, even from a slight injury, such as a fall
- Subcutaneous and intramuscular hemorrhages
- Hemarthrosis (bleeding into the joint cavities), especially the knees, ankles, and elbows
- Hematomas—pain, swelling, and limited motion
- Spontaneous hematuria

vasopressin (DDAVP), increases plasma factor VIII activity and is the treatment of choice in mild hemophilia and certain types of vWD if the child shows an appropriate response. After DDAVP administration, a three-fold to four-fold rise in factor VIII–level activity should occur. It is not effective in the treatment of severe hemophilia A, severe vWD, or any form of hemophilia B. Aggressive factor concentrate replacement therapy is initiated to prevent chronic crippling effects from joint bleeding.

Other medications may be included in the therapy plan, depending on the source of the hemorrhage. Tranexamic acid (Cyklokapron) and aminocaproic acid (Amicar) are effective in both hemophilia A and B, by helping to hold a clot in place once it has formed, particularly in mucous membranes such as the inside of the mouth and nose, intestines, and uterus. Corticosteroids are given for hematuria, acute hemarthrosis, and chronic synovitis. NSAIDs, such as ibuprofen, are effective in relieving pain caused by synovitis; however, they must be used with caution because they may inhibit platelet function.

A regular program of exercise and physiotherapy is an important aspect of therapeutic management. Physical activity within reasonable limits strengthens muscles around joints and may decrease the number of spontaneous bleeding episodes.

Treatment without delay results in more rapid recovery and a decreased likelihood of complications; therefore, most children are treated at home. The family needs to be taught the technique of venipuncture and how to administer the AHF to children older than 2 to 3 years of age. The child can learn the procedure for self-administration at 8 to 12 years of age. Home treatment is highly successful; the rewards, in addition to the immediacy, are less disruption of family life, fewer school or work days missed, and enhancement of the child's self-esteem and independence.

Primary prophylaxis in patients with hemophilia has proved to be effective in preventing bleeding complications by administrating periodic factor replacement. Primary prophylaxis involves the infusion of factor VIII concentrate on a regular basis before the onset of joint or muscle damage. Secondary prophylaxis involves the infusion of factor VIII concentrate on a regular basis after the child experiences their first joint bleed. The infusions are given one or more times per week. Aggressive or on-demand factor replacement may be a cost-effective alternative to primary prophylaxis. This involves the infusion of a high dose of factor VIII concentrate when a joint bleed occurs, followed by 2 days of more standard doses of factor VIII concentrate, with consideration of additional treatment every other day for 1 week (Canadian Hemophilia Society, 2018a; Scott & Flood, 2020a). Prompt appropriate treatment of hemorrhage and prophylactic therapy are key to excellent care and prevention of long-term morbidity in patients with hemophilia.

Prognosis. Although there is no cure for hemophilia, its symptoms can be controlled and its potentially crippling deformities greatly reduced or even avoided. Today, many children with hemophilia function with minimal or no joint damage. They are healthy children with an average life expectancy in every respect but one: they tend to bleed, which is a significant inconvenience but not necessarily a life-threatening event.

Gene therapy may prove to be a treatment option in the future. This therapy involves introducing a working copy of the factor VIII gene into a patient who has a flawed copy of the gene. Challenges exist with appropriate selection of the **vector**, identification of the cell for gene expression, and control of adverse effects (Batty & Lillicrap, 2019; Scott & Flood, 2020a).

Nursing Care. The earlier a bleeding episode is recognized, the more effectively it can be treated. Signs that indicate internal bleeding are especially important to recognize. Children are aware of internal bleeding and are reliable in telling the examiner where an internal bleed is. In addition to the manifestations described (see Box 48.5), the nurse needs to maintain a high level of suspicion when a child with hemophilia demonstrates signs such as headache, slurred speech, loss of consciousness (from cerebral bleeding), and black tarry stools (from GI bleeding).

Preventing bleeding. Prevention of bleeding episodes is directed toward decreasing the risk of injury, which involves appropriate exercises to strengthen muscles and joints and allowing age-appropriate activity. During infancy and toddlerhood, the normal acquisition of motor skills creates innumerable opportunities for falls, bruises, and minor wounds. Restraining the child from mastering motor development can foster more serious long-term issues than allowing the behaviour. However, the environment should be made as safe as possible, with close supervision during playtime to minimize incidental injuries.

The family usually needs assistance in preparing older children for school. A nurse can be instrumental in assisting the family when planning an appropriate activity schedule to be discussed with teachers and coaches. The physical limitations in regard to active sports may be a difficult adjustment, and activity restrictions must be tempered with sensitivity to the child's emotional and physical needs. Use of protective equipment, such as padding and helmets, is particularly important; noncontact sports, especially recreational swimming, walking, jogging, fishing, bowling, cross-country skiing, golf, and dancing, should be encouraged.

To prevent oral bleeding, some readjustment in dental hygiene may be needed to minimize trauma to the gums, such as use of a water irrigating device, softening the toothbrush in warm water before brushing, or using a sponge-tipped disposable toothbrush. A regular toothbrush should be small and have soft bristles.

Because any trauma can lead to a bleeding episode, all persons caring for these children must be aware of their disorder. The children should wear medical identification, and older children should be encouraged to recognize situations in which disclosing their condition is important, such as during dental extraction or injections. Health care providers need to take special precautions to prevent the use of procedures that may cause bleeding, such as IM injections. The subcutaneous route is substituted for IM injections whenever possible. Venipunctures for blood samples are usually preferred for these children. There is usually less bleeding after the venipuncture than after finger or heel punctures. Neither Aspirin nor any Aspirin-containing compound should be used. Acetaminophen is a suitable Aspirin substitute, especially for controlling pain at home.

Recognizing and controlling bleeding. As noted, the earlier a bleeding episode is recognized, the more effectively it can be treated. Factor replacement therapy should be instituted according to established medical protocol, and supportive measures—such as *PRICE*, which stands for *P*rotection, *R*est, *I*ce, *C*ompression, and *E*levation—may be implemented. When parents and older children are taught such measures beforehand, they can be prepared to initiate immediate treatment. Plastic bags of ice or cold packs should be kept in the freezer for such emergencies. However, such measures do not take the place of factor replacement.

Preventing mobility effects of bleeding. As a result of repeated episodes of hemarthrosis, incompletely absorbed blood in the joints, and limitation of motion, bone and muscle changes occur that result in flexion contractures and joint fixation. During bleeding episodes, the joint is elevated and immobilized. Active range-of-motion exercises are usually instituted after the acute episode. This allows the child to control the degree of exercise and discomfort. If an exercise program is instituted in the home, a physiotherapist or community health nurse may need to supervise the regimen. Rarely, orthopedic intervention, such as casting, the application of traction, or the aspiration of blood, may be

necessary to preserve joint function. Diet is also an important consideration because excessive body weight can increase the strain on affected joints, especially the knees, and predispose the child to hemarthrosis. Consequently, calories need to be supplied in accordance with energy requirements.

Supporting the family and preparing for home care. Genetic counselling is essential as soon as possible after diagnosis. Unlike many other disorders in which both parents carry the trait, the feeling of responsibility for this condition usually rests with the mother, and it is important that they have the opportunity to discuss their feelings. Technology is now available to identify carriers in approximately 90 to 99% of cases and may reduce the anxiety regarding childbearing in persons who may be at risk of carrying the defective gene, such as sisters or maternal aunts of an affected male. Factor concentrates have greatly changed the outlook for these children by minimizing bleeding and allowing the child to live an unrestricted life. Children are taught to take responsibility for their disease at an early age. They learn their limitations, other preventive measures, and self-administration of the prophylactic AHF.

The needs of families who have children with hemophilia are best met through a comprehensive team approach of physicians (pediatrician, hematologist, orthopedist), dentist, nurse practitioner, nurse, social worker, and physiotherapist. Parent-group discussions are beneficial in meeting the needs often best met by similarly affected families. For example, with the improved prognosis for these children, parents and adolescents with hemophilia face vocational and financial challenges, in addition to concern over future childbearing. Financial support is particularly important, as a person with severe hemophilia may require factor replacement therapy and other medical treatments that cost in excess of $70 000 to $90 000 a year. The Canadian Hemophilia Society provides numerous services and publications for both health providers and families (see Additional Resources at the end of this chapter).

Immune Thrombocytopenia

Immune thrombocytopenia (ITP) (formerly called *idiopathic thrombocytopenic purpura*) is an acquired hemorrhagic disorder characterized by (1) thrombocytopenia, (2) excessive bruising or bleeding (easy bruising, mucosal bleeding, petechiae) in most childhood cases, and (3) normal bone marrow with a normal or increased number of immature platelets (megakaryocytes) and eosinophils. Although all causes of ITP are not known, it is understood that ITP involves the evolution of antibodies against multiple platelet antigens, leading to reduced platelet survival and impaired platelet production (Friedman et al., 2018/2020; McCrae, 2011). It is the most frequently occurring thrombocytopenia of childhood, affecting approximately 5 in 100 000 children per year. The greatest frequency of occurrence is between 2 and 5 years of age (Friedman et al., 2018/2020).

The disease occurs in one of two forms: an acute, self-limited course or a chronic condition (greater than 6 months' duration). The acute form is most often seen after viral infections such as chicken pox or a respiratory infection, immune disorders such as lupus, or as a reaction to a medication. Approximately 80% of these cases will naturally resolve in 6 to 12 months (Friedman et al., 2018/2020).

Diagnostic Evaluation. The diagnosis is suspected on the basis of clinical manifestations (Box 48.6). In ITP the platelet count is reduced to below 20×10^9/L; thus tests that depend on platelet function, such as the tourniquet test, bleeding time, and clot retraction, are abnormal. Although there is no definitive test on which to establish a diagnosis of ITP, several are usually performed to rule out other disorders in which thrombocytopenia is a manifestation, such as systemic lupus erythematosus, lymphoma, or leukemia.

BOX 48.6 Clinical Manifestations of Immune Thrombocytopenia

Easy bruising
- Petechiae
- Ecchymoses
- Most often over bony prominences

Bleeding from mucous membranes
- Epistaxis
- Bleeding gums

Internal hemorrhage evidenced by
- Hematuria
- Hematemesis
- Melena
- Hemarthrosis
- Menorrhagia

Therapeutic Management. Interprofessional care management of ITP is primarily supportive because the course of the disease is self-limited in most cases. Activity is restricted at the onset while the platelet count is low and while active bleeding or progression of lesions is occurring. Treatment for acute presentation is symptomatic and has included corticosteroids, IV immune globulin (IVIG), and anti-D antibody. These are not curative therapies. Anti-D antibody is generally not considered first-line therapy because of potential serious adverse effects and can only be used in Rh-positive children (Friedman et al., 2018/2020). The platelet count usually increases approximately 48 hours after an infusion of anti-D antibody; therefore, it is not appropriate therapy for patients who are actively bleeding. Tranexamic acid may be used as an adjunct therapy in children who are actively bleeding. A bone marrow examination is no longer necessary in children who present with typical features of ITP and have no other red flag symptoms (Friedman et al., 2018/2020).

! NURSING ALERT

After administration of anti-D antibody, observe the child for a minimum of 8 hours and maintain a patent IV line. Obtain baseline vital signs before the infusion and again 5, 20, and 60 minutes after beginning the infusion. Fever, chills, hematuria, and headache may occur during or shortly after the infusion. If these symptoms occur, diphenhydramine (Benadryl) and hydrocortisone (Solu-Cortef) should be given, and the patient observed for an additional hour.

Splenectomy is for patients who have chronic ITP that is not responsive to pharmacological management and have increased risk for severe hemorrhage. It is an option associated with long-term remission for these children and reduces the risk for hemorrhage (Scott & Flood, 2020b). Before considering splenectomy, it is generally recommended to wait until the child is older than 5 years of age because of the increased risk of bacterial infection. Pneumococcal and meningococcal vaccines are recommended before splenectomy. The child also receives penicillin prophylaxis after splenectomy. The length of prophylactic therapy is unsubstantiated, but in general, a minimum of 3 years is recommended.

Prognosis. Most children have a self-limited course without major complications. Approximately 20% of patients who present with acute ITP have persistent thrombocytopenia for greater than 12 months and are said to have chronic ITP and will require ongoing therapy (Scott & Flood, 2020b). A splenectomy may modify the disease process, and the child will be asymptomatic.

Nursing Care. Nursing care is largely supportive and should include teaching regarding possible adverse effects of therapy and limitation in activities while the child's platelet count is 50 to 100 $\times$ 10^9/L. Children with ITP should not participate in any contact sports, bike riding, skateboarding, in-line skating, gymnastics, climbing, or running. Parents should be encouraged to engage their children in quiet activities and prevent any injuries to the child's head. The harmful effects of using Aspirin and NSAIDs to control pain are critical for these children; therefore, salicylate substitutes (such as acetaminophen) are always used. Antihistamines should also be avoided as they increase the risk of bleeding. As in any condition with an uncertain outcome, the family needs emotional support.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC), also known as *consumption coagulopathy*, is characterized by diffuse fibrin deposition in the microvasculature, consumption of coagulation factors, and endogenous generation of thrombin and plasmin. DIC is a secondary disorder of coagulation that occurs as a complication of a number of pathological processes, such as hypoxia, acidosis, shock, endothelial damage (e.g., burns), and many severe systemic diseases (e.g., congenital heart disease, necrotizing enterocolitis, Gram-negative bacterial sepsis, rickettsial infections, and some severe viral infections). The hallmarks of this disorder are bleeding and clotting that occurs simultaneously.

Pathophysiology. DIC occurs when the first stage of the coagulation process is abnormally stimulated. Although no well-defined sequence of events occurs, two distinct phases can be identified. First, when the clotting mechanism is triggered in the circulation, thrombin is generated in greater amounts than can be neutralized by the body. Consequently, there is rapid conversion of fibrinogen to fibrin, with aggregation and destruction of platelets. If local and widespread fibrin deposition in blood vessels takes place, obstruction and eventual necrosis of tissues occur. The fibrinolytic mechanism is then activated, causing extensive destruction of clotting factors. With a deficiency of clotting factors, the child is vulnerable to uncontrollable hemorrhage into vital organs. An additional complication is damage and hemolysis of RBCs (Figure 48.5).

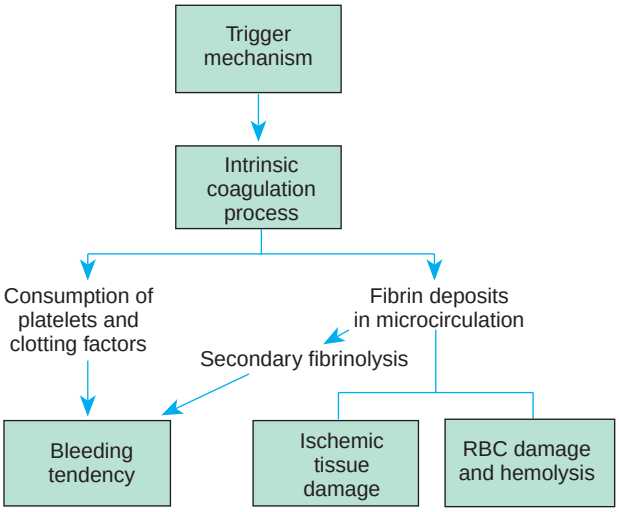

Fig. 48.5 Effects of disseminated intravascular coagulation. *RBC,* Red blood cell.

BOX 48.7 Clinical Manifestations of Disseminated Intravascular Coagulation

Petechiae
Purpura
Bleeding from openings in the skin
- Venipuncture site
- Surgical incision

Bleeding from umbilicus, trachea (newborn)
Evidence of gastrointestinal bleeding
Hypotension
Thrombosis
Organ dysfunction from infarction and ischemia

Diagnostic Evaluation. DIC is suspected when the patient has an increased tendency to bleed (Box 48.7). Hematological findings include prolonged prothrombin time (PT), PTT, serum fibrinogen, and D-dimer. Findings include a profoundly depressed platelet count, fragmented RBCs, and depleted fibrinogen.

Therapeutic Management. Treatment of DIC is directed toward control of the underlying or initiating cause, which in most instances stops the coagulation issue spontaneously. Platelets and fresh frozen plasma may be needed to replace lost plasma components, especially in the child whose underlying disease remains uncontrolled. The extremely ill newborn may require exchange transfusion with fresh blood. The IV administration of heparin to inhibit thrombin formation is most often restricted to patients who have not responded to treatment of the underlying disease or replacement of coagulation factors and platelets.

Nursing Care. The goals of nursing care are to be aware of the possibility of DIC in the severely ill child and to recognize signs that might indicate its presence. The skills needed to monitor IV infusion and blood transfusions and to administer heparin are the same as for any child receiving these therapies.

Epistaxis (Nose-Bleeding)

Isolated and transient episodes of epistaxis, or nose-bleeding, are common in childhood. The nose, especially the septum, is a highly vascular structure, and bleeding usually results from direct trauma, including blows to the nose, foreign bodies, and nose picking, or from mucosal inflammation associated with allergic rhinitis and upper respiratory tract infections. The bleeding ordinarily stops spontaneously or with minimal pressure and requires no medical evaluation or therapy.

Recurrent epistaxis and severe bleeding may indicate an underlying disease, particularly vascular abnormalities, leukemia, thrombocytopenia, and clotting factor–deficiency diseases (e.g., hemophilia, vWD). Nosebleeds are sometimes associated with administration of Aspirin, even in normal amounts. Persistent episodes of epistaxis require medical evaluation.

Nursing Care. In the event of a nosebleed, an essential intervention is to remain calm. Otherwise, the child will become more agitated, the blood pressure will increase, and they may resist treatment. Although in most instances a nosebleed is not serious, it can be upsetting to family members as well. They need reassurance that the loss of blood is not serious and that the bleeding usually stops within 10 to 15 minutes with nasal pressure.

To control the bleeding, the child is instructed to sit up and lean forward (not lie down) to avoid aspiration of blood. Most nose-bleeding

originates in the anterior part of the nasal septum and can be controlled by applying pressure to the soft lower portion of the nose with the thumb and forefinger (see Emergency box: Epistaxis). During this time, the child breathes through the mouth.

EMERGENCY

Epistaxis

- Have child sit up and lean forward (not lie down).
- Apply continuous pressure to nose with thumb and forefinger for at least 10 minutes.
- Insert cotton or wadded tissue into each nostril, and apply ice or cold cloth to bridge of nose if bleeding persists.
- Keep child calm and quiet.

In the event that hemorrhage continues, the child should be evaluated by a health care provider, who may pack the nose with topical tranexamic acid or decongestant or tranexamic acid–soaked gauze placed in the nostril (Smith et al., 2019). After a nosebleed, petroleum or water-soluble jelly can be inserted into each nostril to prevent crusting of old blood and to lessen the likelihood of the child's picking at the nose and restarting the hemorrhage. If a child has numerous nosebleeds, factors believed to increase the likelihood of bleeds should be eliminated, such as discouraging nose picking or altering the household humidity by placing a cool-mist humidifier in the child's room. Repeated bleeding episodes lasting longer than 30 minutes may be an indication to refer the child for evaluation for the possibility of a bleeding disorder.

NEOPLASTIC DISORDERS

Neoplastic disorders are the leading cause of death from disease in children past infancy, and almost half of all childhood cancers involve the blood or blood-forming organs. Leukemias and lymphomas are discussed here. Malignant solid tumours of childhood are discussed elsewhere in relation to the tissues or organs involved.

Leukemias

Leukemia is a broad term given to a group of malignant diseases of the bone marrow and lymphatic system. Research has revealed it to be a complex disease of varying heterogeneity. Consequently, classification has become increasingly complex, sophisticated, and essential, since identification of the subtype of leukemia has therapeutic and prognostic implications. The following is a brief overview of the major classification systems currently being used. Leukemia, a cancer of the blood-forming tissues, is the most common form of childhood cancer.

Morphology. In children, two forms are generally recognized: acute lymphoid leukemia (ALL) and acute myelogenous leukemia (AML). Synonyms for ALL include lymphatic, lymphoid, lymphocytic, and lymphoblastic leukemia. ALL is the most common form of childhood cancer, with an annual incidence of 3 to 4 cases per 100 000 children (Rabin et al., 2016). It is more common in males and White children, with the peak onset between 2 and 5 years of age (Rabin et al., 2016). It is one of the forms of pediatric cancer that has demonstrated dramatic improvements in survival rates. Five-year observed survival proportions for children with acute lymphoid leukemia now approaches 94% (Canadian Cancer Society, 2021b).

Synonyms for the AML type include granulocytic, myelocytic, monocytic, myelogenous, monoblastic, and monomyeloblastic. AML accounts for 20% of all cases of childhood leukemia and has an annual incidence of 8 cases per 1 million children (Arceci & Meshinchi, 2016). The incidence is similar for males and females, and higher rates are seen during the first year of life. Overall survival rates vary dramatically according to sex, race, and constitutional characteristics of the disease, with a nearly 64% survival rate (Arceci & Meshinchi, 2016; Canadian Cancer Society, 2021b).

The most recent incidence statistics for leukemia in children in Canada aged 0 to 14 years are from 2012 to 2016, which show that 985 Canadian children were diagnosed with ALL and 170 were diagnosed with AML (Canadian Cancer Society, 2021b).

Pathophysiology and Related Clinical Manifestations. Leukemia is an unrestricted proliferation of immature WBCs in the blood-forming tissues of the body. Although not a "tumour" as such, the leukemic cells demonstrate the same neoplastic properties as solid cancers. The resulting pathological condition and clinical manifestations are caused by infiltration and replacement of any tissue of the body with nonfunctional leukemic cells. Highly vascular organs, such as the spleen and liver, are the most severely affected.

To understand the pathophysiology of the leukemic process, it is important to clarify two common misconceptions. First, although leukemia is an overproduction of WBCs, most often in the acute form the leukocyte count is low (thus the term *leukemia*). Second, these immature cells do not deliberately attack and destroy the normal blood cells or vascular tissues. Cellular destruction takes place by infiltration and subsequent competition for metabolic elements. The following discussion elaborates on the pathological process and related clinical manifestations in the most susceptible organs of the body (Figure 48.6).

Bone marrow dysfunction. In all types of leukemia the proliferating cells depress the production of formed elements of the blood in bone marrow by competing for and depriving the normal cells of the essential nutrients for metabolism. The three main consequences are (1) anemia from decreased RBCs, (2) infection from **neutropenia**, and (3) bleeding from decreased platelet production. The invasion of the bone marrow with leukemic cells gradually causes a weakening of the bone and a tendency toward fractures. As leukemic cells invade the periosteum, increasing pressure causes severe pain. The most frequent presenting signs and symptoms of leukemia are a result of infiltration of the bone marrow. These include fever, pallor, fatigue, anorexia, hemorrhage (usually petechiae), and bone and joint pain. In the presence of neutropenia, the body's normal bacterial flora can become aggressive pathogens. Any break in the skin is a potential site of infection. Frequently, vague abdominal pain is caused by areas of inflammation from normal flora within the intestinal tract.

Disturbance of involved organs. The spleen, liver, and lymph glands demonstrate marked infiltration, enlargement, and eventually fibrosis. Hepatosplenomegaly is typically more common than lymphadenopathy.

The next most important site of involvement is the central nervous system (CNS). Less than 5% of patients with CNS involvement have B-cell ALL, and 10 to 20% of patients with CNS involvement have T-cell ALL (Rabin et al., 2016). The use of prophylactic CNS intrathecal therapy has dramatically decreased the incidence of CNS relapse in these patients.

Additional sites of involvement may be the cranial nerves (most often cranial nerve VII, or the facial nerve) and spinal nerves, particularly of the lumbosacral plexus, hypothalamus, and cerebellum. Clinical manifestations for these sites are directly related to the area involved. For example, with lumbosacral invasion, the patient has weakness in the lower extremities, pain radiating down the legs to the feet, and difficulty in voiding. Although such signs may suggest a brain tumour, the absence of localized signs often leads to the discovery of CNS

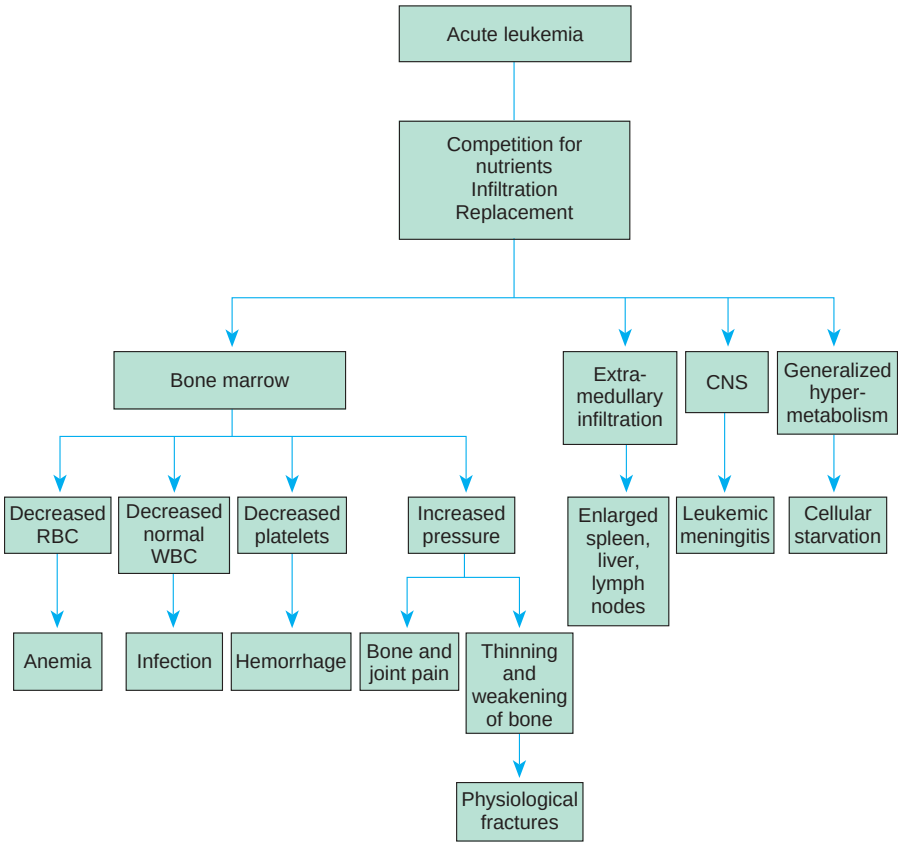

Fig. 48.6 Principal sites of tissue involvement in leukemia. *CNS,* Central nervous system; *RBC,* red blood cell; *WBC,* white blood cell.

involvement in leukemia. Other sites that may become invaded with leukemic cells include the kidneys, testes, prostate, ovaries, GI tract, and lungs.

Onset. The onset of leukemia varies from acute to insidious. In most instances, the child displays remarkably few symptoms. For example, leukemia may be diagnosed when a minor infection, such as a cold, fails to completely disappear. The child is pale, listless, irritable, febrile, and anorexic. Parents often suspect some underlying condition when they observe the weight loss, petechiae, bruising without cause, and continued statements of bone and joint pain.

At other times leukemia is diagnosed after an extended history of signs and symptoms mimicking such conditions as rheumatoid arthritis or mononucleosis. In some cases, the diagnosis of leukemia accompanies some totally unrelated event, such as a routine physical examination or injury.

The history not only yields valuable medical information regarding the subsequent course of the illness but also bears heavily on the parents' emotional reaction to the diagnosis. In most instances, the diagnosis is an unexpected revelation of catastrophic proportion.

Prognostic Factors. The most important prognostic factors for determining long-term survival for children with ALL (in addition to treatment) are (1) the initial WBC count, (2) the child's age at the time of diagnosis (except in T-cell ALL), (3) the type of cell involved, (4) the sex of the child, (5) karyotype analysis, and (6) presence of leukemia cells in the CNS at diagnosis (Canadian Cancer Society, 2021b). Children with a normal or low WBC count and who have non-T, non-B ALL have a much better prognosis than those with a high count or other cell types. Children diagnosed between 2 and 9 years of age have consistently demonstrated a better outlook than those diagnosed before 2 or after 10 years of age, and girls appear to have a more favourable prognosis than boys (Rabin et al., 2016).

Diagnostic Evaluation. Leukemia is usually suspected on the basis of the history and physical manifestations and a peripheral blood smear that contains immature forms of leukocytes, frequently combined with low blood counts. Definitive diagnosis is based on bone marrow aspiration or biopsy. Typically, the bone marrow shows a monotonous infiltrate of **blast cells**. Once the diagnosis is confirmed, a lumbar puncture is performed to determine whether there is any CNS involvement. Although only a small number of children have CNS involvement, they are usually asymptomatic.

Therapeutic Management. Treatment of leukemia involves the use of IV and intrathecal chemotherapeutic agents. Radiation is sometimes used for resistant CNS disease or testicular relapse. Typically leukemia treatment is divided into four phases: (1) *induction therapy*, which achieves a complete remission or less than 5% leukemic cells in the bone marrow; (2) *CNS prophylactic therapy*, which prevents leukemic cells from invading the CNS; (3) *intensification therapy* (or consolidation), which eradicates residual leukemia cells, followed by delayed intensification, which prevents emergence of resistant leukemic clones; and (4) *maintenance therapy*, which serves to maintain the remission phase. Although the combination of medications and possibility of irradiation may vary according to the institution, the patient's prognostic or risk characteristics, and the type of leukemia being treated, the following general principles for each phase are consistently employed.

Induction therapy. Almost immediately after confirmation of the diagnosis, induction therapy is begun and lasts for 4 to 5 weeks. A

complete remission is determined by the absence of clinical signs or symptoms of the disease and the presence of less than 5% blast cells in the bone marrow (Rabin et al., 2016).

Because many of the chemotherapy medications also cause myelosuppression of normal blood elements, the period immediately after a remission can be critical. The body is defenseless against invading organisms (especially normal bacterial flora) and susceptible to spontaneous hemorrhage. Consequently, supportive therapy during this time is essential.

Intensification or consolidation therapy. Intensification or consolidation therapy is used to further decrease the number of leukemic cells in the child's body. The intensification phase consists of pulses of chemotherapy medications given periodically during the first 6 months of treatment. The specific agents used for intensification therapy depend on the type of leukemia and the child's risk factors.

Maintenance therapy. The goal of maintenance therapy is to preserve remission and further reduce the number of leukemic cells. Combined medication regimens have been more successful in maintaining remissions and preventing drug resistance.

During maintenance therapy, weekly or monthly CBCs are taken to evaluate the marrow's response to the medications. If myelosuppression becomes severe or if toxic adverse effects occur, therapy is temporarily stopped or the dose decreased. Duration of therapy has been based on clinical experience comparing survival rates for various time intervals and is concerned with preventing deleterious effects of excessive treatment. Although the optimum time for discontinuing therapy is not known, current practice is to continue treatment for 2 to 3 years. After cessation of therapy, all children require regular medical evaluation for surveillance of relapse and long-term sequelae of treatment.

Central nervous system prophylactic therapy. Children with leukemia are at risk for invasion of the CNS by the leukemic cells. For this reason, many children receive CNS prophylactic therapy. Because of the concern regarding late effects of cranial irradiation and secondary malignancies, this mode of therapy is generally reserved for high-risk patients or those with resistant CNS disease.

Reinduction therapy after relapse. For many children, additional therapy becomes necessary when a relapse occurs, as evidenced by the presence of leukemic cells within the bone marrow. Although remissions may be achieved after more than one relapse, each relapse indicates an increasingly poor prognosis. However, more long-term second and subsequent remissions are occurring, and these may have better outlooks than previously thought.

A site that is resistant to chemotherapy and is responsible for leukemic relapse is the testes. A minority of males experience relapses during maintenance therapy or have occult disease after cessation of therapy. Treatment for testicular disease includes bilateral testicular irradiation and intensive systemic chemotherapy (Rabin et al., 2016).

Hematopoietic stem cell transplantation. HSCT has been used successfully for treating children who have ALL and AML. It is not recommended for children with ALL during the first remission because of the excellent results possible with chemotherapy. Because of the poorer prognosis in children with AML, HSCT may be considered during the first remission when a suitable donor is available (Gottschalk et al., 2016).

HSCT may be not only from antigen-matched related donors but also from matched unrelated or mismatched donors. Peripheral blood stem cell transplants are capable of differentiating into specialized cells of the hematological system and can be obtained from related or unrelated donors or from umbilical cord blood. Regardless of the type of transplant, it is accompanied by significant morbidity and mortality, including graft-versus-host disease (GVHD), overwhelming infection, or severe organ damage.

Late effects of treatment. Although vigorous treatment of childhood cancers has resulted in dramatically improved survival rates, increasing concern surrounds late effects—adverse changes related to treatment modalities—and recurrence of the disease process. Almost no organ is exempt, and almost every antineoplastic agent, especially irradiation, is responsible for some adverse effect.

The most devastating late effect is development of a second malignancy. Children who received cranial irradiation at age 5 years or younger are most susceptible to developing brain tumours (Landier et al., 2015). Treatment with an anthracycline is associated with cardiomyopathy; cranial irradiation and intrathecal chemotherapy are associated with endocrine, cognitive, and neuropsychological deficits; and alkylating agents are associated with bone mineral density deficits, which are just a few of the long-term sequelae (Landier et al., 2015). Consequently, close monitoring for late effects is essential.

Nursing Care. Nursing care of the child with leukemia is directly related to the therapeutic regimen. The Nursing Care Plan: The Child with Cancer is available on Evolve. Myelosuppression, medication toxicity, and leukemic infiltration cause secondary complications that necessitate supportive physical care. The following discussion focuses on supportive interventions for the child with leukemia and the family.

Preparing the child and family for diagnostic and therapeutic procedures. From the time before diagnosis to cessation of therapy, children must undergo several tests; the most traumatic tests are bone marrow aspiration, bone marrow biopsy, and lumbar punctures. Multiple finger sticks and venipunctures for blood analysis and medication infusion are common occurrences. The child needs an explanation of each procedure and what can be expected. In addition, effective pharmacological measures, including conscious and unconscious sedation, and nonpharmacological strategies can be used to reduce discomfort associated with these painful procedures (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44).

Relieving pain. The effective use of analgesia is especially important when the malignant process is uncontrolled and causes acute pain. Dosages of opioids are adjusted, or *titrated*, to the child's needs and administered *around the clock* for optimal pain control. Nonpharmacological strategies should be implemented as needed but are not substitutes for pharmacological management. For a review of the principles of pain assessment and management and specific discussion regarding cancer pain in children, see Chapter 34.

Preventing complications of myelosuppression. The leukemic process and most of the chemotherapeutic agents cause myelosuppression. The reduced numbers of blood cells result in secondary conditions of infection, bleeding tendencies, and anemia. Supportive care involves both medical and nursing management. Because these are so closely linked, they are discussed here together.

Preventing infection. A frequent complication of treatment for childhood cancer is overwhelming infection secondary to neutropenia. The child is most susceptible to overwhelming infection during three phases of the disease: (1) at the time of diagnosis and relapse when the leukemic process has replaced normal leukocytes, (2) during immunosuppressive therapy, and (3) after prolonged antibiotic therapy, which predisposes the child to the growth of resistant organisms. However, the use of granulocyte colony–stimulating factor (GCSF) has reduced the incidence and duration of infection in children receiving treatment for cancer.

The first defence against infection is prevention. When the child is hospitalized, the nurse needs to use all measures to help control transfer of infection. These typically include the use of a private room, restriction of all visitors and health personnel with active infection, and strict hand hygiene technique with an antiseptic solution. Other measures used to help protect the child against infection include having no live plants in the child's room, cleaning and sterilizing toys, and providing education to the parents and family about healthy and safe foods for the child to eat. In some centres special germ-free environments, called *reverse isolation*, are available during complete myelosuppression from intensive chemotherapy or for bone marrow transplant.

! NURSING ALERT

Live or attenuated viral vaccines are contraindicated in immunosuppressed children and should be deferred until the child's **immune system** function has returned to normal. The administration of an attenuated vaccine (MMR, oral polio) during immunosuppression may result in overwhelming infection. There is no special risk with the administration of inactivated vaccines (pneumococcal conjugate [PCV-13], TDaP, Hib); however, the child's immune system will likely not respond adequately. Siblings and other family members can receive all routine age-appropriate vaccines except oral polio. Prophylactic measures need only be taken if the vaccinated child develops wild-type varicella infection. Revaccination is recommended 3 to 6 months after completion of chemotherapy treatment (Government of Canada, 2020).

The child should be evaluated for potential sites of infection (e.g., mucosal ulcerations, skin abrasions, or skin tears, such as a hangnail) and observed for any elevation in temperature. To identify the source of infection, chest radiographs, blood, stool, urine, and nasopharyngeal cultures are taken. IV antibiotics need to be administered; if this therapy is prolonged, a venous access device, such as a peripherally or centrally inserted catheter or **intermittent infusion device** (saline lock or PRN adaptor), is used to maintain IV access.

Prevention of infection continues to be a priority after discharge from the hospital. Ordinarily, the child is allowed to return to school when the WBC count is at a satisfactory level, usually when the absolute neutrophil count (ANC) is $>1.0 \times 10^9$/L. Family members need to be encouraged to practise good hand hygiene at all times to keep from introducing **pathogens** into the home. The child may need to be isolated from school contacts in the event of an outbreak of a childhood disease, especially measles and chicken pox.

Nutrition is another important component of infection prevention. An adequate protein-caloric intake provides the child with better host defences against infection and increased tolerance to chemotherapy and irradiation. However, providing optimal nutrition during periods of anorexia and vomiting from chemotherapy is a tremendous challenge (see Feeding the Sick Child, Chapter 44).

Preventing and treating hemorrhage. Before the use of transfused platelets, hemorrhage was a leading cause of death in patients with leukemia. Now most bleeding episodes can be prevented or controlled with the administration of platelet concentrates or platelet-rich plasma.

Skin punctures should be avoided whenever possible because bleeding sites can become easily infected. When finger sticks, venipunctures, IM injections, and bone marrow aspirations are performed, aseptic technique must be used, along with continued observation for bleeding. Meticulous mouth care is essential, since gingival bleeding with resultant mucositis is a frequent issue. Because the rectal area is prone to ulceration from various medications, feces and urine are to be removed immediately and the perianal area washed. Use of rectal thermometers should be avoided to prevent trauma. Children should be advised to avoid activities that might cause injury or bleeding, such as riding bicycles or skateboards, climbing trees or playground equipment, and playing contact sports.

Platelet transfusions are generally reserved for active bleeding episodes that do not respond to local treatment and that may occur during induction or relapse therapy. Epistaxis and gingival bleeding are most common. The nurse needs to teach parents and older children measures to control nose-bleeding (see discussion earlier in chapter). Pressure at the site without disturbing clot formation is the general rule.

Managing anemia. Initially, anemia may be profound from complete replacement of the bone marrow by leukemic cells. During induction therapy, blood transfusions may be necessary. The usual precautions in caring for the child with anemia are instituted (see discussion earlier in chapter).

Using precautions in administering and handling chemotherapeutic agents. In addition to the nurse's many responsibilities in regard to the child and family, nurses must also use safeguards to protect themselves. Handling chemotherapeutic agents may present risks to handlers and their offspring, although the exact degree of risk is not known. Many chemotherapeutic agents are vesicants (sclerosing agents) that can cause severe cellular damage if even a minute amount of the drug infiltrates surrounding tissue. Only nurses who are both certified and experienced with chemotherapeutic agents should administer vesicants. Guidelines are available and must be followed exactly to prevent tissue damage to patients.

In addition to extravasation, a potentially fatal complication is anaphylaxis, especially from L-asparaginase, teniposide (VM-26), etoposide (VP-16), bleomycin, and cisplatin. Nursing responsibilities include prevention of, recognition of, and preparation for serious reactions. Prevention begins with a careful history of known allergies.

Most children with cancer have a venous access device, which facilitates administration of IV medications. During treatment and remission, many medications are taken orally at home. Adherence to the medication schedule is essential; nurses play an important role in educating the family about the medications and encouraging adherence to the plan.

! NURSING ALERT

Chemotherapeutic medications must be given through a free-flowing IV line. The infusion is stopped immediately if any sign of infiltration (pain, stinging, swelling, or redness at the cannulation site) occurs. When chemotherapeutic and immunological agents are given, the child must be observed for 30 minutes after the infusion for signs of anaphylaxis (cyanosis, hypotension, wheezing, severe urticaria). Emergency equipment (especially a blood pressure monitor and bag-valve-mask) and emergency medications (especially oxygen, epinephrine, antihistamine, aminophylline, corticosteroids, and vasopressors) must be readily available. If a reaction is suspected, the medication is discontinued, the IV line is flushed with saline, and the child's vital signs and subsequent responses are closely monitored.

Managing symptoms of medication toxicity. Chemotherapy presents several nursing challenges. The complexity of the treatment protocols is often overwhelming to families. In addition, each therapy is associated with a number of predictable adverse effects. Nurses must be aware of these effects and use clinical judgement in recognizing reactions and toxicities.

Nausea and vomiting. The nausea and vomiting that occur shortly after administration of several of the medications and from cranial or abdominal radiation can be profound. The serotonin-receptor

antagonists (e.g., ondansetron, granisetron) are effective in the control of nausea and vomiting after emetogenic chemotherapy and radiotherapy. When combined with dexamethasone, these medications are the treatment of choice in the prevention of delayed emesis (Sherani et al., 2019).

The most beneficial regimen for antiemetic control has been administration of the antiemetic before the chemotherapy begins. The goal is to prevent the child from ever experiencing nausea or vomiting, thus preventing development of anticipatory symptoms (the conditioned response of developing nausea and vomiting *before* receiving the medication).

Anorexia. Loss of appetite is a direct consequence of the chemotherapy or irradiation. It is a major concern for parents because it is the one area they feel responsible for, particularly when so many other facets of care are outside their control. There are no universally successful techniques for encouraging a sick child to eat. However, the guidelines in Chapter 44 can be helpful during the anorexic period and can prevent additional adverse effects during the remission.

Some children still do not eat despite these approaches. When loss of appetite and weight persist, the nurse should investigate the family situation to determine whether any factors (e.g., conditioned aversion to food, environmental stress related to eating, controlling behaviour, anger) might be contributing to the child's not eating. Nasogastric tube feedings or total parenteral nutrition may be implemented for children with significant nutritional challenges.

Mucosal ulceration. One of the most distressing adverse effects of several medications is GI mucosal cell damage, which can produce ulcers anywhere along the alimentary tract. Oral ulcers greatly compound anorexia because eating is extremely uncomfortable. The following interventions may be helpful:

- Provide a bland, moist, soft diet appropriate for the child's age and preferences.
- Use a soft sponge toothbrush (Toothettes) or cotton-tipped applicator.
- Provide frequent mouthwashes with normal saline (using a solution of 5 mL of table salt and 500 mL of water) or sodium bicarbonate mouth rinses (using a solution of 5 mL of baking soda in 1 000 mL of water).
- Use local anaesthetics (e.g., Chloraseptic lozenges) or nonprescription preparations without alcohol (e.g., hydrocortisone dental paste [Orabase], antiseptic mouth rinse [UlcerEase], diphenhydramine [Benadryl], and aluminum and magnesium hydroxide [Maalox] solution).

Although local anaesthetics are effective in temporarily relieving the pain, many children dislike the taste and numb feeling they produce.

! NURSING ALERT

Viscous lidocaine is not recommended for young children; if applied to the pharynx, it may depress the gag reflex, increasing the risk of aspiration.

Other preparations that may be used to prevent or treat mucositis include chlorhexidine gluconate (Peridex) because of its dual effectiveness against candidal and bacterial infections; antifungal troches (lozenges) or mouthwash; and lip balm (e.g., Aquaphor), to keep the lips moist. Agents that should not be used include lemon glycerin swabs (which irritate eroded tissue and can decay teeth), hydrogen peroxide (which delays healing by breaking down protein), and milk of magnesia (which dries mucosa).

Stomatitis may cause such difficulty with eating that the child may require hospitalization for hydration, parenteral nutrition, and pain control (often with IV morphine). The child will usually choose the foods that are best tolerated, and the nurse should encourage parents to relax any eating pressures. Because the stomatitis is a temporary condition, the child can resume good food habits after the ulcers heal. Dental hygiene can become a serious issue for children with orthodontic appliances. Sometimes it may be necessary to remove the braces to allow chemotherapy to continue.

Rectal ulcers are managed by meticulous toilet hygiene, warm sitz baths after each bowel movement, and the use of an occlusive ointment or dressing applied to the ulcerated area to promote epithelialization. Stool softeners are necessary to prevent further discomfort. Parents should record bowel movements because the child may voluntarily avoid defecation to prevent discomfort. Rectal thermometers and suppositories are contraindicated because insertion may further traumatize the area.

Neuropathy. Vincristine and, to a lesser extent, vinblastine can cause various neurotoxic effects. Nursing interventions for management of these effects include the following:

- Administering stool softeners or laxatives for severe constipation caused by decreased bowel innervation
- Maintaining good body alignment and, if the patient is on bed rest, using a footboard or high-top shoes to minimize or prevent footdrop
- Carrying out safety measures during ambulation because of weakness and numbing of the extremities, which may cause difficulty in walking or fine hand movement
- Providing a soft or liquid diet for severe jaw pain

Hemorrhagic cystitis. Sterile hemorrhagic cystitis, an adverse effect of chemical irritation to the bladder from cyclophosphamide, can be decreased and often prevented by (1) promoting a liberal fluid intake (at least one and a half times the recommended daily fluid requirement); (2) frequent voiding immediately after feeling the urge, before bed, and after arising; (3) administering the medication early in the day to allow for sufficient oral intake and voiding; and (4) administering mesna (an agent that provides protection to the bladder) as ordered. If oral home administration is prescribed, the family needs specific instructions in exactly how much fluid the child must have.

Alopecia. Hair loss is a common adverse effect of several chemotherapeutic medications and cranial irradiation, although not all children lose their hair during pharmacological therapy. It is better to warn children, adolescents, and parents of this effect than to allow them to think that it is only a remote possibility. A soft cotton cap is the most comfortable head wear for children. Polyester increases perspiration and causes itching. Other options include scarves, hats, or a wig.

The nurse should also inform the family that hair regrows in 3 to 6 months and may be of a different colour and texture. Frequently the hair is darker, thicker, and curlier than before. If the child chooses not to wear a wig, attention to some type of head covering, especially in cold climates and during exposure to sun, and scalp hygiene are important. The scalp should be washed like any other body part.

Steroid effects. Short-term steroid therapy produces no acute toxicities and two beneficial reactions: increased appetite and a sense of well-being. However, it does produce alterations in appearance, which, although not clinically significant, can be distressing to older children and adolescents. One of these is "moon face," in which the child's face becomes rounded and puffy. It is helpful to reassure the child that, after cessation of the medication, the facial shape will return to normal. Unlike hair loss, little can be done to camouflage this obvious change. If the child resumes activity early in the course of treatment, the change may be less noticeable to peers than after a long absence.

Mood changes. Shortly after beginning steroid therapy, children experience a number of mood changes that range from feelings of well-being and euphoria to depression and irritability. If parents are

unaware of these medication-induced changes, they may become unduly concerned. The nurse should warn them of the reactions and encourage them to discuss the behavioural changes with each other and the child.

Providing emotional support. An important aspect of continued emotional support involves the prognosis. Although leukemia is no longer invariably fatal, it must be remembered that survival statistics are only average estimates and apply to children treated with the latest protocols since diagnosis. For the low-risk child the chances may be better, but for the high-risk child they may be significantly poorer. Of those who do survive after discontinuing therapy, some relapse. Only the passage of time is positive confirmation of the child being ultimately "cured" of the disease. Remission, even in excess of 5 years, cannot be equated with a cure. With increasing concern regarding late effects of treatment, continued surveillance of the child's health status is needed. The nurse working with family members must individualize information regarding the "numbers" and the potential risks. An understanding of each member's emotional needs, as well as competent care of physical ones, is essential to the positive, growth-promoting support of the family. Comprehensive emotional support for the family of the child with a potentially fatal illness is discussed in Chapter 41.

Lymphomas

Pediatric lymphomas are the third most common group of malignancies in children and adolescents. The lymphomas, a group of neoplastic diseases that arise from the lymphoid and hematopoietic systems, are divided into Hodgkin disease and non-Hodgkin lymphoma (NHL). These diseases are further subdivided according to tissue type and the extent of disease. NHL is more prevalent in children younger than 14 years of age, whereas Hodgkin disease is prevalent in adolescence and the young-adult period, with a striking increase in incidence between ages 15 and 19 years.

Hodgkin Disease. Hodgkin disease is a neoplastic disease that originates in the lymphoid system and primarily involves the lymph nodes. It predictably metastasizes to non-nodal or extralymphatic sites, especially the spleen, liver, bone marrow, and lungs, although no tissue is exempt from involvement (Figure 48.7). It is classified according to four histological types: (1) lymphocytic predominance, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocytic depletion. With present treatment protocols, the histological stage of the disease has less prognostic significance.

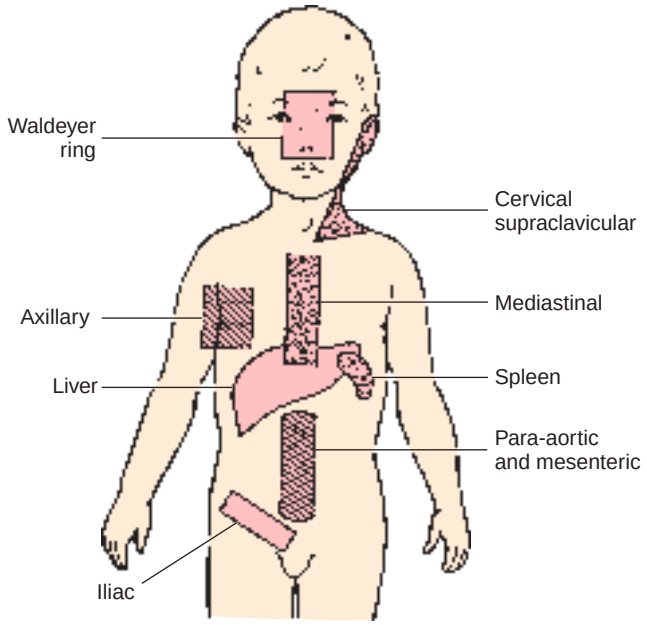

Fig. 48.7 Main areas of lymphadenopathy and organ involvement in Hodgkin disease.

Staging and prognosis. The Ann Arbor and Lugano staging systems assign a stage based on the number of sites of lymph node involvement, presence of extranodal disease, and history of any symptoms. Patients are classified as A if asymptomatic; B if they have the following symptoms: fever, drenching night sweats, or unexplained loss of body weight (10% or more) over the preceding 6 months; E if the lymphoma has spread to an extranodal site; S if the lymphoma has spread to the spleen; and X if there is the presence of "bulky" disease (Canadian Cancer Society, 2021a).

The prognosis for patients with Hodgkin disease has improved dramatically, largely as a result of the systematic staging procedure and improved treatment protocols. Long-term survival for all stages of Hodgkin disease is excellent. Early-stage disease can have survival rates greater than 90%, with advanced stages having rates between 65 and 80%. In Canada, the 5-year observed survival for Hodgkin lymphoma in children 0 to 14 years of age is 97% (Canadian Cancer Society, 2021a). Even in those with disseminated disease, long-term remissions are possible in more than one half of patients. For relapses, complete remission may occur in 30 to 60% of patients undergoing autologous stem cell transplant (Metzger et al., 2016).

Clinical manifestations. Hodgkin disease is characterized by painless enlargement of lymph nodes. The most common finding is enlarged, firm, nontender, movable nodes in the supraclavicular or cervical area. In children, the sentinel node located near the left clavicle may be the first enlarged node. Enlargement of axillary and inguinal lymph nodes is less frequent (see Figure 48.7).

Other signs and symptoms depend on the extent and location of involvement. Mediastinal lymphadenopathy may cause a persistent, nonproductive cough. Enlarged retroperitoneal nodes may produce unexplained abdominal pain. Systemic symptoms include low-grade or intermittent fever (Pel-Ebstein disease), anorexia, nausea, weight loss, night sweats, and pruritus. Generally, such symptoms indicate advanced lymph node and extralymphatic involvement.

Diagnostic evaluation. The history and physical examination often yield important clues to the disease, such as fevers, night sweats, weight loss, and enlarged lymph nodes, spleen, or liver. Because of the multiple organs that can become involved, diagnosis consists of several tests to confirm the presence of Hodgkin disease and to assess the extent of involvement for accurate staging. Tests include CBC, uric acid levels, liver function tests, erythrocyte sedimentation rate or C-reactive protein, alkaline phosphatase, and urinalysis. Radiographic tests include computed tomography (CT) scans of the neck, chest, abdomen, and pelvis; a gallium or positron emission tomography (PET) scan (to identify metastatic or recurrent disease); a chest X-ray; and, if clinically indicated, a bone scan to detect metastasis.

A lymph node biopsy is essential to establish histological diagnosis and staging. The presence of Reed-Sternberg cells is considered diagnostic of Hodgkin disease because it is absent in the other lymphomas; however, it may occur in infectious mononucleosis. A bone marrow aspiration or biopsy is also usually performed.

Therapeutic management. The primary modalities of therapy are chemotherapy and irradiation. Each may be used alone or in combination based on the clinical staging. The goal of treatment is obviously a cure; however, aggressive therapy increases the chances of complications in the disease-free state and can seriously compromise quality of life. Consequently, numerous research studies are currently investigating treatment options to minimize long-term complications. One of the major concerns with combined radiation and antineoplastic

medication therapy is the serious late effects in children with an excellent prognosis.

Radiation may entail involved field radiation, extended field radiation (involved areas plus adjacent nodes), or total nodal irradiation (the entire axial lymph node system), depending on the extent of involvement. In stage IV disease, chemotherapy is the primary form of treatment, although limited irradiation may be given to areas of bulky disease.

Follow-up care of children no longer receiving therapy is essential to identify relapse and second malignancies. In children with splenectomy because of laparotomy, prophylactic antibiotics are administered for an indefinite period. Also, immunizations against pneumococci and meningococci are recommended before the splenectomy.

Nursing care. Nursing care involves preparation for diagnostic and operative procedures, explanation of treatment adverse effects, and child and family support. Once the child is hospitalized for suspected Hodgkin disease, a battery of diagnostic tests is ordered. The family needs an explanation of why each test is performed, because many of them, such as bone marrow aspiration and lymph node biopsy, are invasive procedures (see Chapter 44, Bone Marrow Aspiration or Biopsy). Because this is most often a disease of adolescents and young adults, the nurse must have an appreciation of their psychological needs and reactions during the diagnostic and treatment phases.

Explanations of chemotherapeutic reactions vary with the specific medication regimen. The most common adverse effects, such as nausea and vomiting, body image changes, neuropathy, and mucosal ulceration, are discussed in the Managing Symptoms in Leukemia section earlier in this chapter. Radiation results in few adverse effects, sometimes consisting only of a mild skin reaction. With external field radiation to the chest and abdomen, nausea and vomiting, weight loss, and mucosal ulceration (e.g., esophagitis, gastric ulcers) are common.

The most common adverse effect of extensive irradiation is malaise, which may result from damage to the thyroid gland, causing hypothyroidism. Lack of energy is particularly difficult for adolescents because it prevents them from keeping up with their peers. Regular bedtimes and periodic rest times are important for these children, especially during chemotherapy, when myelosuppression increases the risk for infection and debilitation. Before discharge, the nurse should discuss a feasible school schedule with the parents and child. If alterations are necessary (such as elimination of strenuous physical education), parents are encouraged to discuss this with school personnel. Follow-up care is essential to diagnose hypothyroidism early and institute thyroid replacement.

An area of concern for adolescents is the high risk of sterility from irradiation and chemotherapy. Both medications, particularly procarbazine and alkylating agents, and irradiation to the gonads can lead to infertility. Adolescents should be informed of these adverse effects early in the course of the diagnosis and treatment. Sperm banking and egg freezing are now offered through various referral programs before the initiation of treatment in adolescents. Sexual function is not altered, although the appearance of secondary sexual characteristics and menstruation may be delayed in the pubescent child. Delayed sexual maturation may be a sensitive and stressful issue for children and teenagers.

Non-Hodgkin Lymphoma. NHL occurs more frequently in children than Hodgkin disease. In Canadian children and adolescents under the age of 15, lymphoma remains the third most commonly diagnosed cancer. The most recent Canadian statistics for NHL in children aged 0 to 14 years are from 2012 to 2016, with 160 Canadian children being diagnosed with the disease (Canadian Cancer Society, 2021c).

Staging and prognosis. NHL is heterogeneous, exhibiting a variety of morphological, cytochemical, and immunological features, not unlike the diversity seen in leukemia. Classification is based on the pattern of histological presentation: lymphoblastic, Burkitt or non-Burkitt, or large cell. Immunologically these cells are also classified as T cells; B cells (an example of which is Burkitt lymphoma); or non-T, non-B cells, which lack specific immunological properties.

The clinical staging system used in Hodgkin disease is of little value in NHL, although that system has been modified for NHL and other systems have been developed. A favourable prognosis is defined by young age, low stage without mediastinal involvement, low tumour burden, and good response to initial therapy (Allen et al., 2016). The St. Jude Staging system is commonly used to stage or classify lymphoblastic and anaplastic lymphomas:

- Stage 1: The lymphoma is in a group of lymph nodes but not located in the chest or abdomen.
- Stage 2: The lymphoma is not located in the chest but is located outside of lymph nodes, above or below the diaphragm, or in the digestive tract.
- Stage 3: Lymphoma is located outside of lymph nodes, above and below the diaphragm, in the chest, abdomen, and close to the spine.
- Stage 4 is lymphoma found within the brain, spinal cord, and/or bone marrow.

The prognosis is excellent for children with localized disease, with an almost 100% cure rate; 75 to 90% of children with extensive disease are cured (Allen et al., 2016). Because relapse after 2 years is rare, survival after 24 months is considered a cure. Nonetheless, between the years 2013 to 2017, 28 Canadian children died from NHL (Canadian Cancer Society, 2021c).

Clinical manifestations. Clinical manifestations depend on the anatomical site and extent of involvement. Many of the manifestations seen in Hodgkin disease may be present in NHL, although rarely does a single symptom give rise to the diagnosis. Rather, metastasis to the bone marrow or CNS may produce signs and symptoms typical of leukemia. Lymphoid tumours compressing various organs may cause intestinal or airway obstruction, cranial nerve palsies, or spinal paralysis.

Diagnostic evaluation. Current recommendations for staging include a surgical biopsy for histopathological confirmation of disease with immunophenotyping and cytogenetic evaluation; bone marrow aspiration; radiological studies, especially CT scans of the lungs and GI organs; and lumbar puncture.

Therapeutic management. The present treatment protocols for NHL include an aggressive approach using irradiation and chemotherapy. Similar to leukemic therapy, the protocols include induction, consolidation, and maintenance phases, some with intrathecal chemotherapy. Children with nonlymphoblastic lymphoma are treated with cyclic medication combinations and combination intrathecal chemotherapy. These multiagent regimens are administered for 6 to 24 months.

Nursing care. Nursing care of the child with NHL is similar to that required for children with leukemia. Many of the same medications are used, although the schedules differ. Because of the intense chemotherapy, nursing care is primarily directed toward managing the adverse effects of these agents and providing supportive care to the child and family (see Nursing Care Plan: The Child with Cancer, available on Evolve).

IMMUNOLOGICAL DEFICIENCY DISORDERS

A number of disorders can cause profound, often life-threatening alterations within the body's immune system. The most serious are conditions that completely depress immunity, such as severe combined immunodeficiency disease (SCID). However, the one disorder that

generates the most anxiety, within both the family and the community at large, is HIV infection and the subsequent development of AIDS.

Several classifications of immune dysfunction exist. AIDS, SCID, and Wiskott-Aldrich syndrome (WAS) are syndromes in which the body is unable to mount an immune response. The immune response can also be misdirected. In **autoimmune disorders**, antibodies, macrophages, and lymphocytes attack healthy cells.

HIV Infection and Acquired Immunodeficiency Syndrome

HIV infection and AIDS have generated intense medical investigation and constitute one of world's most serious medical, public health, and social challenges of our time. Research has led to early diagnosis and improved medical treatments for HIV infection, changing this disease from a rapidly fatal one to a chronic disease.

Epidemiology. The principal modes of HIV transmission to the pediatric population are mother-to-child transmission and adolescent risky behaviours such as sexual activity and IV drug use.

The number of newborns born with HIV is decreasing in Canada due to implementation of recommended HIV counselling and voluntary testing practices, optimal prenatal, antenatal and postpartum care, and the use of antiretroviral therapy (ART) to prevent perinatal transmission (see Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome, Chapter 15). Current vertical transmissions rates in Canada from infected mother to infant are well below 2% if the pregnant person is appropriately treated during pregnancy and labour (Moore et al., 2019/2021).

Unsafe sexual activity and IV drug use are major sources of HIV infection in adolescents and young adults. Youth between the ages of 15 and 29 years comprised 23% of all reports of HIV-positive status in 2017 (Challacombe, 2020). Children less than 15 years of age had the lowest average rate of HIV infection in Canada between 2013 and 2017 (Haddad et al., 2018).

Etiology. HIV is a retrovirus that is transmitted by lymphocytes and monocytes. It is found in the blood, semen, rectal fluid, vaginal secretions, and breast milk. It has an incubation or latency period of months to years (Government of Canada, 2016). There are different strains of HIV. HIV-2 is prevalent in Africa, whereas HIV-1 strain B is the dominant strain in Canada. *Horizontal transmission* of HIV occurs through intimate sexual contact or parenteral exposure to blood or body fluids containing visible blood. *Perinatal (vertical) transmission* occurs when an HIV-infected pregnant person passes the infection to their infant.

Pathophysiology. The HIV virus primarily infects a specific subset of T lymphocytes, the CD4 T cells, but it can also invade cells of the monocyte-macrophage lineage. The virus takes over the machinery of the CD4 lymphocyte, using it to replicate itself, rendering the CD4 cell dysfunctional. The CD4 lymphocyte count gradually decreases over time, leading to progressive immunodeficiency. The count eventually reaches a critical level below which there is substantial risk of opportunistic illnesses, followed by death.

Clinical Manifestations. Common clinical manifestations of HIV infection in children are varied (Box 48.8). The diagnosis of AIDS is associated with certain illnesses or conditions. The most common AIDS-defining conditions observed among Canadian children are listed in Box 48.9. Other manifestations in these children may include short stature, malnutrition, and cardiomyopathy. CNS abnormalities resulting from HIV infection may include neuropsychological deficits; developmental disabilities; and impairments in motor skills, communication, and behavioural functioning.

BOX 48.8 Common Clinical Manifestations of HIV Infection in Children

- Lymphadenopathy
- Hepatosplenomegaly
- Oral candidiasis
- Chronic or recurrent diarrhea
- Failure to thrive
- Developmental delay
- Behavioural abnormalities
- Parotitis

BOX 48.9 Common Defining Conditions for AIDS in Children

- *Pneumocystis carinii* pneumonia
- Lymphoid interstitial pneumonia, pulmonary lymphoid hyperplasia, or both
- Recurrent bacterial infections
- Wasting syndrome
- Candidal esophagitis
- Human immunodeficiency virus encephalopathy
- Cytomegalovirus disease
- *Mycobacterium avium-intracellulare* complex infection
- Pulmonary candidiasis
- Herpes simplex disease
- Cryptosporidiosis

Diagnostic Evaluation. For children 18 months of age and older, the HIV enzyme-linked immunosorbent assay (ELISA) and Western blot immunoassay are performed to determine HIV infection. In infants born to HIV-infected mothers, these assays will be positive because of the presence of maternal antibodies derived transplacentally. Maternal antibodies may persist in infants up to 18 months of age. Thus other diagnostic tests are used, most commonly the HIV polymerase chain reaction (PCR) for detection of proviral DNA. Recombinase polymerase amplification (RPA) is a technology that is ideal for early infant diagnosis of HIV-1, because it amplifies target DNA in less than 20 minutes at a constant temperature without the need for complex thermocycling equipment needed for the PCR assay (Boyde et al., 2013). RPA may become a beneficial yet inexpensive test for early diagnosis of HIV-infected individuals worldwide. Further research is needed to compare the RPA assay to the gold-standard PCR-based assay in a real-world setting. With these techniques, almost all infected infants can be diagnosed between 1 and 6 months of age.

The Centers for Disease Control and Prevention (1994) developed a classification system that is still used to describe the spectrum of HIV disease in children (Table 48.2). The system indicates the severity of clinical signs and symptoms and the degree of immunosuppression. The nonsymptomatic category includes either no signs and symptoms or one of the conditions listed in the mildly symptomatic category. Mild signs and symptoms include lymphadenopathy, parotitis, hepatosplenomegaly, and recurrent or persistent sinusitis or otitis media. Moderate signs and symptoms include lymphoid interstitial pneumonitis (LIP) and a variety of organ-specific dysfunctions or infections. Severe signs and symptoms include AIDS-defining illnesses with the exception of LIP. Children with LIP have a better prognosis than those with other AIDS-defining illnesses. In children whose HIV infection is not yet confirmed, the letter *E* (vertically exposed) is placed in front of

TABLE 48.2 Pediatric HIV Infection Classification*

Immunological Category	N: No Signs/ Symptoms	A: Mild Signs/ Symptoms	B: Moderate Signs/ Symptoms	C: Severe Signs/ Symptoms
No evidence of suppression	N1	A1	B1	C1
Evidence of moderate suppression	N2	A2	B2	C2
Severe suppression	N3	A3	B3	C3

*Children whose HIV infection status is not confirmed are classified by using the above table with the letter *E* (for perinatally exposed) placed before the appropriate classification code (e.g., EN2).
From Centers for Disease Control and Prevention. (1994). 1994 revised classification system for human immunodeficiency virus infection in children less than 13 years of age. *MMWR: Recommendations & Reports, 43*(RR-12), 1–10.

the classification. The immune categories are based on CD4 lymphocyte counts and percentages.

Therapeutic Management. The interprofessional care team establishes goals of therapy for HIV infection, include slowing the growth of the virus, preventing and treating **opportunistic infections**, and providing nutritional support and symptomatic treatment. Antiretroviral medications work at various stages of the HIV life cycle to prevent reproduction of functional new virus particles. Although not a cure, these medications can suppress viral replication, preventing further deterioration of the immune system, thus delaying disease progression. Classes of antiretroviral agents include nucleoside reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), integrase strand transfer inhibitors (INSTIs), protease inhibitors (PIs), fusion inhibitors, CCR5 antagonists, and postattachment inhibitors. Combinations of antiretroviral medications are used to forestall the emergence of drug resistance. ART regimens and guidelines are continually evolving. Therapy is lifelong, which can be difficult for some patients. Laboratory markers (CD4 lymphocyte count, viral load) assist in monitoring both disease progression and response to therapy. The Canadian Paediatric Society (CPS) (Robinson & CPS, Infectious Diseases and Immunization Committee, 2010/2018) recommends following the US Panel on Antiretroviral Therapy and Medical Management of Children Living with HIV (2020) clinical guidelines for the management of HIV.

Pneumocystis carinii pneumonia (PCP) is the most common opportunistic infection of children infected with HIV. It occurs most frequently between 3 and 6 months of age. All infants born to HIV-infected women should receive prophylaxis during the first year of life (Panel on Antiretroviral Therapy and Medical Management of Children Living with HIV, 2020). Trimethoprim-sulfamethoxazole (TMP-SMZ) is the agent of choice. If adverse effects are experienced with TMP-SMZ, dapsone or pentamidine can be used.

Prophylaxis is often used for other opportunistic infections, such as disseminated *Mycobacterium avium-intracellulare* complex (MAC), candidiasis, or herpes simplex. IVIG has been helpful in preventing recurrent or serious bacterial infections in some HIV-infected children.

Immunization against common childhood illnesses is recommended for all children exposed to and infected with HIV, including Hib (*Haemophilus influenzae* type b), pneumococcal and meningococcal conjugates, and hepatitis A and B (Government of Canada, 2020). Varicella (chicken pox) vaccine, MMR vaccine, and herpes zoster vaccine can be administered if there is no evidence of severe immunocompromise. Because antibody production to vaccines may be poor or decrease over time, immediate prophylaxis after exposure to several vaccine-preventable diseases (e.g., measles, varicella) is warranted. Children receiving IV gamma-globulin (IVGG) prophylaxis may not respond to the MMR vaccine if given in close proximity to the IVGG dose (BC Centre for Disease Control, 2021).

HIV infection often leads to marked failure to thrive and multiple nutritional deficiencies. Nutritional management may be difficult because of recurrent illness, diarrhea, and other physical challenges. Intensive nutritional interventions should be instituted when the child's growth begins to slow or weight begins to decrease.

Prognosis. As noted above, early recognition and improved medical care have changed HIV disease from being a rapidly fatal illness to a chronic disease. After the introduction of combination ART, the numbers of new AIDS cases and deaths declined substantially.

Nursing Care. Education concerning transmission and control of infectious diseases, including HIV infection, is essential for children with HIV infection and anyone involved in their care. The basic tenets of routine practices should be presented in an age-appropriate manner, with careful consideration of the educational levels of the individuals (see Infection Control, Chapter 44). Safety issues, including appropriate storage of special medications and equipment (e.g., needles and syringes), need to be emphasized.

Unfortunately, relatives, friends, and the general public may be fearful of contracting HIV infection, and the child and family may be criticized and ostracized. In an effort to protect the child, the family may limit the child's activities outside the home. Although certain precautions are justified in limiting exposure to sources of infections, they must be tempered with concern for the child's normal developmental needs. Both the family and the community need ongoing education about HIV to dispel many of the myths that have been perpetuated by uninformed persons (see Additional Resources at the end of this chapter).

Prevention is a key component of HIV education. Educating adolescents about HIV is essential in preventing HIV infection in this age group. It should include the routes of transmission, the hazards of IV and other recreational drug use, and safer sex practices. Such education should be a part of anticipatory guidance provided to all adolescent patients. Nurses can also encourage adolescents at risk to undergo HIV counselling and testing. In addition to identifying infected teenagers and getting them into care, such counselling affords adolescents an opportunity to learn about, and possibly change, their risk-related behaviours.

The multiple complications associated with HIV disease are potentially painful (Grace, 2014). Aggressive pain management is essential for these children to have an acceptable quality of life. Their pain may be caused by infections (e.g., otitis media, dental abscess), encephalopathy (e.g., spasticity), adverse effects of medications (e.g., peripheral neuropathy), or an unknown source (e.g., deep musculoskeletal pain). Sources of pain are related not only to disease processes but

also to various treatments these children often undergo, including venipunctures, lumbar punctures, biopsies, and endoscopies. Ongoing assessment of pain is crucial and is most easily accomplished in older children who are able to communicate. Nonverbal and developmentally delayed children are more difficult to assess. The nurse should be alert for signs of pain such as emotional detachment, lack of interactive play, irritability, and depression. Effective pain management depends on the appropriate use of pharmacological agents, including EMLA cream, acetaminophen, NSAIDs, muscle relaxants, and opioids. Tolerance to opioids may indicate increased dosing; monitored use ensures safety. Nonpharmacological interventions (e.g., guided imagery, hypnosis, relaxation, and distraction techniques) are useful adjuncts.

Common psychosocial concerns include disclosing the diagnosis to the child, making custody plans when the parent is infected, and anticipating the loss of a family member. Other stressors may include financial difficulties, HIV-associated stigma, efforts to keep the diagnosis secret, other infected family members, and the multiple losses associated with HIV. Family members are often involved in the care of the child, particularly if the parent has symptomatic illness. Nursing is an integral part of the interprofessional team necessary for the successful management of the complex medical and social issues of these families.

Children with HIV infection attend day care centres and schools. It is well established that the risk of HIV transmission in these settings is minimal. These institutions are required to follow Canada's National Workplace Health and Safety (CanOSH) guidelines for infection-control measures. Routine practices involving proper management of blood and body fluids should also be followed. It is recommended that school personnel receive current HIV information and include it in the health education curriculum for kindergarten through grade 12. Privacy and confidentiality are major issues in day care or school attendance. Parents and legal guardians have the right to decide whether to inform these agencies of their child's HIV diagnosis. Unfortunately, myths about HIV infection continue to exist, and the family often wishes to avoid any potential criticism or ostracism of the child.

Severe Combined Immunodeficiency Disease

SCID is a defect characterized by the absence of both humoral and cell-mediated immunity. The terms *Swiss-type lymphopenic agammaglobulinemia* (an autosomal recessive form of the disease) and *X-linked lymphopenic agammaglobulinemia* have been used to describe this disorder, which, as the names imply, can follow either mode of inheritance. Approximately 1 in 70 000 infants born in Canada are diagnosed with SCID. It is more common in Indigenous infants, with an estimated 1 in 20 000 births (Alberta Health Services, 2020).

Susceptibility to infection occurs early, most often in the first month of life. The child with chronic infection fails to completely recover from an infection, is frequently reinfected, and is infected with unusual agents. Failure to thrive is a consequence of the persistent illnesses.

Diagnosis is usually based on a history of recurrent, severe infections from early infancy, a family history of the disorder, and specific laboratory findings, which include lymphopenia, lack of lymphocyte response to antigens, and absence of plasma cells in the bone marrow. Documentation of immune globulin deficiency is difficult during infancy because of the normally delayed response of infants in producing their own immune globulins and material transfer of immune globulin G (IgG). However, newborn screening is available in a few Canadian provinces, including Ontario, Alberta, Nova Scotia, New Brunswick, the Northwest Territories, and Manitoba, as of 2020.

Therapeutic Management. The definitive treatment for SCID is HSCT from a histocompatible donor, a haploidentical donor (usually a parent), or a matched unrelated donor. Other approaches to management of SCID include providing passive immunity with IVIG infusions and maintaining the child in a sterile environment. PCP prophylaxis is used to augment the humoral immunity until the transplant is performed. Several investigators are attempting enzyme replacement and gene therapy with some success, but there is a potential complication of insertional mutagenesis (Sullivan & Buckley, 2020b).

Nursing Care. Nursing care focuses on preventing infection and supporting the child and family. The care is consistent with that needed for HSCT for any condition. Because the prognosis for SCID is very poor if a compatible bone marrow donor is not available, nursing care is directed at supporting the family in caring for a child with a life-threatening illness (see Chapter 41). Genetic counselling is essential because of the modes of transmission in either form of the disorder.

Wiskott-Aldrich Syndrome (WAS)

WAS is an X-linked recessive disorder characterized by atopic dermatitis, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and susceptibility to infection. A defective gene has been identified and designated the WAS protein (WASP) (Sullivan & Buckley, 2020a). At birth the presenting symptom may be bloody diarrhea as a result of thrombocytopenia. As the child grows older, recurrent infection and eczema become more severe, and the bleeding becomes less frequent.

Eczema is typical of the allergic type and easily becomes superinfected. Chronic infection with herpes simplex is a frequent concern and may lead to chronic keratitis of the eye with loss of vision. Chronic pulmonary disease, sinusitis, and otitis media result from repeated infections. In children who survive the bleeding episodes and overwhelming infections, malignancy presents an additional risk to survival. Medical treatment involves the following:

- Counteracting the bleeding tendencies with platelet transfusions
- Using IVGG to provide passive immunity
- Administering prophylactic antibiotics to prevent and control infection
- Providing aggressive local therapy for the eczema

The only curative therapy is HSCT from a matched donor (Sullivan & Buckley, 2020a).

Nursing Care. Because of the poor prognosis for these children, the main nursing consideration is supporting the family in the care of a terminally ill child (see Chapter 41). Physical care should be directed at controlling the difficult health conditions imposed by the disorder. The measures used to control bleeding are similar to those for hemophilia and vWD (see previous discussions). Another major goal is prevention or control of infection. Nursing measures specific to eczema are especially important (see Chapter 52). The genetic implications of this X-linked recessive disorder differ little from those of any other X-linked disorder.

TECHNOLOGICAL MANAGEMENT OF HEMATOLOGICAL AND IMMUNOLOGICAL DISORDERS

Blood Transfusion Therapy

Technological advances in blood banking and transfusion medicine enable the administration of only the blood component needed by the child, such as packed RBCs in anemia or platelets for bleeding disorders. However, regardless of the blood component infused, all transfusions have some risks. Nurses need to be aware of the possible complications and the appropriate interventions. Table 48.3 summarizes

TABLE 48.3 Nursing Care of the Child Receiving Blood Transfusions*

Complications	Signs and Symptoms	Precautions and Nursing Responsibilities
Immediate Reactions		
Hemolytic Reactions		
Most severe type, but rare Incompatible blood Incompatibility in multiple transfusions	Sudden severe headache Chills Shaking Fever Pain at needle site and along venous tract Nausea and vomiting Sensation of tightness in chest Red or black urine Flank pain Progressive signs of shock or renal failure	Identify donor blood type before transfusion is begun; verify with another nurse or practitioner. Transfuse blood at rate of 1–2 mL/min for the first 15 min; remain with patient; remain with patient during this time. Stop transfusion immediately if signs or symptoms occur, maintain patent intravenous line, and notify practitioner. Save donor blood to re-cross-match with patient's blood. Monitor for evidence of shock. Insert urinary catheter and monitor hourly outputs. Send sample of patient's blood and urine to laboratory for presence of hemoglobin (indicates intravascular hemolysis). Observe for signs of hemorrhage resulting from disseminated intravascular coagulation. Support medical therapies to reverse shock.
Febrile Reactions		
Leukocyte or platelet antibodies Plasma protein antibodies	Fever Chills Shaking Nausea Vomiting Headache	Acetaminophen may be given for prophylaxis. Leukocyte-poor red blood cells (RBCs) are less likely to cause reaction. Stop transfusion immediately; report to health care provider for evaluation.
Allergic Reactions		
Recipient reaction to allergens in donor's blood	Urticaria Pruritus Flushing Nausea/vomiting Anxiety Asthmatic wheezing Laryngeal edema	Give antihistamines for prophylaxis to children with tendency to allergic reactions. Stop transfusion immediately. Administer epinephrine for wheezing or anaphylactic reaction.
Circulatory Overload		
Too rapid transfusion (even a small quantity) Transfusion of excessive quantity of blood (even slowly)	Precordial pain Dyspnea Rales Cyanosis Dry cough Distended neck veins Hypertension	Transfuse blood slowly (usually 1.5 to 2 hours to infuse 1 unit but up to 4 hours if sensitive to volume overload). Prevent overload by using packed RBCs or administering divided amounts of blood. Use infusion pump to regulate and maintain flow rate. Stop transfusion immediately if there are signs of overload. Place child upright with feet in dependent position to increase venous resistance.
Air Emboli		
May occur when blood is transfused under pressure	Sudden difficulty in breathing Sharp pain in chest Apprehension	Normalize pressure before container is empty when infusing blood under pressure. Clear tubing of air by aspirating it with syringe at nearest Y connector if it is observed in tubing; disconnect tubing and allow blood to flow until air has escaped only if a Y connector is not available.
Hypothermia		
	Chills Low temperature Irregular heart rate Possible cardiac arrest	Allow blood to warm at room temperature (<1 hr). Use approved mechanical blood warmer or electric warming coil to warm blood rapidly; never use microwave oven. Take temperature if patient states they have chills; if subnormal, stop transfusion.

Continued

TABLE 48.3 Nursing Care of the Child Receiving Blood Transfusions—cont'd

Complications	Signs and Symptoms	Precautions and Nursing Responsibilities
Electrolyte Disturbances		
Hyperkalemia (in massive transfusions or in patients with renal issues)	Nausea, diarrhea Muscle weakness Flaccid paralysis Paresthesia of extremities Bradycardia Apprehension Cardiac arrest	Use washed RBCs or fresh blood if patient is at risk.
Delayed Reactions		
Alloimmunization		
Antibody formation Occurs in patients receiving multiple transfusions	Increased risk of hemolytic, febrile, and allergic reactions	Use limited number of donors. Observe carefully for signs of reactions.
Delayed Hemolytic Reaction		
	Destruction of RBCs and fever 5–10 days after transfusion	Observe for post-transfusion anemia and decreasing benefit from successive transfusions.

*Some institutions may have more rigorous guidelines for checking blood and more frequent taking of vital signs during the initial portion of the administration. Therefore, nurses should familiarize themselves with their specific facility's policies and procedures surrounding blood transfusion administration.

From Yung, D. (2012). *Blood transfusion reactions*. http://learn.pediatrics.ubc.ca/body-systems/hematology-oncology/blood-transfusion-reactions/.

the major hazards of transfusions, the signs and symptoms typically associated with each, and nursing responsibilities. General guidelines that apply to all transfusions include the following:

- Take vital signs, including blood pressure, *before* administering blood, to establish **baseline data** for intratransfusion and post-transfusion comparison, and then every 15 minutes for 1 hour while blood is infusing and on completion of transfusion.
- Check the identification of the recipient with the donor's blood group and type, regardless of the blood product being used.
- Administer the first 50 mL of blood or 20% of the volume (whichever is smaller) *slowly* (and in some facilities at half rate) and stay with the child.
- Administer with normal saline on a piggyback setup or have normal saline available.
- Administer blood through an appropriate filter to eliminate particles in the blood and prevent the precipitation of formed elements; gently shake the container frequently.
- Use blood within 30 minutes of its arrival from the blood bank; if it is not used, return to the blood bank—do not store in the regular unit refrigerator.
- Infuse a unit of blood (or the specified amount) within 4 hours. If the infusion will exceed this time, the blood should be divided into appropriately sized quantities by the blood bank, and the unused portion should be refrigerated under controlled conditions.
- If a reaction of any type is suspected, take vital signs, stop the transfusion, maintain a patent IV line with normal saline and new tubing, notify the health care provider, and do not restart the transfusion until the child's condition has been medically evaluated.

Although hemolytic reactions are rare, ABO incompatibility remains the most common cause of death from blood transfusion, and human error is usually responsible (administration of the wrong type to the patient or mislabelling of the blood product) (Tondon et al., 2010). Hemolysis can also cause the release of large quantities of phospholipids, which are capable of stimulating DIC (see discussion above). Acute kidney shutdown and eventual renal failure are the results of renal vasoconstriction from antigen–antibody complexes derived from the RBC surface.

Blood is usually administered to children by infusion pump; thus the usual precautions and management related to pumps apply. When the blood is started with a standard transfusion set, the filter chamber is filled to allow the total filter to be used. The drip chamber is partially filled with blood to permit counting of the drops. In adjusting the flow rate, it is important to remember that blood administration sets do not use microdrops (60 drops/mL) but regular drops (usually 10 or 15 drops/mL). The nurse must consider this when calculating the flow rate.

Hematopoietic Stem Cell (Bone Marrow) Transplantation (HSCT)

HSCT is used to establish healthy hemopoiesis in both malignant and nonmalignant disease. Candidates for transplantation are children who have disorders that are unlikely to be cured by other means. Most HSCT patients undergo intensive ablative therapy using high-dose combination chemotherapy with or without total body irradiation (Gottschalk et al., 2016). After the immune system is suppressed to prevent rejection of the transplanted marrow, the stem cells harvested from the bone marrow, peripheral blood, or umbilical vein of the placenta are given to the patient by IV transfusion. The newly transfused stem cells will begin to repopulate the ablative bone marrow. In essence, a new blood-forming organ will be accepted by the recipient.

The selection process for a suitable donor and the potential complications in transplantation are related to the *HLA system complex*. Some of the major HLAs are A, B, C, D, and DR. There is a wide diversity for each of these HLA loci. There are more than 20 different HLA-As that can be inherited and more than 40 different HLA-Bs.

The genes are inherited as a single unit or *haplotype*. A child inherits one unit from each parent; thus a child and each parent have one identical and one nonidentical haplotype. Because the possible haplotype combinations among siblings follow the laws of Mendelian genetics, there is a one-in-four chance that two siblings have two identical haplotypes and are perfectly matched at the HLA loci.

The importance of HLA matching is to prevent the serious complication known as *graft-versus-host disease* (GVHD). Because the child's immune system is essentially rendered nonfunctional, there is little difficulty with bone marrow rejection by the recipient. However, the donor's marrow may contain antigens not matched to the recipient's antigens, which begin attacking body cells. The more closely the HLA systems match, the less likely GVHD will develop. However, it can occur even with a perfect HLA match because there are as yet unidentified and thus unmatched histocompatibility antigens (Gottschalk et al., 2016; Phelan & Margolis, 2020).

Different types of HSCT are now performed in children with cancer. Allogeneic HSCT involves matching a histocompatible donor with the recipient. However, allogeneic HSCT is limited by the presence of a suitable marrow donor.

Because of the limited numbers of patients having HLA-identical siblings, other types of allogeneic transplants have evolved. Umbilical cord blood stem cell transplantation is an established, rich source of hematopoietic stem cells for use in children with cancer. Because stem cells can be found with high frequency in the circulation of newborns, cord blood transplantation has become an alternative for some children. The benefit of using umbilical cord blood is the blood's relative immunodeficiency at birth, allowing for partially matched unrelated cord blood transplants to be successful, with a lower risk of GVHD-related complications (Gottschalk et al., 2016; Phelan & Margolis, 2020).

Autologous HSCTs use the patient's own marrow that was collected from disease-free tissue, frozen, and sometimes treated to remove malignant cells. Children with solid tumours such as neuroblastoma, Hodgkin disease, NHL, rhabdomyosarcoma, Ewing sarcoma, and Wilms tumour have been treated with autologous HSCTs (Phelan & Margolis, 2020).

Peripheral stem cell transplants (PSCTs) are also used in children with cancer. PSCT, a type of autologous transplant, differs in the way stem cells are collected from the patient. CSF is first given to stimulate the production of many stem cells. After the WBC count is high enough, the stem cells are collected by an apheresis machine. This machine filters out peripheral stem cells from whole blood, returning the remainder of the blood cells and plasma to the child. Stem cells have been collected in very small children without complications. The peripheral stem cells are then frozen until the patient is ready for the PSCT.

Nursing Care. The care of children undergoing HSCT is similar to that of any child receiving chemotherapy and radiotherapy. The hospitalization is typically 3 to 6 weeks in an isolated environment, during which time the child is subjected to numerous procedures and adverse effects of therapy.

Throughout this long ordeal the family is concerned with successful engraftment and fear of fatal complications (see Family-Centred Care box: The Decision for a Hematopoietic Stem Cell Transplant). Consequently, nurses involved with the child and family need to provide sensitive care and maintain a supportive attitude during the many crises that may arise. If the procedure is not successful, the families need care consistent with that required by the family of any child with a life-threatening disorder (see Chapter 41).

FAMILY-CENTRED CARE

The Decision for a Hematopoietic Stem Cell Transplant

A family's decision for a child to undergo hematopoietic stem cell transplantation (HSCT) may be fraught with challenges. Often the child is facing certain death from the malignancy. The preparation of the child for the transplant also places the patient at great medical risk.

Once the preparatory regimen is begun and the child's immune system is destroyed, there is no turning back. Unlike kidney transplantation, HSCT does not have a "rescue" procedure, such as dialysis, for supportive therapy. If the donor is a sibling, the issue of their marrow "saving" the brother or sister can be a concern, especially if the transplant fails. Parents often must leave the home to stay at the transplant centre and encounter additional stressors such as arranging child care, taking a leave from work, and managing finances. The patient faces the greatest stress—fear of HSCT failure or life-threatening complications.

Apheresis

Apheresis is the removal of blood from an individual, separation of the blood into its components, retention of one or more of these components, and reinfusion of the remainder of the blood into the individual. It is most often used to remove large quantities of platelets from healthy adult donors. These transfusion products have greatly prolonged the survival of patients with hematological and oncological diseases.

This technique is used to remove peripheral blood stem cells (PBSCs) from children before they receive HSCT or high-dose chemotherapy or radiotherapy, which is severely toxic to the bone marrow. These PBSCs can then be used to restore the child's bone marrow. Apheresis is also used as a therapeutic modality. The blood component that is diseased or toxic is separated from the blood, and the remainder is returned to the individual. Therapeutic apheresis is considered part of standard therapy for many diseases. Plasma is selectively removed from individuals with hyperviscosity, life-threatening complications of myasthenia gravis, Guillain-Barré syndrome, thrombotic thrombocytopenic purpura, and certain drug overdoses. WBCs are removed from individuals with high–WBC count leukemia.

Nursing Care. Difficult venous access and small blood volume can limit the ability to use this therapy in the infant and young child. Education of the family and child includes the purposes of the therapy and the technology.

Specially trained individuals perform the apheresis procedure. Attention focuses on the rate of removal, blood component separation, and reinfusion of blood into the child. Vital signs need to be monitored and the child continuously observed for any adverse reactions secondary to the circulatory volume changes and the anticoagulant used.

When apheresis components are infused, nursing measures differ depending on whether the product is autologous (blood component from the child) or allogeneic (blood component from another individual). Autologous components are the child's own blood; thus a major precaution is proper identification to ensure the correct component. The rate of infusion should be adjusted to the child's tolerance. If the product is allogeneic, all precautions for blood transfusions apply.

KEY POINTS

- *Anemia* is defined as the reduction of RBCs or Hgb concentration to levels below normal for gender and age; disorders are classified either by etiology and physiology or by morphology.
- The nurse's role in treatment of anemia is to gather information necessary to assist in establishing a diagnosis, prepare the child for laboratory tests, administer prescribed medications, decrease tissue oxygen needs, implement safety precautions, and observe for complications.
- The main nursing goal in prevention of nutritional anemia is parent education regarding correct feeding practices.
- Sickle cell anemia (SCA) is a hereditary hemoglobinopathy caused by normal adult Hgb (HgbA) being partly or completely replaced by sickle Hgb (HgbS).
- Nursing care of the child with SCA focuses on teaching the family how to prevent and recognize sickle cell conditions; managing pain during crises; and helping the child and parents adjust to a lifelong chronic disease.
- Nursing care of the child with beta thalassemia includes observing for complications of multiple blood transfusions, assisting the child in coping with the effects of illness, and fostering parent–child adjustment to long-term illness.
- Causes of acquired aplastic anemia (AA) include irradiation, medications, industrial and household chemicals, infections, and infiltration and replacement of myeloid elements; however, most cases are idiopathic.
- Clotting depends on three processes: vascular spasm, platelet aggregation, and coagulation and clot formation.
- Nursing care of the child with hemophilia involves preventing bleeding by decreasing the risk of injury, recognizing and managing bleeding with factor replacement, preventing the crippling effects of joint degeneration, and preparing and supporting the child and family for home care.
- Goals in the care of the child with leukemia are to prepare the family for diagnostic and therapeutic procedures, help prevent complications of myelosuppression, manage adverse effects of irradiation and drug toxicity, and provide continued emotional support.
- The lymphomas include Hodgkin lymphoma and NHL and are disorders involving the lymphoid system.
- Immunodeficiency disorders render the affected individual unable to fight infectious organisms.
- HIV infection in infants is primarily acquired during pregnancy or birth from an infected mother, and in adolescents from engaging in high-risk behaviours.
- Blood transfusions supply needed blood components.
- HSCT replaces the diseased or malfunctioning bone marrow with viable blood stem cells.
- Apheresis is the selective removal of a blood component. It can be used to supply cellular elements needed for therapy (i.e., platelets or stem cells) or to remove diseased components.

Genitourinary Conditions

Mandy Rickard
Originating US chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Demonstrate an understanding of diagnostic procedures related to genitourinary disease.
2. Describe the various factors that contribute to urinary tract infections in infants and children.
3. Discuss the preoperative preparation and postoperative care of the child and parents when the child has a structural defect of the genitourinary tract.
4. Demonstrate an understanding of the causes and mechanisms of edema formation in nephrotic syndrome.
5. Outline a nursing care plan for a child with nephrotic syndrome.
6. Compare the child with minimal-change nephrotic syndrome and the child with acute glomerulonephritis in terms of clinical manifestations and nursing care.
7. Contrast the causes, complications, and management of acute and chronic renal failure.
8. Demonstrate an understanding of the types of renal dialysis.
9. Recognize signs of kidney transplant rejection.

URINARY SYSTEM STRUCTURE AND FUNCTION

The urinary system is an excretory system that consists of the kidneys, which produce urine; the ureters, which transport urine to the bladder; the urinary bladder which stores urine; and the urethra, which discharges urine from the bladder.

Kidney Structure and Function

The major purpose of the kidneys is to balance the body fluids, which include water and electrolytes. The kidneys must adapt to external and internal factors in order to maintain this equilibrium. These factors include diet, hydration variables, and extrarenal losses of water and solutes. Glomerular filtration produces urine, and tubular reabsorption creates equilibrium. **Reabsorption** occurs when substances are moved from the tubular lumen to the blood. **Secretion** is the movement of substances back from the blood to the lumen. Kidneys remove metabolic wastes from the blood and excrete the wastes in urine.

In addition, the kidneys help to regulate the production of red blood cells (RBCs) by converting plasma globulin into erythropoietin and stimulating erythropoiesis production in the bone marrow. A lack of erythropoietin decreases the number of RBCs and can lead to anemia when significant kidney disease is present. The kidneys also aid in calcium absorption and in maintaining blood volume, composition, and pH. The enzyme *renin* is secreted by the kidneys in response to a lowered blood volume, lowered blood pressure, or an increase in the secretion of catecholamines. Renin stimulates the production of angiotensin, which creates constriction of the arterioles. This in turn leads to an increase in blood pressure and stimulates the production of aldosterone by the adrenal cortex.

The functional unit of the kidney is the **nephron**. The nephron contains a renal corpuscle and a renal tubule. Kidney and nephron structures are illustrated in Figure 49.1. The corpuscle consists of the glomerulus and a Bowman's capsule. The glomerular capillary receives blood from the afferent arteriole and passes it to the efferent arteriole. The efferent arteriole gives rise to the peritubular capillary system and loops of Henle and then into collecting ducts. Nephrons function to remove wastes, such as urea from the blood, and to regulate water and electrolyte concentrations. Urine is formed when water and dissolved material are forced out of the glomerular capillaries. Filtration pressure is the force that moves materials out of the glomerulus and into the Bowman's capsule via hydrostatic pressure inside glomerular capillaries. The *glomerular filtration rate (GFR)* is the amount of fluid filtered from the capillaries into the Bowman's capsule of the kidneys. This filtration is affected by the osmotic pressure of the plasma, hydrostatic pressure in Bowman's capsule, and the diameter of the efferent and afferent arterioles. The kidneys produce about 125 mL of glomerular fluid per minute, and most of this is reabsorbed.

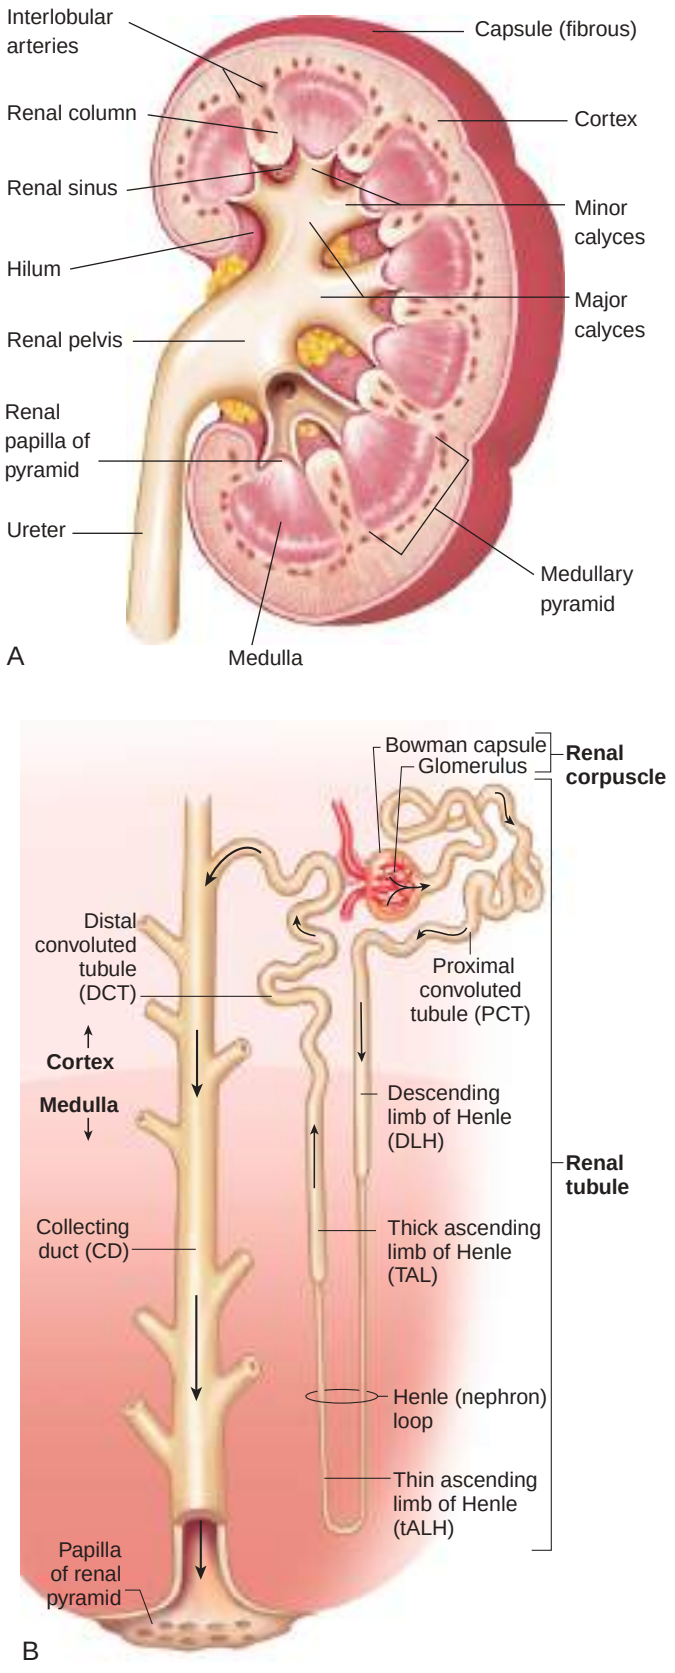

Fig. 49.1 **A:** Kidney structure. **B:** Components of the nephron. (From Patton, K. T., & Thibodeau, G. A. [2010]. *Anatomy and physiology* [7th ed.]. Mosby.)

Glomerular filtration and absorption are relatively low in the infant and do not reach adult levels until the ages of 1 or 2 years. This may be related to the glomerular epithelia cells being more shaped like a cube, a high afferent arteriole resistance, and incomplete formation of the tubules and smaller glomeruli. As a result, the newborn is at risk of being unable to excrete excess water and solutes quickly or efficiently. Substances are selectively reabsorbed by the tubules; glucose and amino acids are reabsorbed by active transport, water is reabsorbed by osmosis, and proteins are reabsorbed by pinocytosis and returned to the blood. Excess of these substances may be excreted in the urine. Sodium is mostly reabsorbed before urine is excreted and is concentrated in the renal medulla. Antidiuretic hormone (ADH), also known as *vasopressin*, from the posterior pituitary gland causes the permeability of the distal tubule and collecting ducts to increase and promotes the reabsorption of water.

Electrolytes are moved by active transport and diffusion. There is a limit to the concentration gradient against which sodium can be transported out; if there is a larger than normal amount remaining in the tubules, water stays with the sodium.

GENITOURINARY DYSFUNCTION

Clinical Manifestations

As in most disorders of childhood, the incidence and type of kidney or urinary tract dysfunction change with the child's age and maturation. In addition, the presenting health concerns and the significance of these concerns vary with age. For example, urinary tract infections have a greater significance in infancy than at an older age. In newborns, renal abnormalities may be associated with a number of other malformations, for example, obvious neural tube defects to the subtle abnormal shape or position of the outer ear. Failure to thrive in children may be a sign of impaired renal function.

While many of the clinical manifestations of renal disease are common to a variety of childhood disorders, their presence is an indication to obtain further information from the child's history, family history, and laboratory studies as part of a complete physical examination. Suspected renal disease can be further evaluated by means of radiographic studies and renal biopsy (Table 49.1).

Laboratory Tests. Both urine and blood studies, including routine urinalysis, contribute vital information for the detection of renal conditions. Specific urine and blood tests provide additional information. Because nurses are usually the persons who collect the specimens for examination and who often perform many of the screening tests, they should be familiar with the tests, their functions, and the factors that can alter or distort the results of the tests. The major urine and blood tests are outlined in Tables 49.2 and 49.3.

Nursing Care. Nursing responsibilities in assessment of genitourinary disorders or diseases begin with observation of the child for any manifestations that might indicate dysfunction. Many conditions have specific characteristics that distinguish them from other disorders. These are discussed throughout the chapter.

The nurse is generally responsible for preparing infants, children, and parents for tests and for collecting urine and (sometimes) blood specimens for observation and laboratory analysis (see Collection of Specimens, Chapter 44). An important nursing responsibility is to maintain careful intake and output and blood pressure measurements in children with genitourinary dysfunction and those who might be at risk for developing renal complications (e.g., children in **shock**, postoperative patients). For example, any significant degree of renal disease can diminish the GFR, a measure of the amount of plasma from which a

TABLE 49.1 Radiological and Other Tests of Urinary System Function

Test	Procedure	Purpose	Comment and Nursing Responsibilities
Urine culture and sensitivity	Collection of sterile specimen	Determines presence of pathogens and the medications to which they are sensitive	Send specimen to laboratory immediately after collection. Use catheterization, midstream urine (MSU), or suprapubic aspiration specimen.
Renal and bladder ultrasound	Transmission of ultrasonic waves through renal parenchyma, along ureteral course, and over bladder	Allows visualization of renal parenchyma and renal pelvis and any dilatation/hydronephrosis without exposure to external beam radiation or radioactive isotopes Visualization of dilated ureters and bladder wall are also possible. Doppler ultrasound can be used to evaluate renal vascular flow.	Noninvasive procedure
Testicular (scrotal) ultrasound	Transmission of ultrasonic waves through scrotal contents and testis	Allows visualization of scrotal contents, including testis Testicular ultrasound is used to identify masses, and Doppler-enhanced ultrasound is used to differentiate hyperemia of epididymo-orchitis from ischemia or torsion.	Noninvasive procedure Should not be routinely used for diagnosis of cryptorchidism (undescended testes)
Scout film	Flat plate roentgenogram of abdomen and pelvis for kidney, ureters, bladder (KUB)	Detects and establishes renal outlines, presence of calculi, or opaque foreign bodies in bladder	Prepare as for routine X-ray film.
Voiding cystourethrography	Contrast medium injected into bladder through urethral catheter until bladder is full; films taken before, during, and after voiding	Visualizes bladder outline and urethra. Determines presence of vesicoureteral reflux (retrograde flow of urine into ureters/kidneys), and shows complications of bladder emptying such as bladder outlet obstruction	Prepare child for catheterization.
Radionuclide (nuclear) cystogram	Radionuclide-containing fluid injected through urethral catheter until bladder is full; images generated before, during, and after voiding	Alternative to voiding cystourethrography in children with allergy to intravesical contrast material Allows evaluation of reflux, although visualization of anatomical details is relatively poor	Prepare child for catheterization. Reassure patient and parents that allergic response to contrast materials is avoided by use of radionuclide.
Radioisotope imaging studies (renal scans)	Contrast medium injected intravenously; computer analysis to measure uptake or washout (excretion) for analysis of organ function	DTPA radioisotope used to measure glomerular filtration rate; estimate of differential renal function and renal washout to determine presence and location of upper urinary tract obstruction DMSA radioisotope is used to visualize renal scars and differential renal function; it does not visualize ureters and bladder. MAG3 radioisotope combines features of DTPA (evaluation of upper urinary tract obstruction) with features of DMSA radioisotope (differential renal function and drainage time for assessment of obstruction).	Insert or assist with insertion of intravenous infusion. Monitor intravenous infusion. Urethral catheterization may accompany DTPA radioisotope scan; prepare child for catheterization when indicated.
Intravenous pyelography (IVP) (intravenous urogram; excretory urogram)	Intravenous injection of a contrast medium Medium secreted and concentrated by tubules X-ray films made 5, 10, and 15 min after injection; delayed films (30, 60 min, etc.) are obtained if obstruction suspected	Defines urinary tract Provides information about integrity of kidneys, ureters, and bladder Retroperitoneal masses visualized when they shift position of ureters	Preparation for test: **Infants <2 yr of age**—Give no solid food, omit one breastfeeding/bottle on morning of examination; perform studies early to avoid withholding of fluids. **Children 2–14 yr of age**—Give cathartic evening before examination, nothing orally after midnight, enema (soapsuds) morning of examination. Rare test in pediatrics and not commonly requested

TABLE 49.1 Radiological and Other Tests of Urinary System Function—cont'd

Test	Procedure	Purpose	Comment and Nursing Responsibilities
Computed tomography (CT)	Narrow-beam X-rays and computer analysis providing precise reconstruction of area	Visualizes vertical or horizontal cross-section of kidney Especially valuable to distinguish tumours and cysts	Noncontrast scan is noninvasive. Contrast-enhanced CT scan preparation is similar to that for IVP.
Cystoscopy	Direct visualization of bladder and lower urinary tract through small scope inserted via urethra	Investigation of bladder and lower tract lesions; visualizes ureteral openings, bladder wall, trigone, and urethra	NPO orders per protocol, typically no solid food after midnight, liquids until 4 to 6 hr before procedure. Carry out preoperative preparations; cystoscopy is done under anaesthesia in children.
Retrograde pyelography	Contrast medium injected through ureteral catheter	Visualizes pelvic calyces, ureters, and bladder Usually done in conjunction with a surgical procedure to delineate anatomy prior to surgery.	Give cathartic if ordered. Give preoperative medication if ordered. Observe for reaction to contrast medium. Monitor vital signs after procedure.
Renal angiography	Contrast medium injected directly into renal artery via catheter placed in femoral artery (or umbilical artery in newborn) and advanced to renal artery	Visualizes renal vascular system, especially for renal arterial stenosis	Prepare child for insertion of a spinal needle or perfusion catheter in renal pelvis (anaesthetic often required).
Renal biopsy	Removal of kidney tissue by open or percutaneous technique for study by light, electron, or immunofluorescent microscopy	Yields histological and microscopic information about glomeruli and tubules; helps distinguish between types of nephritic syndromes and identification of renal masses Distinguishes other renal disorders	Usually done under anaesthesia in image guided therapy department.
Urodynamics	Set of tests designed to measure bladder filling, storage, and evacuation functions **Uroflowmetry**—Test to determine efficiency of urination **Cystometrogram**—Graphic comparison of bladder pressure as a function of volume **Voiding pressure study**—Comparison of detrusor contraction pressure, sphincter electromyelogram, and urinary flow	Determine characteristic of voiding dysfunction Used to identify type (cause) of incontinence or urinary retention Usually reserved for assessment of bladder function in children with neurogenic bladder or congenital bladder outlet obstruction	Prepare child for urinary catheterization. The bladder will be filled with saline solution and filling pressures will be recorded; the child may experience fullness, coolness from the saline fluid, and urine leakage during the study. To measure sphincter EMG, it may be necessary to insert needles.

DMSA, Dimercaptosuccinic acid; *DTPA*, diethylenetriamine pentaacetic acid; *EMG*, electromyography; *MAG3,* mercaptoacetyltriglycine; *NPO*, nothing by mouth.

TABLE 49.2 Urine Tests of Renal Function

Test	Normal Range	Deviations	Significance of Deviations
Physical Tests			
Volume	Age-related Infants—<1 mL/kg/hr Children—0.5 mL/kg/hr	Polyuria	Osmotic factors (urinary glucose level in diabetes mellitus)
		Oliguria	Retention caused by obstructive disease Inadequate bladder emptying caused by neurogenic bladder or obstructive disorder
		Anuria	Obstruction of urinary tract; acute renal failure
Specific gravity	With normal fluid intake—1.016–1.022 Newborn—1.001–1.020	High	Dehydration Presence of protein or glucose Presence of radiopaque contrast medium after radiological examinations
	Others—1.001–1.030	Low	Excessive fluid intake Distal tubular dysfunction Insufficient antidiuretic hormone Diuresis Chronic glomerular disease

Continued

TABLE 49.2 Urine Tests of Renal Function—cont'd

Test	Normal Range	Deviations	Significance of Deviations
Osmolality	Newborn— 274–305 mmol/kg H_2O Thereafter— 282–300 mmol/kg H_2O	High or low	Same as for specific gravity More sensitive index than specific gravity
Appearance	Clear pale yellow to deep gold	Cloudy	Contains sediment
		Cloudy reddish pink to reddish brown	Blood from trauma or disease Myoglobin after severe muscle destruction
		Light	Dilute
		Dark	Concentrated
		Red	Trauma
Chemical Tests			
pH	Newborn—5–7 Thereafter— 4.8–7.8 Average—6	Weak acid or neutral	If associated with metabolic acidosis, suggests tubular acidosis If associated with metabolic alkalosis, suggests potassium deficiency Urinary infection
		Alkaline	Metabolic alkalosis
Protein level	Absent	Present	Abnormal glomerular permeability (e.g., glomerular disease, changes in blood pressure) Most kidney disease
Glucose level	Absent	Present	Diabetes mellitus Infusion of concentrated glucose-containing fluids Glomerulonephritis Impaired tubular reabsorption
Ketone levels	Absent	Present	Conditions of acute metabolic demand (stress) Diabetic ketoacidosis
Leukocyte esterase	Absent	Present	Can identify both lysed and intact white blood cells via enzyme detection
Nitrites	Absent	Present	Most species of bacteria convert nitrates to nitrites in the urine
Microscopic Tests			
White blood cell count	<1 or 2	>5 polymorphonuclear leukocytes/field	Urinary tract inflammatory process
		Lymphocytes	Allograft rejection Malignancy
Red blood cell count	<1 or 2	4–6/field in centrifuged specimen	Trauma Stones Glomerular injury Infection Neoplasms
Presence of bacteria	Absent to a few	>100 000 organisms/mL in centrifuged specimen	Urinary tract infection
Presence of casts	Occasional	Granular casts	Tubular or glomerular disorders
		Cellular casts White blood cell Red blood cell	Degenerative process in advanced renal disease Pyelonephritis Glomerulonephritis
		Hyaline casts	Proteinuria; usually transient

given substance is totally cleared in 1 minute. A number of substances can be used, but the most useful clinical estimation of glomerular filtration is the clearance of creatinine, an end product of protein metabolism in muscle and a substance that is freely filtered by the glomerulus and secreted by renal tubular cells. The nurse's responsibility in conducting this test is the collection of urine, usually a 12- or 24-hour specimen.

GENITOURINARY TRACT DISORDERS AND DEFECTS

Urinary Tract Infection

Urinary tract infections (UTIs) occur in 1% of boys and 1 to 3% of girls. During the first year of life, UTIs are more common in males, particularly in uncircumcised boys (Sorokan et al., 2015/2021). Circumcision status should be assessed in male infants with unexplained fever.

TABLE 49.3 Blood Tests of Renal Function

Test	Normal Range	Deviations	Significance of Deviations
Urea	Newborn—2.9–10.0 mmol/L Infant, child—2.0–7.1 mmol/L	Elevated	Renal disease—acute or chronic (the higher the urea, the more severe the disease) Increased protein catabolism Dehydration Hemorrhage High protein intake Corticosteroid therapy
Uric acid	Child—120–360 mcmol/L	Increased	Severe renal disease
Creatinine	Infant—10–56 mcmol/L Child—<53 mcmol/L Adolescent—<98 mcmol/L	Increased	Severe renal impairment

UTI may involve the urethra and bladder (lower urinary tract) or the kidneys (upper urinary tract). True UTIs involving the upper urinary tract are usually associated with fever, whereas lower urinary tract infections consist of lower urinary tract symptoms such as dysuria, urinary frequency, and urgency. The Canadian Paediatric Society (CPS) recommends suprapubic aspiration or urethral catheterization to diagnose UTIs in young infants (see Chapter 44). Urine obtained by bag is frequently inaccurate because of contamination and should be avoided for UTI diagnosis (Robinson et al., 2014/2020). Because it is often impossible to localize the infection, the broad designation *UTI* is applied to the presence of significant numbers of microorganisms anywhere within the urinary tract, except the distal third of the urethra, which is usually colonized with bacteria.

Various terms used to describe urinary tract disorders include the following:

Bacteriuria—Presence of bacteria in the urine

Asymptomatic bacteriuria—Significant bacteriuria (usually defined as more than 100 000 colony-forming units [CFU]) with no evidence of clinical infection. May occur in children predisposed to colonization.

Symptomatic bacteriuria—Bacteriuria accompanied by physical signs of UTI (dysuria, suprapubic discomfort, hematuria, fever)

Recurrent UTI—Repeated episode of bacteriuria or symptomatic UTI

Persistent UTI—Persistence of bacteriuria despite antibiotic treatment

Febrile UTI—Bacteriuria accompanied by fever and other physical signs of UTI; presence of a fever typically implies a pyelonephritis

Diagnosis of UTI requires obtaining a sterile specimen (in and out catheter, suprapubic aspiration in infants and in children who have not achieved toilet independence; midstream urine (MSU) in older children), a positive urinalysis (leukocyte esterase ± nitrites), positive routine and microscopy (+ white blood cell [WBC], + bacteria), and a positive urine culture (>50 000 CFU of a single organism) (Robinson et al., 2014/2020).

Cystitis—Inflammation of the bladder; relatively uncommon in children

Urethritis—Inflammation of the urethra

Pyelonephritis—Inflammation of the upper urinary tract and kidneys

Urosepsis—Febrile UTI coexisting with systemic signs of bacterial illness; blood culture reveals presence of urinary pathogen

Etiology. A variety of organisms can be responsible for UTI. *Escherichia coli* (80% of cases) and other Gram-negative enteric organisms are the most common uropathogens; these organisms are usually found in the anal and perineal region. Other organisms associated with UTI include *Proteus, Pseudomonas, Klebsiella, Staphylococcus aureus, Haemophilus,* and coagulase-negative *Staphylococcus* organisms. Most uropathogens originate in the gastrointestinal (GI) tract, migrate to the periurethral area, and ascend to the bladder. Several factors contribute to the development of UTI in childhood including anatomical, physical, and chemical conditions or properties of the child's urinary tract.

Anatomical and physical factors. The structure of the lower urinary tract is believed to account for the increased incidence of bacteriuria in females. The short urethra, which measures about 2 cm in young girls and 4 cm in mature women, provides a ready pathway for invasion of organisms. In addition, the closure of the urethra at the end of micturition may return contaminated bacteria to the bladder. The longer male urethra (as long as 20 cm in an adult) and the antibacterial properties of prostatic secretions inhibit the entry and growth of pathogens. However, when considering newborns and infants, risk stratification for development of UTI falls into three categories: females, circumcised males and uncircumcised males, with the latter being at an increased risk of bacterial contamination of the bladder for the first several months of life. This is particularly true in the presence of urinary tract anomalies such as hydronephrosis, hydroureter, or vesicoureteral reflux (VUR).

Under normal conditions the act of completely and repeatedly emptying the bladder (i.e., every 2 hours in children with toilet independence) flushes away any organisms before they have an opportunity to multiply and lead to symptoms. However, holding or infrequent voiding patterns or high postvoid residuals (PVRs) allow bacteria from the urethra to rapidly become established in the rich medium. Elevated PVR urines more commonly occur in girls and may be caused by dysfunctional voiding (miscommunication between bladder and pelvic floor muscles), constipation, or urinary tract pathologies that affect the functioning of the bladder.

Altered urine and bladder chemistry. Several mechanical and chemical characteristics of the urine and bladder mucosa help maintain urinary sterility. An increased fluid intake promotes flushing of the normal bladder and lowers the concentration of organisms in the infected bladder by encouraging more frequent voiding. Diuresis also seems to enhance the antibacterial properties of the renal medulla.

Most pathogens favour an alkaline medium. Normally, urine is slightly acidic, with a median pH of 6.0. A urine pH of about 5 hampers but does not eliminate bacterial multiplication. Much has been reported about the use of cranberry products to increase urine acidity in an effort to prevent UTI. Studies done in adults offer limited evidence for the value of cranberry products in promoting urinary tract health. A Cochrane Review concluded that the benefit of cranberry juice was too small to recommend its use for prevention of UTIs (Jepson et al., 2012).

Diagnostic Evaluation. The clinical manifestations of UTI depend on the child's age (Box 49.1). Diagnosis of UTI is confirmed by detection of bacteriuria in urine culture combined with positive urinalysis, microscopy, and symptom development. But urine collection is often difficult, especially in infants and very small children. Unless the specimen is a first-morning sample, a recent high fluid intake may indicate

BOX 49.1 Clinical Manifestations of Urinary Tract Infections

Birth to 1 Month
Fever
Poor feeding
Vomiting
Failure to gain weight
Rapid respiration (acidosis)
Respiratory distress
Spontaneous pneumothorax or pneumomediastinum
Weak urine stream
Jaundice
Seizures
Dehydration
Other anomalies or stigmata
Enlarged kidneys or bladder

1 to 24 Months
Poor feeding
Vomiting
Failure to gain weight
Excessive thirst
Foul-smelling urine
Pallor
Fever
Seizures (with or without fever)
Dehydration
Enlarged kidneys or bladder

2 to 14 Years
Poor appetite
Vomiting
Growth failure
Excessive thirst
Painful urination
Swelling of face
Seizures
Pallor
Fatigue
Blood in urine
Abdominal or back pain
Edema
Hypertension
Tetany

a falsely low organism count. Thus, children should not be encouraged to drink large volumes of water in an attempt to obtain a specimen quickly.

! NURSING ALERT

A child who exhibits the following should be evaluated for UTI:
- Fever with no obvious source
- Dysuria
- Strong-smelling urine in association with other symptoms
- Frequency or urgency

The most accurate estimates of bacterial content are obtained from suprapubic aspiration (in children younger than 2 years of age) or properly performed in and out bladder catheterization (as long as the first few millilitres are excluded from collection).

Tests to detect bacteriuria are being used with increasing frequency in screening for UTI. The dipstick tests for leukocyte esterase and nitrites are quick and inexpensive methods for detecting infection before obtaining final culture results. In the absence of a positive urinalysis, routine culture and sensitivity testing is not routinely advised because of the risk of false positive results and unnecessary treatment with antibiotics.

Once infection has been confirmed, other tests such as ultrasonography, voiding cystourethrogram (VCUG), intravenous (IV) pyelogram, and dimercaptosuccinic acid (DMSA) scan may be performed after the infection subsides, to identify anatomical abnormalities and existing kidney damage from recurrent infection. Localization of the infection site may involve more specific tests, including percutaneous kidney taps and bladder washout procedures; however, these tests are exceedingly rare in children.

Therapeutic Management. The objectives of treatment of children with UTI are to (1) eliminate current infection, (2) identify contributing factors to reduce the risk of recurrence, (3) prevent systemic spread of the infection, and (4) preserve renal function. Antibiotic therapy should be initiated on the basis of identification of the pathogen, the child's history of antibiotic use, and the location of the infection. Several antimicrobial medications are available for treating UTI, but all of them can occasionally be ineffective because of resistance of organisms. Common anti-infective medications used for UTI include the penicillins, sulfonamide (including trimethoprim and sulfamethoxazole in combination), the cephalosporins, and nitrofurantoin.

The CPS has recommended significant changes in managing UTIs, given new research findings in children over 2 months of age until 24 months of age with an acute UTI and no underlying urinary tract issues or risks for a neurogenic bladder (Robinson et al., 2014/2020). The recommendations include antibiotic treatment for 7 to 10 days for a febrile UTI. Oral antibiotics may be prescribed initially if the child is not seriously ill. Children who are over 2 years of age should have a renal/bladder ultrasound with first febrile UTI to rule out any significant renal abnormalities. A voiding cystourethrogram is not required for children with a first UTI unless the renal/bladder ultrasound is abnormal and suggestive of renal anomalies or obstructive uropathy.

It is important to carefully separate UTIs in children less than 24 months of age and those in older children, as the management of infection, the prevention of future infections, and the diagnostic workup for UTI is different between these groups. UTI in older children who develop a UTI after developing toilet independence can be usually managed with conservative measures and aggressive management of bladder and bowel dysfunction. Even if structural abnormalities are detected (such as VUR), most cases will not require any invasive management of these issues (Lorenzo et al., 2019). In infants, if anatomical defects such as VUR or bladder neck obstruction are present, surgical correction of these abnormalities may be necessary to prevent recurrent infection. Ongoing follow-up is an important component of medical management for monitoring and prevention of recurrence of infections.

Vesicoureteral reflux. *Vesicoureteral reflux* (*VUR*) refers to the abnormal retrograde flow of urine from the bladder, through the ureters to the kidneys. During filling, the bladder is a low-pressure reservoir; however, once full, the mechanism of the bladder contracting causes it to become high pressure. With VUR, the ureters are not tunnelled into the bladder mucosa in a standard fashion, which allows this high-pressure contraction to force urine back through the ureters and into the kidneys. When the bladder is colonized with bacteria, this may predispose children to UTIs. *Primary reflux* results from congenitally abnormal insertion of ureters into the bladder; *secondary reflux* occurs

as a result of chronically high bladder pressures, persistent PVRs, or voiding dysfunction.

VUR itself does not cause UTIs. In the presence of reflux, infected urine (bacteria) from the bladder has access to the kidney, resulting in kidney infection (pyelonephritis). These children are usually very symptomatic with high fever, vomiting, and chills. Reflux, when associated with UTI, is the most common cause of renal scarring in children. Renal scarring may occur with the first episode of febrile UTI; however, one infection does not necessarily equate to one scar (RIVUR Trial Investigators, 2014). VUR is managed conservatively with daily low-dose antibiotic therapy in infants, typically with trimethoprim 2 mg/kg/day, usually until toilet independence has been achieved. Urine should only be checked if the child is symptomatic for UTI as routine urine cultures risk growing contaminants and overtreatment with antibiotics. Routine VCUGs are not commonly employed because of the invasiveness of the test, and most cases of VUR are not clinically significant. Some evidence suggests that children may outgrow VUR over time.

Current management of VUR is conservative with monitoring and prophylaxis. A small subset of children with VUR may require surgical management in the instance of breakthrough UTIs (i.e., infection while on prophylaxis) or UTIs after cessation of prophylaxis. Surgical management consists of a minimally invasive endoscopic injection of a bulking agent at the ureterovesical junction, which prevents reflux from occurring. Overall cure rates relate to the degree of reflux and range from 72 to 96% (Chen et al., 2010). An alternative surgical procedure is a ureteric reimplantation, which can be done open or laparoscopically and involves tunnelling the ureters into the bladder. It is considered the definitive procedure for correction of reflux. However, given the invasiveness of this procedure and the potential for complications it is reserved for a very small subset of patients with VUR.

Prognosis. With prompt and adequate treatment at the time of diagnosis, the long-term prognosis for UTI is usually excellent. The hazard of progressive renal injury is greatest when infection occurs in young children (especially those younger than 2 years of age) and is associated with congenital renal malformations or reflux. Therefore, early diagnosis of children at risk is particularly important.

Nursing Care. Nurses should instruct parents to consider the possibility of UTI should their child have a fever with no obvious source, especially in children with urinary tract abnormalities that may predispose them to infections. This is more important in infants as fever may be the only sign of a UTI. In general, any infant less than 3 months of age should be assessed in an emergency department where screening for UTI will occur as a part of standardized workup. Fussiness, crying, poor feeding, and vomiting could also be presenting signs of UTI in infants. Older children, particularly once they have achieved toilet independence, may experience more traditional signs of UTI, such as dysuria, frequency, urgency, and fever.

When infection is suspected, collecting an appropriate specimen is essential. It is the nurse's responsibility to take every precaution to obtain acceptable clean-voided specimens so that the use of other, more invasive collecting procedures can be avoided except when absolutely indicated. Given the unreliability of a specimen obtained via a urine collection bag, suprapubic aspiration of urine or sterile catheterization should be done in the infant or young child who has fever.

Frequently, additional tests are performed to detect anatomical defects. Children need to be prepared for these tests as appropriate for their age. This includes an explanation of the procedure, its purpose, and what the child will experience (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44). Sometimes a simple description of the urinary system is helpful. For children younger than 3 to 4 years of age, the procedure can be explained on a doll. For those who are older, a simple drawing of the bladder, urethra, ureters, and kidneys makes the procedure more understandable.

Handling actual equipment, when feasible, can be helpful in allaying anxiety in children of all ages. Anticipatory instruction on distraction techniques such as deep breathing, storytelling, and imagery may help the child relax during the actual procedures. If surgery is indicated, the child's understanding of the procedure can help decrease their fear and anxiety concerning more extensive medical-surgical intervention.

Because antibacterial medications are indicated in treating UTI, the nurse needs to advise parents on proper dosage and administration. When antibiotics such as nitrofurantoin are used for prolonged therapy to maintain urine sterility, parents need an explanation of the medication's continued necessity when no signs of infection are present. For all children an adequate or increased fluid intake should be encouraged.

One adverse effect that can occur with antibiotic treatment is antibiotic-associated diarrhea (AAD). The CPS defines AAD as three or more loose stools per day for 2 or more days occurring for up to 2 weeks after the initiation of antibiotics; it occurs in about 30% of patients. Parents should be made aware that probiotics (specifically *Lactobacillus rhamnosus* GG and *Saccharomyces boulardii*) may decrease the incidence of AAD (Marchand & Canadian Paediatric Society, Nutrition and Gastroenterology Committee, 2012/2019).

Prevention. Prevention is the most important goal in both primary and recurrent infection, and most preventive measures are simple hygienic habits that should be a routine part of daily care (see Guidelines box: Prevention of Urinary Tract Infection and Clinical Reasoning Case Study: Urinary Tract Infection and Constipation).

Sexually active females should be advised to urinate as soon as possible after they have intercourse, to flush out bacteria introduced during the activity.

GUIDELINES

Prevention of Urinary Tract Infection

Factors Predisposing to Development

Infants

- Underlying renal/urinary tract abnormalities (hydronephrosis; hydroureteronephrosis; vesicoureteral reflux)
- Sex (in decreasing order: uncircumcised males, females, circumcised males)

Older Children

- Bladder and bowel dysfunction
- Short female urethra close to vagina and anus
- High postvoid residuals
- Urine withholding
- Constipation

Measures of Prevention

- Timed voiding—child is reminded to void every 2 hours regardless of feeling sensation to void
- Double voiding—empty bladder normally, then sit and count to 10 and attempt to void again to facilitate complete emptying
- Ensure adequate fluid intake
- Monitor for and aggressively manage constipation—child should have Bristol 4 bowel movements one to two times per day (see Figure 46.1)
- Improved toilet posture for girls to prevent intravaginal voiding—sitting up straight with legs wide apart
- Practise good perineal hygiene: wipe from front to back.
- Avoid tight clothing or diapers; wear cotton panties rather than nylon.
- Check for vaginitis or pinworms, especially if child scratches between their legs.

CLINICAL REASONING CASE STUDY

Urinary Tract Infection and Constipation

During the nurse's assessment of Lisa, a 5-year-old admitted to the hospital for a severe urinary tract infection (UTI), her mother tells the nurse that Lisa has bowel movements every third or fourth day. They are usually large, hard-formed stools, and Lisa sometimes has trouble evacuating the stool.

1. Evidence—Is there sufficient evidence to draw conclusions about Lisa's UTI and constipation?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. UTIs and females
   b. Normal bowel patterns for 5-year-old children
   c. Association between UTIs and constipation
3. What priorities for nursing care should be established for Lisa?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to Lisa.

Obstructive Uropathy

Structural or functional abnormalities of the urinary system that obstruct the normal flow of urine can lead to dilatation of the urinary tract (kidneys or ureters). This dilatation is referred to as *hydronephrosis,* which is not an illness or disease but a finding on ultrasound. This is detected prenatally in one in five pregnancies and is self-limiting in up to 85% of children (Rickard et al., 2017). In some children, the dilatation may be due to an underlying pathology such as obstruction, which may require a surgical intervention.

Obstruction may be congenital or acquired, unilateral or bilateral, complete or incomplete, with acute or chronic manifestations. The obstruction can occur at any level of the upper or lower urinary tract (Figure 49.2). Partial obstruction may not be symptomatic, and changes caused may be partially or completely reversible if there is early intervention. Boys are affected more frequently than girls, and malformations are more common in children with other congenital abnormalities (e.g., prune belly syndrome, chromosomal anomalies, anorectal malformations, defects of the pinna of the ear).

If the obstruction is not diagnosed or left untreated, damage to distal nephrons in chronic uropathy alters the ability to concentrate urine, contributing to increased urine flow and metabolic **acidosis** occurring from the decreased excretion of acid secondary to the impaired ability of the distal nephron to secrete hydrogen ions. In addition, static urine serves as a medium for bacterial growth; therefore, UTIs may be more likely in children with urinary tract dilatation, which eventually may further increase the extent of renal damage.

Most cases of urinary tract obstruction in children born in developed countries are detected prenatally, and any surgical correction required is carried out before deterioration of renal function. Typically, surgical procedures to relieve obstruction are performed (such as pyeloplasty or ureterovesicostomy, or ureterostomy) instead of using external drainage devices as these may make future surgical correction more difficult. Medical complications of acute or chronic renal failure (chronic kidney disease [CKD]) or infection are managed as described later for those disorders.

Nursing Care. Nursing goals in urinary tract obstruction include assistance in its identification, assisting with diagnostic procedures, and caring for children with complications. Preparing parents and children for diagnostic procedures is a major nursing responsibility, as is preparation for surgical procedures (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44).

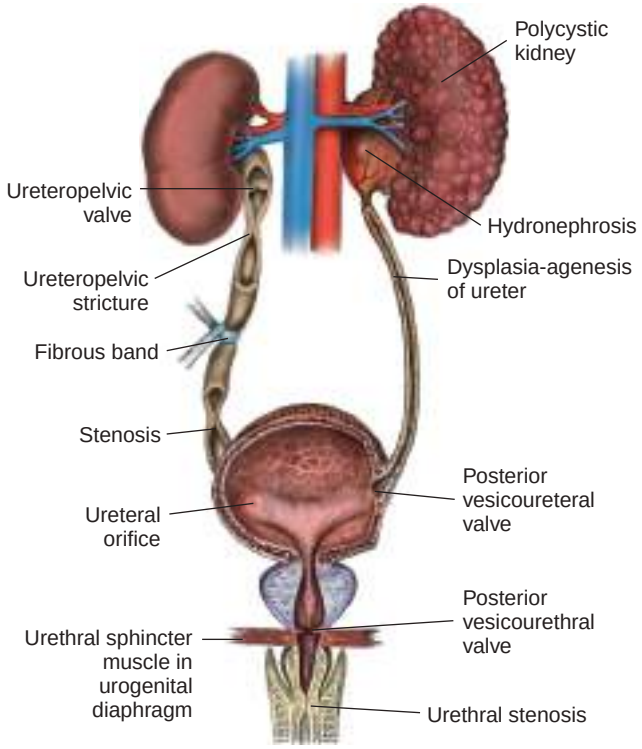

Fig. 49.2 Major sites of urinary tract obstruction.

Parents and children need emotional support and counselling during the lengthy management of these disorders. Children may be discharged with urinary drainage systems that require nursing education of the parents and older child regarding home care as well as recognition of complications, such as obstruction of urine flow or infection. Drainage tubes should be observed for obstruction resulting from sediment, small blood clots, or kinking. If indicated, instructions on site care and drainage tube irrigation need to be provided, including observation for signs of infection or dislodgement.

Those with progressive renal deterioration may face the prospect of dialysis or transplantation, as well as the emotions that accompany these procedures.

External Defects

Defects of the external genitourinary tract are serious conditions, primarily because some require multiple operations, interprofessional care, and lifelong follow-up, which may affect the psychological well-being of the child. The major anomalies of the lower genitourinary tract, their description, and their management are summarized in Table 49.4.

Phimosis. *Phimosis* refers to tight foreskin that precludes retraction over the glans. Phimosis can be classified as physiological or pathological. Physiological phimosis is a normal finding in infants and young boys and usually resolves as the child grows and may persist until adolescence. Ballooning with voiding commonly occurs in boys with phimosis and does not require treatment. Pathological phimosis occurs

TABLE 49.4 Anomalies of the Genitourinary Tract

Anomaly	Therapeutic Management
Inguinal hernia—Protrusion of abdominal contents through inguinal canal into scrotum	Detected as painless inguinal swelling of variable size Surgical closure of inguinal defect
Hydrocele—Fluid in scrotum that fluctuates in size	Surgical repair indicated if spontaneous resolution does not occur by 24 mo of age
Phimosis—Tight, nonretractile foreskin; Physiological—Normal with healthy supple foreskin Pathological occurs as a result of scarring from forceful retraction, recurrent infection (balanitis/balanoposthitis) or a skin condition called *balanitis xerotica obliterans (BXO)*	Physiological—Gentle stretching with or without the application of topical steroid ointment Pathological—Circumcision
Hypospadias—Urethral opening located on the ventral aspect of penis	*Objectives of surgical correction:* • Enable child to void in standing position and direct stream voluntarily in usual manner • Appearance of a circumcised penis • Sexually functional
Chordee—Ventral curvature of penis, often associated with hypospadias	Surgical repair
Epispadias—Meatal opening located on dorsal surface of penis	Surgical correction, usually including penile and urethral lengthening and bladder neck reconstruction (if necessary)
Cryptorchidism—Failure of one or both testes to descend normally through inguinal canal	Detected by inability to palpate testes within scrotum Surgical—Orchiopexy *Objectives of therapy:* • Optimize testicular function • Prevent damage to undescended testicle • Decrease incidence of malignant tumour formation that, while rare, has been reported to be increased with untreated undescended testes, particularly those that are intra-abdominal • Avoid trauma and torsion • Close inguinal canal
Exstrophy of bladder—Eversion of posterior bladder through anterior bladder wall and lower abdominal wall; associated with open pubic arch (a severe defect)	*Potential objectives of surgical correction:* • Preserve renal function • Attain urinary control • Perform adequate reconstructive repair • Improve sexual function (especially in males)

secondary to a chronic inflammatory process, forceful retraction resulting in scarring, or recurrent episodes of infections. Pathological phimosis has a characteristic appearance of white scar tissue around the preputial opening and will not improve on its own. A circumcision is required for management of pathological phimosis.

Balanitis is an inflammation or infection of the glans penis. *Balanoposthitis* is infection of phimotic foreskin, which is usually managed with topical treatments and, rarely, oral antibiotics. See Table 49.4 for more information.

Nursing care. Proper hygiene of the phimotic foreskin in infants and young boys consists of external cleansing during routine bathing. The foreskin should not be forcibly retracted, because it may create scarring that can prevent future retraction. Furthermore, retraction of the tight foreskin can result in *paraphimosis*, a condition in which the retracted foreskin cannot be replaced in its normal position over the glans. This causes edema and venous congestion created by constriction by the tight band of foreskin—a urological emergency that requires immediate evaluation.

Hydrocele. A *hydrocele* is the presence of peritoneal fluid in the scrotum between the parietal and visceral layers of the tunica vaginalis and is the most common cause of painless scrotal swelling in children and adolescents. Hydroceles may be communicating or noncommunicating. A communicating hydrocele usually develops when the processus vaginalis does not close during development, allowing for communication with the peritoneum. Noncommunicating hydroceles have no connection to the peritoneum with fluid coming from the mesothelial lining of the tunica vaginalis. Hydroceles are common in newborns and often resolve spontaneously, usually by 24 months of age. In older children, noncommunicating hydroceles may be idiopathic or a reactive hydrocele that occurs secondary to scrotal issues such as trauma.

Communicating hydroceles may change in size during the day or with straining, whereas noncommunicating hydroceles are not reducible and do not change size with crying or straining. Surgical repair is indicated for communicating hydroceles persisting past 2 year of age, because there is a risk for development of incarcerated inguinal hernia. Idiopathic hydroceles are repaired if symptomatic, and reactive hydroceles usually resolve with treatment of the underlying cause, such as epididymitis.

Nursing care. Surgical correction is an outpatient procedure. Parents should be advised that there may be temporary swelling and

discoloration of the scrotum that resolves spontaneously. The child should avoid using straddle toys for 2 to 4 weeks, and strenuous activities in older boys may need to be avoided for 1 month. If a dressing is used, it is removed in 2 to 3 days, and typically the child can bathe in 3 days.

Cryptorchidism (Undescended Testes). *Cryptorchidism* is failure of one or both testes to descend normally through the inguinal canal into the scrotum. The incidence of cryptorchidism is common in premature babies, multiple births, and other genetic conditions. The testes spontaneously descend by 6 months of age in most cases. Absence of testes within the scrotum can be a result of undescended (cryptorchid) testes, retractile testes, or anorchism (absence of testes).

Anorchism is the complete absence of a testis. Anorchism is suspected whenever one or both testes cannot be palpated in the patient with apparent cryptorchidism. In some cases, bilateral anorchism is associated with disorders of sex development with genotypic and phenotypic abnormalities, specifically congenital adrenal hyperplasia (CAH).

Retractile testes can be found at any level within the path of testicular descent, but they are most commonly identified in the groin. Fortunately, they are not truly cryptorchid. Instead, they are introverted to an inguinal or abdominal position because of an overactive cremasteric reflex. The cremasteric reflex, observed as withdrawal of the testis above the scrotum and into the inguinal canal in response to various stimuli, including exposure to cool temperatures, is active during infancy and peaks around 4 to 5 years of age. Unlike the cryptorchid testis, the retractile testis can be gently moved into the scrotum without residual tension and does not require treatment. Retractile testes can become ascending testes and require annual monitoring.

Therapeutic management. *Orchiopexy,* or surgical repositioning of the testis, is performed on palpable testes. Exploratory surgery may be required if the testis is not palpable. The goal of surgery is to place and fix viable undescended testes to a normal scrotal position or to remove nonviable testicular remnants. Scrotal positioning reduces the risk for torsion and trauma and permits easier examination of the testis, because there is an increased risk for testicular cancer despite treatment of undescended testes. In the routine surgical procedure for undescended testes, the testes are brought down into the scrotum and secured in that position without tension or torsion. A simple orchiopexy for a palpable testis can usually be performed as an outpatient procedure. If exploratory surgery is needed to determine if a testis is present, an examination under anaesthesia is the initial step. Depending on findings, a diagnostic laparoscopic procedure or an open inguinal approach may be performed. If an intra-abdominal testis is identified, a definitive procedure follows, which may be open or laparoscopic. Approximately 10% of boys with nonpalpable testes are found to have an absent testicle at the time of surgery.

Nursing care. Postoperative nursing care is directed toward preventing infection and instructing parents in home care of the child, including pain control. Observation of the wound for complications and activity restrictions are discussed. The child should avoid vigorous activities and use of straddle toys for 2 to 4 weeks postoperatively. General care is similar to that described for hydrocele repair.

Parents may be concerned about the child's future fertility. Recent studies show some decreased fertility in bilateral cryptorchism, but in patients with unilateral cryptorchism the fertility rate approximates that found in the general population. The risk for testicular cancer is a concern, which is decreased if surgery is done before puberty, but all boys with cryptorchidism should be taught testicular self-examination at puberty to facilitate early detection (Kolon et al., 2014). Surgical treatment is indicated as soon as possible after 6 months of age and should be completed by 2 years of age because spontaneous descent rarely occurs after 6 months of age, and treatment by 1 to 2 years of age is associated with improved fertility and testicular growth.

Hypospadias and Epispadias. **Hypospadias** is a common congenital defect of the penis that occurs in approximately 1 in 250 males (Elder, 2020b). There are three characteristics typically associated with hypospadias: meatal position that can open below the glans penis or anywhere along the ventral surface of the penis, the scrotum, or the perineum; ventral skin deficiency with a hooded dorsal foreskin; and ventral curvature/chordee.

Mild cases of hypospadias (Figure 49.3) may be repaired for cosmetic reasons and usually involve a single surgical procedure. More severe forms of hypospadias (e.g., proximal or severe chordee) may require a staged repair; surgical repair is recommended in order to minimize functional disturbances in the future. The surgical goals of hypospadias repair are a normally positioned urethral meatus, a straight penis when erect, the ability to void standing up, and healthy sexual function. Infants born with hypospadias should not be circumcised, as the procedure is much more complex than a standard newborn circumcision. Also, the foreskin is used during the urethral reconstruction, which may take place once the child is older than 6 months of age. Any infant born with a suspected hypospadias should be referred to a pediatric urologist.

Epispadias results from failure of urethral canalization. About 55% of the affected infants are boys who have a widened pubic symphysis and a broad, spadelike penis with the urethra opening on its dorsal surface. Girls have a wide urethra and a bifid clitoris. Severity ranges from mild anomaly to a severe form associated with exstrophy of the bladder. Surgical correction is usually necessary. Affected male infants should not be circumcised.

Exstrophy of the Bladder. Bladder exstrophy (Figure 49.4) is rare, occurring only in about 1 in 35 000 to 40 000 live births (Elder, 2020a). It often occurs in conjunction with epispadias and is more common in males than in females. It results from abnormal development of the bladder, abdominal wall, and symphysis pubis that causes the bladder, urethra, and ureteral orifices to all be exposed due to the abdominal wall defect. The bladder is visible in the suprapubic area as a red mass with numerous folds, with urine draining from it onto the infant's skin.

Immediately after birth, the exposed bladder is covered with a sterile, nonadherent dressing to protect it until closure can be performed.

Fig. 49.3 Hypospadias. (Courtesy H. Gil Rushton, MD, Children's National Medical Center.)

Fig. 49.4 Exstrophy of bladder. (Courtesy H. Gil Rushton, MD, Children's National Medical Center.)

Historically, early multidisciplinary surgery was performed within the newborn period, usually within the first several days of life. It has now become more common to wait until infants are several months old before attempting the repair.

Disorders of Sex Development. A disorder of sex development (DSD) in the newborn (Figure 49.5) often is discovered by the nurse during a physical assessment. Erroneous or abnormal sexual differentiation may be a genetic defect, such as congenital adrenal hypoplasia, which can be life-threatening because it involves deficiency of all adrenocortical hormones. Other possible causes of DSD include chromosomal abnormalities, defective sex hormone synthesis in males, and the placental transfer of masculinizing agents to female fetuses. Gender assignment should be based on data gathered from the following sources: family history, including the ingestion of steroids during pregnancy and relatives who had DSD or who died during the newborn period; physical examination; chromosomal analysis (results are available in 2 or 3 days); endoscopy, ultrasonography and radiographic contrast studies; biochemical tests, such as analysis of urinary steroid excretion, which helps detect several of the adrenocortical syndromes; and, in some instances, laparotomy or gonad biopsy. The infant and child with DSD pose very complex management questions, including sex assignment and potential genital surgery. Traditional approaches are being questioned and continue to evolve. Infants should be referred to an interprofessional team consisting of urology, endocrinology, general surgery, psychiatry, and social work as soon as possible to ensure timely and accurate diagnosis.

Fig. 49.5 Disorder of sex development (i.e., structure may be enlarged clitoral hood and clitoris or micropenis and bifid scrotum). (Courtesy Edward S. Tank, MD, Division of Urology, Oregon Health Sciences University.)

Therapeutic intervention, including any counselling and surgery, should be started as soon as possible. Any child born with DSD should not receive gender assignment until a proper assessment has been done. Gender assignment is a complex topic and should be based on age at presentation, potential for mature sexual function, potential fertility, and the long-term psychological and emotional impact on the child and family. Parents need much support as they learn to address this challenging situation.

Psychological Issues Related to Genital Surgery. Surgery involving sexual organs can be particularly disruptive to children, especially preschoolers and school-age children. Some of the difficulties of hospitalization, separation, and anxiety can be eased by hospital practices that are sensitive to the child's needs (see Chapter 43).

A child's **body image** is largely derived as a result of feedback from the primary caregivers, and parental anxiety regarding an acceptable physical appearance and adequate future sexual competency is readily communicated to an affected child. Children with **birth defects** are at risk for developing a distorted body image that reflects the caregiver's subtly communicated evaluation of their bodies.

After extensive review of the emotional, cognitive, and body image issues that may occur in children undergoing surgical reconstruction of a genital abnormality, if surgery is indicated, it is recommended that surgery be accomplished between the ages of 6 and 15 months, to minimize the psychological effects of surgery and anaesthesia.

Nursing care. Preparing children and their families for diagnostic and surgical procedures (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44) and for home care is a major nursing function. Most postoperative care involves care of the surgical site. Tub baths are discouraged for 1 week after simple surgeries. The surgical site needs to be kept clean and otherwise protected from infection and should be inspected for signs of infection. Dressings, if any, should be inspected regularly. More complex surgeries require additional care and observation (e.g., catheter care for urethral reconstruction and care of urinary diversion stomas and collection devices).

Some older children's activities, such as pushing, lifting, playing with straddle toys or in sandboxes, swimming, and engaging in rough activities, may be restricted after some types of surgical repairs. Precise restrictions depend on the specific type of surgery. Activities of infants and toddlers are not limited.

In most cases the results of surgery are satisfactory. However, in some of the more severe anomalies, such as exstrophy and those that require stomas, additional emotional interventions may be needed. A major concern of parents and children is related to surgery affecting the genitalia directly. Concerns about penis size, appearance of the genitalia, potential ability to procreate, and rejection by peers are potential fears that require psychological adjustment, particularly during adolescence.

GLOMERULAR DISEASE

Nephrotic Syndrome

Nephrotic syndrome is a clinical state that includes massive **proteinuria**, **hypoalbuminemia**, **hyperlipidemia**, and **edema**. The disorder can occur as (1) a primary disease known as *idiopathic nephrosis, childhood nephrosis*, or *minimal-change nephrotic syndrome (MCNS)*; (2) a secondary disorder that occurs as a clinical manifestation after or in association with glomerular damage that has a known or presumed cause; or (3) a congenital form inherited as an autosomal recessive disorder. The disorder is characterized by increased glomerular permeability to plasma protein, which results in massive urinary protein loss. The glomerulus is responsible for the initial step in the formation of urine, and the filtration rate depends on an intact glomerular membrane. This discussion is devoted to MCNS because it constitutes 80% of nephrotic syndrome cases.

Pathophysiology. The onset of MCNS can occur at any age but predominantly occurs in children between 2 and 7 years of age. It is rare in children younger than 6 months of age, uncommon in infants younger than 1 year of age, and unusual after the age of 8 years. Patients with MCNS are twice as likely to be male.

The pathogenesis of MCNS is not understood. There may be a metabolic, biochemical, physiochemical, or immune-mediated disturbance that causes the basement membrane of the glomeruli to become increasingly permeable to protein, but the cause and mechanisms are only speculative.

The glomerular membrane, normally impermeable to albumin and other proteins, becomes permeable to proteins, especially albumin, which leak through the membrane and are lost in urine (*hyperalbuminuria*). This permeability reduces the serum albumin level (*hypoalbuminemia*), decreasing the colloidal osmotic pressure in the capillaries. As a result, the vascular hydrostatic pressure exceeds the pull of the colloidal osmotic pressure, causing fluid to accumulate in the interstitial spaces (*edema*) and body cavities, particularly in the abdominal cavity (*ascites*). The shift of fluid from the plasma to the interstitial spaces reduces the vascular fluid volume (*hypovolemia*), which in turn stimulates the renin–angiotensin system and the secretion of ADH and aldosterone. Tubular reabsorption of sodium and water is increased in an attempt to increase intravascular volume. The elevation of serum lipids is not fully understood. The sequence of events in nephrotic syndrome is diagrammed in Figure 49.6.

Diagnostic Evaluation. The disease is suspected on the basis of clinical manifestations (Box 49.2). Generalized edema may develop rapidly or gradually but eventually prompts the parents to seek medical attention. Parents usually give a history of the child being well but steadily gaining weight, appearing edematous, and then becoming anorexic, irritable, and less active.

The diagnosis of MCNS is made on the basis of the history and clinical manifestations (edema, proteinuria, hypoalbuminemia, and hypercholesterolemia in the absence of hematuria and hypertension) in children between 2 and 8 years of age. The hallmark of MCNS is massive proteinuria (higher than 2+ on urine dipstick). Hyaline casts, oval

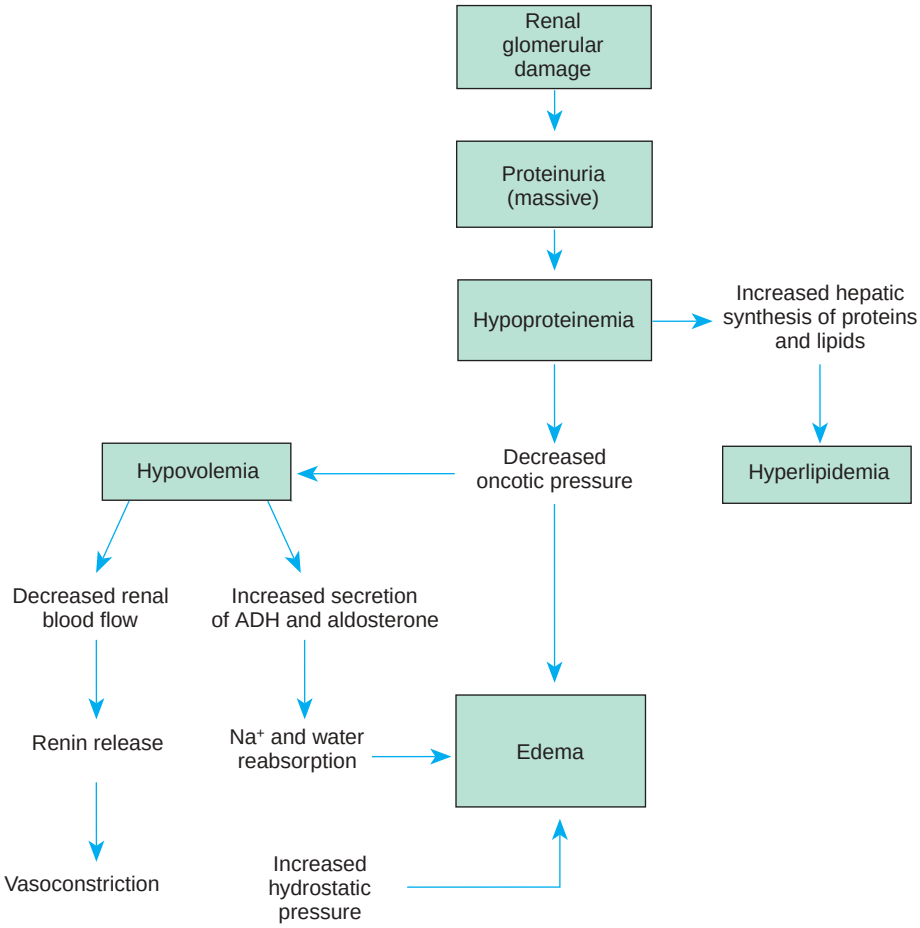

Fig. 49.6 Sequence of events in nephrotic syndrome. *ADH,* Antidiuretic hormone.

BOX 49.2 Clinical Manifestations of Nephrotic Syndrome

Weight gain
Puffiness of face (facial edema):
- Especially around the eyes
- Apparent on arising in the morning
- Subsides during the day

Abdominal swelling (ascites)
Pleural effusion
Labial or scrotal swelling
Edema of intestinal mucosa, possibly causing:
- Diarrhea
- Anorexia
- Poor intestinal absorption

Ankle or leg swelling
Irritability
Tendency to fatigue easily
Lethargy
Blood pressure normal or slightly decreased
Susceptibility to infection
Urine alterations:
- Decreased volume
- Frothy

fat bodies, and a few RBCs can be found in the urine of some affected children, although there is seldom gross hematuria. The GFR is usually normal or high. Kidney function must be monitored because acute kidney injury (AKI) may occur due to intravascular volume depletion, interstitial nephritis, acute tubular necrosis, or other factors (Rheault et al., 2014).

Total serum protein concentration is low, with the serum albumin significantly reduced and plasma lipids elevated. Hemoglobin and hematocrit are usually normal or elevated as a result of hemoconcentration. The platelet count may be elevated. Serum sodium concentration may be low. If the patient does not respond to a 4- to 8-week course of steroids, a renal biopsy may be needed to distinguish between other types of nephrotic syndrome. The biopsy results of children with MCNS are remarkable for effacement of the foot processes of the epithelial cells lining the basement membrane, but otherwise the kidney tissue appears normal.

Therapeutic Management. Objectives of therapeutic management include (1) reducing the excretion of urinary protein, (2) reducing fluid retention in the tissues, (3) preventing infection, and (4) minimizing complications related to therapies. Dietary restrictions include a low-salt diet and, in more severe cases, fluid restriction. If complications of edema develop, diuretic therapy may be initiated to provide temporary relief from edema. Sometimes infusions of 25% albumin are used. Acute infections are treated with appropriate antibiotics.

Corticosteroids are the first line of therapy for MCNS. The starting dosage for prednisone is usually 2 mg/kg body weight per day, in one or more divided doses for 6 weeks, followed by 1.5 mg/kg body weight per alternate days for 6 weeks (Erkan, 2020). Most children respond within 7 to 21 days. The medication is then tapered over a period of several months and eventually stopped if the child remains asymptomatic.

About two thirds of children with MCNS have a relapse, heralded first by increased urine protein. Relapses can be diagnosed early if parents are taught routine home monitoring of urine protein by dipstick. Relapses are treated with a repeated course of high-dose steroid therapy. Adverse effects of the steroids include weight gain, rounding of the face ("moon face"), behaviour changes, and increased appetite. Long-term therapy may result in hirsutism, growth restriction, **cataracts**, hypertension, GI bleeding, bone demineralization, infection, and **hyperglycemia**. Children who do not respond to steroid therapy, those who have frequent relapses, and those in whom the adverse effects threaten their growth and general health may be considered for a course of therapy using other immunosuppressant medications (cyclophosphamide, chlorambucil, or cyclosporine).

MCNS episodes, both the first episode and the relapse, often happen in conjunction with a viral or bacterial infection. Relapses can also be triggered by allergies and immunizations. Relapses in children with MCNS may continue over many years.

Complications of nephrotic syndrome include infection, circulatory insufficiency secondary to hypovolemia, and thromboembolism. Infections that may be seen in children with nephrotic syndrome include peritonitis, cellulitis, and pneumonia and require prompt recognition and vigorous treatment with appropriate antibiotic therapy.

Prognosis. The prognosis for ultimate recovery in most cases is good. It is a self-limiting disease, and in children who respond to steroid therapy the tendency to relapse decreases with time. With early detection and prompt implementation of therapy to eradicate proteinuria, progressive basement membrane damage is minimized, so that when the tendency to relapse is past, renal function is usually normal or near normal. It is estimated that approximately 80% of affected children have this favourable prognosis.

Nursing Care. Continuous monitoring of fluid intake and output is an important nursing function. Strict intake and output records are essential but may be difficult to obtain from very young children. Application of collection bags is irritating to edematous skin that is readily subject to breakdown. Applying diapers or weighing wet pads may be necessary.

Other methods of monitoring progress include urine examination for albumin, taking daily weight, and measurement of abdominal girth. Assessment of edema (e.g., increased or decreased swelling around the eyes and dependent areas), the degree of pitting, and the colour and texture of skin are part of nursing care. Assessing for signs of skin breakdown due to severe edema is necessary. With severe scrotal swelling, the use of a scrotal sling may be indicated to decrease pressure and discomfort. Vital signs need to be monitored to detect any early signs of complications such as shock or an infective process. Infection is a constant source of danger to edematous children and those receiving corticosteroid therapy. These children are particularly vulnerable to upper respiratory tract infection; they must be kept warm and dry, active, and protected from contact with infected individuals (e.g., roommates, visitors, and personnel).

Loss of appetite accompanying active nephrosis can create a perplexing issue for nurses. The combined efforts of nurse, dietitian, parents, and child are needed to formulate a nutritionally adequate and appealing diet. Salt is usually restricted (but not eliminated) during the edema phase and while the child is on steroid therapy. Fluid restriction (if prescribed) is limited to short-term use during massive edema. Every effort should be made to serve attractive meals with preferred foods and a minimum of fuss, but it usually requires considerable ingenuity to entice the child to eat (see Feeding the Sick Child, Chapter 44).

Children usually adjust activities according to their tolerance level. However, they may require guidance in selecting play activities. Suitable recreational and diversional activities are an important part of their care. Irritability and mood swings that accompany steroid therapy are not unusual in these children and may create an additional challenge for the nurse and family.

Family support and home care. Continuous support of the child and family is one of the major nursing considerations. Many children are treated at home during relapses. Parents need to be taught to detect signs of relapse and to call for changes in treatment at the earliest indications. Unless the edema and proteinuria are severe or the parents are unable to care for the ill child, home care is preferred. Parents should be instructed in testing urine for albumin, administering medications, and providing general care. Parents also need to encourage the child to avoid contact with infected playmates, but the child should attend school. Psychological support may be indicated because of body image changes associated with prolonged and frequent steroid use.

The prolonged course of the relapsing form of nephrotic syndrome is taxing to both the child and the family. The up-and-down course of remissions and exacerbations with periodic disruption of family life by hospitalization places a strain on the child and their family. Success is more likely when relapses are detected and therapy is instituted early, and remissions have a longer course when care instructions are carried out.

Acute Glomerulonephritis

Acute glomerulonephritis (AGN) may be a primary event or a manifestation of a systemic disorder that can range from minimal to severe. Common features include oliguria, edema, hypertension and circulatory congestion, hematuria, and proteinuria. Most cases are postinfectious and have been associated with pneumococcal, streptococcal, and viral infections. *Acute poststreptococcal glomerulonephritis* (APSGN) is the most common of the postinfectious renal diseases in childhood and the one for which a cause can be established in most cases. While APSGN can occur at any age, it affects primarily early school-age children, with a peak age of onset of 6 to 7 years. It is uncommon in children younger than 2 years of age, and males outnumber females 2:1.

Etiology. APSGN is an immune-complex disease that occurs after an antecedent streptococcal infection with certain strains of the group A beta-hemolytic streptococcus. Most streptococcal infections *do not* cause APSGN. A latent period of 10 to 21 days occurs between the streptococcal infection and the onset of clinical manifestations. Disease secondary to streptococcal pharyngitis is more common in the winter or spring, but when APSGN is associated with pyoderma (principally impetigo), it may be more prevalent in later summer or early fall, especially in warmer climates. Second episodes of AGN are rare. APSGN is typically self-limiting and recovery occurs spontaneously.

Pathophysiology. The pathophysiology of APSGN is still uncertain. Immune complexes are deposited in the glomerular basement membrane. The glomeruli become edematous and infiltrated with polymorphonuclear leukocytes, which occlude the capillary lumen. The resulting decrease in plasma filtration results in an excessive accumulation of water and retention of sodium that expands plasma and interstitial fluid volumes, leading to circulatory congestion and edema. The cause of the hypertension associated with AGN cannot be completely explained by fluid retention. Excess renin may also be produced.

Diagnostic Evaluation. Typically, affected children are in good health until they experience the streptococcal infection. In some instances they have a history of only a mild cold or no previous infection at all. The onset of nephritis appears after an average latency period of about 1 to 3 weeks (Box 49.3). Because the child appears to be well during the latency period, parents do not recognize the association. The edema is relatively moderate and may not be appreciated by someone unfamiliar with the child's normal appearance.

BOX 49.3 Clinical Manifestations of Acute Poststreptococcal Glomerulonephritis

Edema:
- Especially periorbital
- Facial edema more prominent in the morning
- Spreads during the day to involve extremities and abdomen

Anorexia

Urine:
- Cloudy, smoky brown (resembles tea or cola)
- Severely reduced volume

Pallor

Irritability

Lethargy

Child appearing ill

Child seldom expressing specific health concerns

Older children:
- Headaches
- Abdominal discomfort
- Dysuria

Vomiting possible

Mild to moderately elevated blood pressure

Urinalysis during the acute phase characteristically shows hematuria and proteinuria. Proteinuria generally parallels the hematuria and may be 3+ or 4+ in the presence of gross hematuria. Gross discoloration of the urine reflects RBC and hemoglobin content. Microscopic examination of the sediment shows many RBCs, leukocytes, epithelial cells, and granular and RBC casts. Bacteria are not seen.

Azotemia that results from impaired glomerular filtration is reflected in elevated urea and creatinine levels in at least 50% of cases. Occasionally proteinuria is excessive and the patient may have nephrotic syndrome (i.e., hypoproteinemia and hyperlipidemia).

Cultures of the pharynx are rarely positive for streptococci, since the renal disease occurs weeks after the infection.

Some serological tests are necessary to make the diagnosis of APSGN. Circulating serum antibodies to streptococci indicate the presence of a previous infection. The antistreptolysin O (ASO) titre is the most familiar and readily available test for streptococcal infection. Other antibodies that may aid in diagnosis are elevated antihyaluronidase (AHase), antideoxyribonuclease B (ADNase-B), and streptozyme. All patients with APSGN have reduced serum complement (C3) activity in the early stages of the disease. Rising C3 levels are used as a guide to indicate improvement of the disease and should be normal in almost all patients 8 weeks after disease onset.

Studies that may be useful include chest X-ray examination, which generally shows cardiac enlargement, pulmonary congestion, or pleural effusion during the edematous phase of acute disease. Renal biopsy for diagnostic purposes is seldom required but may be useful in the diagnosis of atypical cases.

Therapeutic Management. Disease management consists of general supportive measures and early recognition and treatment of complications. Children who have normal blood pressure and a satisfactory urine output can generally be treated at home. Those with substantial edema, hypertension, gross hematuria, or significant oliguria should be hospitalized because of the unpredictability of complications.

Dietary restrictions depend on the stage and severity of the disease, especially the extent of edema. Moderate sodium restriction and even fluid restriction may be instituted for children with hypertension and

edema. Foods with substantial amounts of potassium are generally restricted during the period of oliguria.

Regular measurement of vital signs, body weight, and intake and output is essential to monitor the progress of the disease and to detect complications that may appear at any time during the course of the disease. A record of daily weight is the most useful means for assessing fluid balance. Rarely, children with APSGN will develop acute kidney injury (AKI) with oliguria that significantly alters the fluid and electrolyte balance (resulting in **hyperkalemia**, acidosis, hypocalcemia, or hyperphosphatemia). These children require careful therapeutic management. Peritoneal dialysis or hemodialysis is seldom needed.

Acute hypertension must be anticipated and identified early. Blood pressure measurements should be taken every 4 to 6 hours. A variety of antihypertensive medications and diuretics can be used to control hypertension. Antibiotic therapy is indicated only for those children with evidence of persistent streptococcal infections. It is used to prevent transmission of nephritogenic streptococci to other family members.

Prognosis. Almost all children correctly diagnosed as having APSGN recover completely, and specific immunity is conferred, so subsequent recurrences are uncommon. Some of these children have been reported to develop chronic disease, but most of these cases are now believed to be different glomerular diseases misdiagnosed as poststreptococcal disease.

Nursing Care. Nursing care of the child with glomerulonephritis involves careful assessment of the disease status, with regular monitoring of vital signs (including frequent measurement of blood pressure), fluid balance, and behaviour.

Vital signs provide clues to the severity of the disease and early signs of complications. They need to be carefully measured and any deviations reported and recorded. The volume and character of urine should be noted and the child weighed daily. Children with restricted fluid intake, especially those who are not severely edematous or those who have lost weight, should be observed for signs of dehydration.

Assessment of the child's appearance for signs of cerebral complications is an important nursing function, since the severity of the acute phase is variable and unpredictable. The child with edema, hypertension, and gross hematuria may be subject to complications, and anticipatory preparations such as seizure precautions and IV equipment should be included in the nursing care plan.

For most children a regular diet is allowed, but it should contain no added salt. Foods high in sodium and salted treats need to be eliminated, and parents and friends should be advised not to bring snacks such as potato chips or pretzels. The total amount of salt ingested is usually less because of poor appetite. Fluid restriction, if prescribed, is more difficult, and the amount permitted should be evenly divided throughout the waking hours. Meal preparation and service require special attention, since the child is indifferent to meals during the acute phase. Again, collaboration between parents and the dietitian and special consideration for food preferences can facilitate meal planning.

During the acute phase, children are generally content to lie in bed. As they begin to feel better and their symptoms subside, they will want to be up. Activities should be planned to allow for frequent rest periods and to avoid fatigue. Children who have mild edema and no hypertension, as well as convalescent children who are being treated at home, need follow-up care. Parents need to be instructed in general measures, including diet and prevention of infection.

Health supervision is continued, with weekly, followed by monthly, visits for evaluation and urinalysis. Parent education and support is needed to get the child's discharge organized and home care set up. The family needs to learn how to care for the child at home and to have the follow-up care and health supervision arranged.

MISCELLANEOUS RENAL DISORDERS

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is an uncommon, acute renal disease that occurs primarily in infants and small children between the ages of 6 months and 5 years. HUS is one of the most frequent causes of acquired AKI in children (Grisaru, 2014). The clinical features of the disease include acquired hemolytic anemia, thrombocytopenia, renal injury, and central nervous system symptoms. The etiology of HUS is thought to be associated with bacterial toxins, chemicals, and viruses. The appearance of the disease has been associated with *Rickettsia* organisms, viruses (especially coxsackievirus, echovirus, and adenovirus), *E. coli*, pneumococci, shigellae, and salmonellae and may represent an unusual response to these infections. Multiple cases of HUS caused by enteric infection of the *E. coli* O157:H7 serotype have been traced to undercooked meat, especially ground beef. Other sources are unpasteurized milk or fruit juice, especially apple, alfalfa sprouts, lettuce, and salami. Drinking or swimming in sewage-contaminated water can also cause infection. The clinical presentation is usually a history of a prodromal illness (most often gastroenteritis or an upper respiratory tract infection) followed by the sudden onset of hemolysis and renal failure.

Pathophysiology. The primary site of injury appears to be the endothelial lining of the small glomerular arterioles, which become swollen and occluded with deposits of platelets and fibrin clots (intravascular coagulation). RBCs are damaged as they attempt to move through the partially occluded blood vessels and are removed by the spleen, causing acute hemolytic anemia. The platelet aggregation within the damaged blood vessels or the damage and removal of platelets produce the characteristic thrombocytopenia.

Diagnostic Evaluation. The triad of anemia, thrombocytopenia, and renal failure is sufficient for diagnosis (Box 49.4). Renal involvement is evidenced by proteinuria, hematuria, and urinary casts; blood urea nitrogen (BUN) and serum creatinine levels are elevated. A low hemoglobin and hematocrit and a high reticulocyte count confirm the hemolytic nature of the anemia.

Therapeutic Management. The goals of therapy are early diagnosis and aggressive, supportive care of the AKI and hemolytic anemia. The most consistently effective treatment of HUS is hemodialysis or peritoneal dialysis, which is instituted in any child who has been anuric

BOX 49.4 Clinical Manifestations of Hemolytic Uremic Syndrome

Central nervous system involvement:
- Seizures
- Stupor or coma

Signs of acute heart failure (sometimes)

for 24 hours or who demonstrates oliguria with uremia or hypertension and seizures. Other treatments include pharmacological agents, fresh frozen plasma, and plasmapheresis. Blood transfusions with fresh, washed packed cells are administered for severe anemia but are used with caution to prevent circulatory overload from added volume.

Prognosis. With prompt treatment the recovery rate is about 95%, but residual renal impairment ranges from 10 to 50%. Long-term complications include CKD, hypertension, and central nervous system disorders. Death is usually caused by residual renal impairment or central nervous system injury.

Nursing Care. Nursing care is the same as that provided in AKI and, for children with continued impairment, includes management of chronic disease. Because of the sudden and life-threatening nature of the disorder in a previously well child, parents are often ill prepared for the impact of hospitalization and treatment and require support and understanding.

Wilms Tumour

Wilms tumour (WT), or nephroblastoma, is the most common malignant renal and intra-abdominal tumour of childhood. Its frequency is estimated to be 7 cases per million children younger than 15 years (Daw et al., 2020). Approximately 75% of the cases occur in children younger than 5 years, with a peak incidence at 2 to 3 years of age; 2% of cases have a familial origin (Daw et al., 2020). Unfortunately, there is no method of identifying gene carriers at this time. The Canadian Cancer Society reported that between 2012 and 2016, there were 170 cases of kidney and renal pelvis cancer diagnosed in Canadian children 0 to 14 years of age. Almost all of these were WT cases. In addition, there were 11 deaths from WTs in children 0 to 14 years of age from 2013 to 2017 (Canadian Cancer Society, 2021).

Clinical Manifestations. The most common presenting sign is painless swelling or mass within the abdomen. The mass is characteristically firm, nontender, confined to one side, and deep within the flank. If it is on the right side, it may be difficult to distinguish from the liver, although, unlike that organ, it does not move with respiration. Parents usually discover the mass during routine bathing or dressing of the child.

Other clinical manifestations are the result of compression from the tumour mass, metabolic alterations secondary to the tumour, or metastasis. Hematuria occurs in less than one fourth of children with WT. Anemia, usually secondary to hemorrhage within the tumour, results in pallor, anorexia, and lethargy. Hypertension, caused by secretion of excess amounts of renin by the tumour, occurs occasionally. Other effects of malignancy include weight loss and fever. If metastasis has occurred, symptoms of lung involvement (e.g., dyspnea, cough, shortness of breath, and chest pain) may be evident.

Diagnostic Evaluation. In a child suspected of having WT, special emphasis is placed on the history and physical examination for the presence of congenital anomalies, a family history of cancer, and signs of malignancy (e.g., weight loss, size of liver and spleen, indications of anemia, lymphadenopathy). Most children with WT are brought to the health care provider because of abdominal swelling or an abdominal mass (Box 49.5). Canadian children with WT are referred to tertiary and quaternary pediatric institutions for initial diagnosis and surgical management. All children with WT in North America are managed according to treatment protocols developed by the Children's Oncology Group (COG) regardless of location of treatment. Specific tests include radiographic studies, including abdominal ultrasound and abdominal and chest computed tomography (CT) scan; hematological studies; biochemical studies; and urinalysis. Studies to demonstrate the relationship of the tumour to the ipsilateral kidney and the presence of a normal functioning kidney on the contralateral side are essential. If a large tumour is present, there may be possible involvement of the vena cava.

BOX 49.5 Clinical Manifestations of Wilms Tumour

Abdominal swelling or mass:
- Firm
- Nontender

Hematuria (less than one fourth of cases)
Fatigue and malaise
Hypertension (occasionally)
Weight loss
Fever
Manifestations resulting from compression of tumour mass
Secondary metabolic alterations from tumour or metastasis
If metastasis, symptoms of lung involvement:
- Dyspnea
- Cough
- Shortness of breath
- Chest pain (sometimes)

Staging and Prognosis. WT arises from a malignant, undifferentiated cluster of primordial cells capable of initiating the regeneration of an abnormal structure. It occurs slightly more often in the left kidney, and in about 10% of cases both kidneys are involved. WT occurs more often in children with hemihypertrophy, aniridia, genitourinary anomalies, and a variety of predisposition syndromes, including Beckwith-Wiedemann syndrome and Denys-Drash syndrome (Daw et al., 2020).

The histology of the tumour cells is identified and classified according to two groups: favourable histology (FH) and unfavourable histology (UH). Only about 10% of WTs demonstrate UH, which is associated with a poorer prognosis and demands a more aggressive treatment protocol, regardless of the clinical stage (Daw et al., 2020). Survival rates for WT are the highest among all childhood cancers. Children with localized tumour (stages I and II) have a 90% chance of cure with multimodal therapy. Very rarely, WT may recur, especially in the lungs. Both chemotherapy and radiotherapy can induce second malignancies, usually in areas that have been irradiated.

Therapeutic Management. Combined treatment with surgery and chemotherapy with or without radiation is based on the histological pattern and clinical stage. A large transabdominal incision is performed for optimal visualization of the abdominal cavity. In certain circumstances, the mass may be removed using a laparoscopic approach. For radical nephrectomies, the tumour, affected kidney, and sometimes the adjacent adrenal gland are removed. Great care is taken to keep the encapsulated tumour intact, since rupture can seed cancer cells throughout the abdomen, lymph channel, and bloodstream. Regional lymph nodes are inspected, and a biopsy is performed when indicated. Any involved structures, such as part of the colon, diaphragm, or vena cava, are removed.

If both kidneys are involved, the child may be treated with chemotherapy before surgery to decrease the size of the tumour, allowing for

more successful surgery. It may be possible to perform a partial nephrectomy on the less affected kidney, with a total nephrectomy on the opposite side.

Postoperative radiotherapy is indicated for children with high-risk WT, metastasis, residual postoperative disease, unfavourable histological characteristics, tumour rupture, or recurrence. Chemotherapy is indicated for all children. The duration of therapy ranges from 6 to 15 months.

Nursing Care. Nursing care of the child with WT is similar to that for children with other cancers treated with surgery, irradiation, and chemotherapy. However, there are some significant differences; these are discussed below for each phase of nursing care.

Preoperative care. As with many of the other cancers, the diagnosis of WT is a shock. Frequently the child has no physical indication of the seriousness of the disorder other than a palpable abdominal mass. Because the parents usually discover the mass, the nurse needs to take into account their feelings regarding the diagnosis. Whereas some parents are grateful for their detection of the tumour, others feel guilty for not finding it sooner or anger toward the health care provider for missing it on earlier examinations.

The preoperative period is one of swift diagnosis. The nurse must prepare the child and parents for all laboratory and operative procedures. Explanations should be simple, repeated as needed, and focused on the child's actual experiences. In addition to the usual preoperative observations, blood pressure is monitored, since hypertension from excess renin production is a possibility.

There are several special preoperative concerns, the most important of which is that *tumour palpation should be minimized and conducted by experienced clinicians*, given the unlikely but possible dissemination of cancer cells to adjacent and distant sites in the event of rupture.

! NURSING ALERT

To reinforce the need for caution, it may be necessary to post a sign on the bed that reads "DO NOT PALPATE ABDOMEN." Careful bathing and handling are also important in preventing trauma to the tumour site.

Because radiotherapy and chemotherapy are usually begun immediately after surgery, parents need an explanation of what to expect, such as major benefits and adverse effects (see Chapter 48). The timing of the information should be considered, to avoid overwhelming the family. Ideally, the nurse should be present during physician–parent conferences to answer questions as they arise. It is usually better to postpone telling the child about these adverse effects until after surgery. **Alopecia**, usually of most concern to older children, does not occur until approximately 2 weeks after the initial treatment regimen. Therefore, the child can be prepared for the hair loss postoperatively in conjunction with the family and care team; this should be individualized by child and stage of development.

Postoperative care. Despite the extensive surgical intervention necessary in many children with WT, the recovery is usually rapid. The major nursing responsibilities are the same as those after any abdominal surgery. Because these children are at risk for intestinal obstruction from vincristine-induced ileus, radiation-induced edema, and postsurgical adhesion formation, the nurse needs to carefully monitor GI activity, such as bowel movements, bowel sounds, distension, vomiting, and pain. The nurse should also monitor blood pressure, urine output, and signs of infection, as well as institute pulmonary hygiene to prevent postoperative pulmonary complications.

Family support. The postoperative period is frequently difficult for parents. The shock of seeing their child immediately after surgery may be the first realization of the seriousness of the diagnosis. From surgery, the stage and pathology of the tumour are determined. During this period, the nurse should be with the parents to assure them of the child's recovery after surgery and to assess their understanding of the total experience. Older children need an opportunity to express their feelings concerning the many procedures to which they have been subjected in rapid succession. **Play therapy** with dolls or puppets or through drawing can be beneficial in helping them adjust. It is not unusual for children to feel angry or stressed because of the extent of the surgery, the need for additional therapy, or the seriousness of the disorder.

! NURSING ALERT

Children with only one kidney should avoid taking medicines that are harmful to the kidneys and should wear protective equipment when they play contact sports (Canadian Cancer Society, 2021). Prompt detection and treatment of any genitourinary signs or symptoms are also important.

RENAL FAILURE

Renal failure is the inability of the kidneys to excrete waste material, concentrate urine, and conserve electrolytes. It can occur suddenly as AKI in response to inadequate perfusion, kidney disease, or urinary tract obstruction, or it can develop slowly as a result of long-standing CKD or an anomaly.

Azotemia and *uremia* are terms often used in relation to renal failure. *Azotemia* is the accumulation of nitrogenous waste within the blood. *Uremia* is a more advanced condition in which retention of nitrogenous products produces toxic symptoms. Azotemia is not life-threatening, whereas uremia is a serious condition that often involves other body systems.

Acute Kidney Injury

AKI is said to exist when the kidneys suddenly are unable to regulate the volume and composition of urine appropriately in response to food and fluid intake and the needs of the organism. The principal feature of AKI is *oligoanuria*, or reduced urine volume, associated with azotemia, metabolic acidosis, and diverse electrolyte disturbances. AKI is not common in childhood. The outcome depends on the cause, associated findings, and prompt recognition and treatment.

The pathological conditions that produce AKI caused by glomerulonephritis and HUS are discussed earlier in the chapter in relation to those disorders. AKI can also develop as a result of a large number of related or unrelated clinical conditions: poor renal perfusion, urinary tract obstruction, acute renal injury, cardiac surgery, or the final expression of chronic, irreversible renal disease. The most common cause in children is transient renal failure resulting from severe dehydration or other causes of poor perfusion that may respond to restoration of fluid volume.

Pathophysiology. AKI is usually reversible, but the deviations of physiological function can be extreme, and mortality in the pediatric age group remains high. There is severe reduction in the GFR, an elevated urea level, and a significant reduction in renal blood flow.

The clinical course is variable and depends on the cause. In reversible AKI there is a period of severe oliguria, or a low-output phase, followed by an abrupt onset of diuresis, or a high-output phase, and then a gradual return to (or toward) normal urine volumes.

BOX 49.6 Clinical Manifestations of Acute Kidney Injury

Specific
- Oliguria
- Anuria uncommon (except in obstructive disorders)

Nonspecific (May Develop)
- Nausea
- Vomiting
- Drowsiness
- Edema
- Hypertension

Other
- Manifestations of underlying disorder or pathological condition

Diagnostic Evaluation. In many instances of AKI the infant or child is already critically ill with the precipitating disorder, and the explanation for development of oliguria may or may not be readily apparent (Box 49.6). When a previously well child develops AKI without obvious cause, a careful history is taken to reveal symptoms that may be related to glomerulonephritis, obstructive uropathy, or exposure to nephrotoxic chemicals (e.g., ingestion of heavy metals, inhalation of carbon tetrachloride or other organic solvents, or high doses of medications such as nonsteroidal anti-inflammatory drugs [NSAIDs] [Blatt & Liebman, 2013] known to be toxic to the kidneys). Significant laboratory measurements during renal shutdown that serve as a guide for therapy are urea, serum creatinine, pH, sodium, potassium, and calcium.

Diminished urine output and lethargy in a child who is dehydrated, is in shock, or has recently undergone surgery should be evaluated for possible AKI.

Therapeutic Management. Treatment of AKI is directed toward (1) treatment of the underlying cause, (2) management of the complications of renal failure, and (3) provision of supportive therapy within the constraints imposed by the renal failure.

Treatment of poor perfusion resulting from dehydration consists of volume restoration, as described in Chapter 46 in the treatment of dehydration. If oliguria persists after restoration of fluid volume or if the renal failure is caused by intrinsic renal damage, the physiological and biochemical abnormalities that have resulted from kidney dysfunction must be corrected or controlled. Initially, a Foley catheter is inserted to rule out urine retention, to collect available urine for analysis, and to monitor the results of diuretic administration. The catheter may or may not be removed during the oliguric phase.

The amount of exogenous water provided should not exceed the amount needed to maintain zero water balance. It is calculated on the basis of estimated endogenous water formation and losses from sensible (primarily gastrointestinal) and insensible sources. No allotment is calculated for urine as long as oliguria persists.

When the output begins to increase, either spontaneously or in response to diuretic therapy, the intake of fluid, potassium, and sodium must be monitored and adequate replacement provided to prevent depletion and its consequences. Some patients pass enormous amounts of electrolyte-rich urine.

Complications. The child with AKI has a tendency to develop water intoxication and hyponatremia, which makes it difficult to provide calories in sufficient amounts to meet the child's needs and reduce tissue catabolism, metabolic acidosis, hyperkalemia, and uremia. If the child is able to tolerate oral foods, food sources high in concentrated carbohydrate and fat but low in protein, potassium, and sodium may be provided. However, many children have functional disturbances of the GI tract, such as nausea and vomiting; thus the IV route is generally preferred and usually consists of essential amino acids or a combination of essential and nonessential amino acids administered by the central venous route.

Control of water balance in these patients requires monitoring of accurate intake and output, body weight, and electrolyte measurements. In general, during the oliguric phase, no sodium, chloride, or potassium is given unless there are other large, ongoing losses. Regular measurement of plasma electrolyte, pH, urea, and creatinine levels is required to assess the adequacy of fluid therapy and to anticipate complications that require specific treatment.

Hyperkalemia is the most immediate threat to the life of the child with AKI. Hyperkalemia can be minimized and sometimes avoided by eliminating potassium from all food and fluid, by reducing tissue catabolism, and by correcting acidosis. Measures to reduce serum potassium levels are oral or rectal administration of an ion-exchange resin such as sodium polystyrene sulphonate (Kayexalate) and peritoneal dialysis or hemodialysis (see later in this chapter). The resin produces its effect by exchange of its sodium for the potassium, thus binding potassium for removal from the body. This increased sodium concentration may contribute to fluid overload, hypertension, and cardiac failure. Dialysis removes potassium and other waste products from the serum by diffusion through a semipermeable membrane.

! NURSING ALERT

Any of the following signs of hyperkalemia constitute an emergency and need to be reported immediately:
- Serum potassium concentrations in excess of 7 mmol/L
- Electrocardiographic abnormalities, such as prolonged QRS complex, depressed ST segment, high peaked T waves, bradycardia, or heart block

Hypertension is a frequent and serious complication of AKI, and to detect it early, blood pressure measurements are taken every 4 to 6 hours. The most common cause of hypertension in AKI is overexpansion of extracellular fluid and plasma volume together with activation of the renin–angiotensin system. Hypertension is controlled with antihypertensive medications. Other measures that may be used include limiting fluids and salt.

Anemia is frequently associated with AKI, but transfusion is not recommended unless the hemoglobin drops below 60 g/L. Transfusions, if used, consist of fresh washed, packed RBCs given slowly to reduce the likelihood of increasing blood volume, hypertension, and hyperkalemia.

Seizures occur often when renal failure progresses to uremia and are also related to hypertension, hyponatremia, and hypocalcemia. Treatment is directed at the specific cause when known. More obscure causes are managed with antiepileptic medications.

Cardiac failure with pulmonary edema is almost always associated with hypervolemia. Treatment is directed toward reduction of fluid volume, with water and sodium restriction and administration of diuretics.

Prognosis. The prognosis of AKI depends largely on the nature and severity of the causative factor or precipitating event and the promptness and competence of its management. The outcome is least favourable in children with rapidly progressive nephritis and cortical necrosis. Children in whom AKI is a result of HUS or AGN may recover completely, but residual renal impairment or hypertension is more often the rule. Complete recovery is usually expected in children whose

renal failure is a result of dehydration, nephrotoxins, or ischemia. AKI after cardiac surgery is less favourable. It is often impossible to assess the extent of recovery for several months.

Nursing Care. Meticulous attention to fluid intake and output is essential and includes all of the physical measurements discussed previously in relation to fluid balance. Monitoring fluid balance and vital signs is a continuous process, and nurses need to be constantly on the alert for signs of complications so that appropriate interventions can be implemented. Because these children require intensive observation and often specialized treatment, such as dialysis, they are usually admitted to a critical care unit in which needed equipment and trained personnel are available (see Nursing Care Plan available on Evolve).

Limiting fluid intake requires ingenuity on the part of caregivers to cope with the child who is thirsty. Rationing the daily intake in small amounts of fluid served in containers that give the impression of larger volumes is one strategy. Older children who understand the rationale of fluid limits can help determine how their daily ration should be distributed.

Meeting nutritional needs is sometimes a challenge; the child may be nauseated, and encouraging concentrated foods without fluids may be difficult. When nourishment is provided via the IV route, careful monitoring is essential to prevent fluid overload. In addition, nursing measures such as maintaining an optimal thermal environment, reducing any elevation of body temperature, and reducing restlessness and anxiety are used to decrease the rate of tissue catabolism.

The nurse must be continually alert for changes in symptoms that indicate the onset of complications. Infection from reduced resistance, anemia, and general morbidity are constant threats. Fluid overload and electrolyte disturbances can precipitate cardiovascular complications such as hypertension and heart failure. Fluid and electrolyte imbalances, acidosis, and accumulation of nitrogenous waste products can produce neurological involvement manifested by coma, seizures, or alterations in sensorium.

Although children with AKI are usually quite ill and voluntarily diminish their activity, infants may become restless and irritable, and children are often anxious and frightened. Frequent, painful, and stress-producing treatments and tests must be performed. A supportive, empathetic nurse can provide comfort and stability in a threatening and unnatural environment.

Supporting the family. Providing support and reassurance to parents is among the major nursing responsibilities. The seriousness of AKI and its emergent nature are stressful to parents. They also need to be kept informed of the child's progress and provided with explanations regarding the therapeutic regimen. The equipment and the child's behaviour are sometimes frightening and anxiety provoking. Nurses can do much to help parents comprehend and cope with the stresses of the situation.

Chronic Kidney Disease

The kidneys are able to maintain the chemical composition of fluids within normal limits until more than 50% of functional renal capacity is destroyed by disease or injury. Chronic renal disease insufficiency or failure (CKD) begins when the diseased kidneys can no longer maintain the normal chemical structure of body fluids under normal conditions. Progressive deterioration over months or years produces a variety of clinical and biochemical disturbances that culminate in the clinical syndrome known as *uremia*.

A variety of diseases and disorders can result in CKD. The most frequent causes are congenital renal and urinary tract malformations, VUR associated with recurrent febrile UTI (pyelonephritis), hereditary disorders, chronic glomerulonephritis, and glomerulonephropathy associated with systemic diseases such as anaphylactoid purpura and lupus erythematosus. In Canada, there is an increasing concern about the higher incidence of kidney disease in children with poorly controlled diabetes. Indigenous children are particularly affected. See Chapter 51 for more information on diabetes.

Pathophysiology. Early in the course of progressive nephrotic destruction, the child remains asymptomatic with only minimal biochemical abnormalities. Unless the presence of CKD is detected in the process of routine assessment, signs and symptoms that indicate advanced renal damage frequently emerge only late in the course of the disease. Midway in the disease process, as increasing numbers of nephrons are lost and most others are damaged to varying degrees, the few that remain intact are hypertrophied but functional. These few normal nephrons are able to make sufficient adjustments to stresses to maintain reasonable degrees of fluid and electrolyte balance. Definitive biochemical examination at this time will reveal limited tolerance to excesses or restrictions. As the disease progresses to the end stage, because of a severe reduction in the number of functioning nephrons, the kidneys are no longer able to maintain fluid and electrolyte balance, and the features of uremic syndrome appear.

The accumulation of various biochemical substances in the blood, those that result from diminished renal function, produces complications such as the following:

- **Retention of waste products**, especially urea and creatinine
- **Water and sodium retention**, which contributes to edema and vascular congestion
- **Hyperkalemia** of dangerous levels
- **Metabolic acidosis** of a sustained nature because of continual hydrogen ion retention and bicarbonate loss
- **Calcium and phosphorus disturbances**, resulting in altered bone metabolism, which in turn causes growth arrest or restriction, bone pain, and deformities known as *renal osteodystrophy*
- **Anemia** caused by hematological dysfunction, including the shortened lifespan of RBCs, impaired RBC production related to decreased production of erythropoietin, prolonged bleeding time, and nutritional anemia
- **Growth disturbance**, probably caused by such factors as renal osteodystrophy, malnutrition associated with dietary restrictions and loss of appetite, and biochemical abnormalities

Children with CKD seem to be more susceptible to infection, especially pneumonia, UTI, and septicemia, although the reason for this is unclear. These children become extraordinarily sensitive to changes in vascular volume that may cause pulmonary overload, central nervous system symptoms, hypertension, and cardiac failure.

Diagnostic Evaluation. The diagnosis of CKD is usually suspected on the basis of any number of clinical manifestations, a history of prior renal disease, or biochemical findings. The onset is usually gradual, and the initial signs and symptoms are vague and nonspecific (Box 49.7).

Laboratory and other diagnostic tools and tests are of value in assessing the extent of renal damage, biochemical disturbances, and related physical dysfunction (see Tables 49.1 to 49.3). Often they can help establish the nature of the underlying disease and differentiate between other disease processes and the pathological consequences of renal dysfunction.

Therapeutic Management. In irreversible renal failure the goals of medical management are to (1) promote maximum renal function, (2) maintain body fluid and electrolyte balance within safe biochemical limits, (3) treat systemic complications, and (4) promote as active and healthy a life as possible for the child for as long as possible. The child is

BOX 49.7 Clinical Manifestations of Chronic Kidney Disease

Early Signs
- Loss of normal energy
- Increased fatigue on exertion
- Pallor, subtle (may not be noticed)
- Elevated blood pressure (sometimes)

As the Disease Progresses
- Decreased appetite (especially at breakfast)
- Less interest in normal activities
- Increased or decreased urine output with compensatory intake of fluid
- Pallor more evident
- Sallow, muddy appearance of skin

Child May Develop
- Headaches
- Muscle cramps
- Nausea

Other Signs and Symptoms
- Weight loss
- Facial edema
- Malaise
- Bone or joint pain
- Growth restriction
- Dryness or itching of the skin
- Bruised skin
- Sensory or motor loss (sometimes)
- Amenorrhea (common in adolescent girls)

Uremic Syndrome (Untreated)
- Gastrointestinal symptoms: anorexia, nausea, and vomiting
- Bleeding tendencies: bruises, bloody diarrheal stools, stomatitis, bleeding from lips and mouth
- Intractable itching
- Uremic frost (deposits of urea crystals on skin)
- Unpleasant "uremic" breath odour
- Deep respirations
- Hypertension
- Heart failure
- Pulmonary edema
- Neurological involvement
- Progressive confusion
- Dulled sensorium
- Coma (ultimately)
- Tremors
- Muscular twitching
- Seizures

allowed unrestricted activity and is allowed to set their own limits. School attendance is encouraged as long as the child is able, or home tutoring is arranged.

Diet regulation is the most effective means, short of dialysis, for reducing the quantity of materials that require renal excretion. The goal of diet management in renal failure is to provide sufficient calories and protein for growth while limiting the excretory demands made on the kidney, to minimize metabolic bone disease (*osteodystrophy*), and to minimize fluid and electrolyte disturbances. Dietary protein intake is limited only to the reference daily intake for the child's age. Restriction of protein intake below the Recommended Daily Allowance (RDA) is believed to negatively affect growth and neurodevelopment. Malnutrition due to factors including anorexia, dietary restrictions, metabolic acidosis, and increased energy expenditure is common in these children (Carrero et al., 2013).

Sodium and water are not usually limited unless there is evidence of edema or hypertension, and potassium is not usually restricted. However, restrictions of any or all three may be imposed in later stages or at any time that abnormal serum concentrations are evident.

Dietary phosphorus is controlled through reduction of protein, milk, and soft-drink intake to prevent or correct the calcium/phosphorus imbalance. Phosphorus levels can be further reduced by oral administration of calcium carbonate preparations or other phosphate-binding agents that combine with the phosphorus to decrease GI absorption and thus the serum levels of phosphate. Treatment with 25-OH vitamin D is begun to increase calcium absorption and suppress elevated parathyroid hormone levels.

Metabolic acidosis is alleviated through the administration of alkalizing agents such as sodium bicarbonate or a combination of sodium and potassium citrate.

Growth failure is one major consequence of CKD, especially in the preadolescent. These children grow poorly both before and after the initiation of hemodialysis. The use of recombinant human growth hormone to accelerate growth in children with growth restriction secondary to CKD has been successful. Osseous deformities that result from renal osteodystrophy, especially those related to ambulation, are troublesome and require correction if they occur.

Dental issues are common in children with CKD, and the earlier the onset of the disease, the more severe are the dental manifestations (including hypoplasia, hypomineralization, tooth discoloration, alteration in size and shape of teeth, malocclusion, and ulcerative stomatitis). Therefore, regular dental care is especially important in children with CKD.

Anemia in children with CKD is related to decreased production of erythropoietin. Recombinant human erythropoietin is offered to these children as thrice-weekly or weekly subcutaneous injections and replaces the need for frequent blood transfusions. The medication corrects the anemia and in turn increases appetite, activity, and general well-being. In addition, a variety of iron preparations are often administered.

Hypertension of advanced renal disease may be managed initially by cautious use of a low-sodium diet, fluid restriction, and perhaps diuretics such as hydrochlorothiazide or furosemide. Severe hypertension requires the use of antihypertensive medications, singly or in combination.

Intercurrent infections are treated with appropriate antimicrobials at the first sign of infection; however, any medication eliminated through the kidneys should be administered with caution. Other complications are treated symptomatically (e.g., central-acting antiemetics for nausea, antiepileptics for seizures, and diphenhydramine [Benadryl] for pruritus).

Once evidence of end-stage renal disease (ESRD) appears in a child, the disease runs its relentless course and results in death in a few weeks, unless waste products and toxins are removed from body fluids by dialysis or kidney transplantation. These techniques have been adapted for infants and small children and are implemented in most cases of renal failure after conservative management is no longer effective (see Technological Management of Chronic Kidney Disease later in this chapter).

Prognosis. Dialysis and transplantation are the only treatments currently available for children with ESRD. Although children may survive on dialysis, it is not an ideal long-term modality. Complications of dialysis include infection of access sites, growth failure, and disruption of socialization. Kidney transplant is a better option for treatment, if available. Living-donor transplants have better outcomes than cadaver kidneys and should be advocated at every opportunity (Hooper & Varnell, 2020).

Post-transplantation complications include infection, hypertension, steroid toxicity, hyperlipidemia, aseptic necrosis, malignancy, and growth restriction (Hooper & Varnell, 2020). Long-term graft survival is not guaranteed, and many children require a second or third transplant. Successful kidney transplantation does improve the health of children with ESRD, both educationally and psychologically. Increasing use of primary or pre-emptive kidney transplants is becoming the optimal form of renal replacement therapy, leading to substantial improvement in quality of life (Hooper & Varnell, 2020).

Nursing Care. The multiple complications of ESRD are managed according to evidence-informed clinical practice guidelines, such as the *Clinical Practice Guidelines for the Evaluation and Management of Chronic Kidney Disease* (Kidney Disease: Improving Global Outcomes, 2012). However, progressive disease places a number of stresses on the child and family, including those of a potentially fatal illness (see Chapter 41). There is a continuing need for repeated examinations that often entail painful procedures, adverse effects, and frequent hospitalizations. Diet therapy becomes progressively more restricted and intense, and the child is required to take a variety of medications. Ever present in all aspects of the treatment regimen is the agonizing realization that without treatment, death is inevitable.

Some specific stresses related to ESRD and its treatment are predictable. When it first becomes apparent that ESRD is inevitable, both the parents and child can experience depression and anxiety. Acceptance is particularly difficult if renal failure progresses rapidly after diagnosis. Denial and disbelief are usually pronounced, especially for the parents. The initiation of dialysis is usually perceived as a positive experience, and after experiencing initial concerns regarding the treatment, the child begins to feel better and parental anxiety is relieved for a time.

Initiating a dialysis regimen is a traumatic and anxiety-provoking experience for most children because it involves surgery for implantation of a vascular access (central venous line, graft, or fistula) for hemodialysis, or a peritoneal catheter for peritoneal dialysis. The initial experience with this procedure is frightening to most children. They need reassurance about the nature of the preparations for dialysis and the conduct of the treatment.

For hemodialysis, the fistula or graft requires needle insertions at each treatment. The goal is to perform pain-free venipuncture. Using buffered lidocaine with a small-gauge needle (30 gauge) to anaesthetize the area before venipuncture of the graft or fistula is one method. Using an anaesthetizing topical preparation such as EMLA (eutectic mixture of local anaesthetics [lidocaine and prilocaine]) 1 hour before venipuncture is another approach (see Pain Management, Chapter 34). Central venous lines eliminate the need for needles but are more prone to infection and other central-line complications.

Adolescents, with their increased need for independence and their urge for rebellion, usually adapt less well than younger children. They may resent the control and enforced dependence imposed by the rigorous and unrelenting therapy program. They may resent being dependent on hemodialysis technology, their parents, and the professional staff. Depression or hostility is common in adolescents undergoing hemodialysis.

The availability of home peritoneal dialysis has offered a greater degree of freedom for persons undergoing long-term dialysis. Independently managing dialysis treatments at home is less disruptive to school and social activities. Patients and their families need to receive an in-depth teaching program to prepare them for assessing, implementing, and monitoring dialysis treatments.

Body changes related to the disease process, including skin discoloration, growth restriction, and lack of sexual maturation, can be stress provoking. Dietary and fluid restrictions are particularly burdensome for both children and parents. Children may feel deprived when they are unable to eat foods previously enjoyed and that are unrestricted to other family members. Consequently, they may fail to adhere to their food plan. Patient, supportive, and encouraging nursing care is essential. Children, especially adolescents, should be allowed maximum participation in and responsibility for their own treatment program.

After months or years of dialysis, the parents and child may feel anxiety associated with the prognosis and continued pressures of the treatment. Vascular-access and peritoneal dialysis exit site infections may develop and present a common source of aggravation. The time spent in transportation to and from the hemodialysis unit and the time spent undergoing dialysis treatments can interfere with the acquisition of developmental and social milestones (see Family-Centred Care box: Family Priorities).

The Kidney Foundation of Canada and other agencies provide a number of services and information for families of children with renal disease (see Additional Resources at the end of this chapter).

FAMILY-CENTRED CARE

Family Priorities

Families with children with long-term chronic illnesses, such as end-stage renal disease (ESRD), spend much time in hospitals, outpatient clinics, and primary health care facilities. When they miss appointments or respond less quickly than anticipated, sometimes they are quickly labelled "noncompliant." It is important to remember that families have to develop priorities for the unit as a whole. Sometimes the family may decide that it is more important for the parent to go to work or to attend a sibling's school performance than to attend an appointment scheduled for them by health care personnel. The chronically ill child cannot and should not always be the number-one priority for the family. The professional staff who works with the family can help the parents prioritize the needs of the ill child within the needs of the family constellation.

TECHNOLOGICAL MANAGEMENT OF CHRONIC KIDNEY DISEASE

Dialysis

Dialysis is the process of separating colloids and crystalline substances in solution by the difference in their rate of diffusion through a semipermeable membrane. Methods of dialysis currently available for clinical management of renal failure are *peritoneal dialysis*, in which the abdominal cavity acts as a semipermeable membrane through which water and solutes of small molecular size move by osmosis and diffusion according to their respective concentrations on either side of the membrane, and *hemodialysis*, in which blood is circulated outside the body through artificial membranes that permit a similar passage of water and solutes. A third type of dialysis is *hemofiltration*, in which blood filtrate is circulated outside the body by hydrostatic pressure

exerted across a semipermeable membrane with simultaneous infusion of a replacement solution. Types of hemofiltration include continuous venovenous hemofiltration, continuous venovenous hemodialysis, and continuous venovenous hemodiafiltration. Hemofiltration is generally reserved for use in AKI, severe fluid overload, inborn errors of metabolism, or after bone marrow transplant.

Peritoneal dialysis is the preferred form of dialysis for infants, children, and parents who wish to remain independent; for families who live a long distance from the medical centre; and for children who prefer fewer dietary restrictions and a gentler form of dialysis. Chronic peritoneal dialysis is most often performed at home. The two types of peritoneal dialysis are continuous ambulatory peritoneal dialysis and continuous cycling peritoneal dialysis. In both methods, commercially available sterile dialysis solution is instilled into the peritoneal cavity through a surgically implanted in-dwelling catheter that is tunnelled subcutaneously and sutured into place. The warmed solution is allowed to enter the peritoneal cavity by gravity and remains a variable length of time according to the rate of solute removal and glucose absorption in individual patients. The fluid and accumulated toxic wastes are then drained from the peritoneal cavity and a new cycle of fresh dialysis solution is reinstilled. The frequency and timing of the cycles depend on the child's age, fluid balancing needs, and solute removal requirements. Performing this form of dialysis in the home can be empowering for families, especially adolescents. However, the nurse needs to carefully assess for signs of patient and caregiver burnout and arrange for respite care as necessary.

! NURSING ALERT

Observe for changes in the colour of the dialysate draining from the child. The spent solution should be clear. If the colour is cloudy, notify the health care provider immediately.

Hemodialysis requires the surgical creation of a vascular access and the use of special dialysis equipment—the hemodialyzer, or so-called artificial kidney. Vascular access may be one of three types: fistulas, grafts, or external vascular access devices. An *arteriovenous fistula* is an access in which a vein and artery are connected surgically. The preferred site is the radial artery and a forearm vein that produces dilation and thickening of the superficial vessels of the forearm to provide easy access for repeated venipuncture. An alternative is the creation of a subcutaneous (internal) arteriovenous graft by anastomosing artery and vein, with a synthetic prosthetic graft for circulatory access. The most commonly used material is expanded polytetrafluoroethylene (ePTFE). Both the graft and the fistula require needle insertions with each dialysis treatment.

For external vascular access devices, percutaneous catheters are inserted in the femoral, subclavian, or internal jugular veins, even in very small children. A more permanent form of external access is available via a central catheter inserted surgically into the internal jugular vein. Catheters eliminate the need for skin punctures but require dressing changes and are prone to infection. Home care may need to be arranged to assist families with caring for their catheter at home, in between hemodialysis treatments.

Hemodialysis is best suited to children who do not have someone in the family who is able to perform peritoneal dialysis and to those who live close to a dialysis centre. The procedure is usually performed three times per week for 4 to 6 hours, depending on the child's size. Hemodialysis achieves rapid correction of fluid and electrolyte abnormalities but can cause adverse effects in association with this rapid change, such as muscle cramping, headaches, nausea and vomiting, and hypotension. Disadvantages include school absence during hemodialysis treatments and strict fluid and dietary restrictions. Boredom for the child and family is often experienced during the mobility-limiting treatments, so planned activities should be introduced (Figure 49.7).

Fig. 49.7 Diversional activities help lessen the boredom children can experience during hemodialysis.

Most children show rapid clinical improvement with the implementation of dialysis, although it is directly related to the duration of uremia before dialysis and good nutrition. Growth rate and skeletal maturation improve, but recovery of normal growth is infrequent. In many cases, sexual development, although delayed, progresses to completion.

Transplantation

Kidney transplantation is an effective means of renal replacement therapy in children. Although peritoneal dialysis and hemodialysis are life preserving, both require major alterations in lifestyle. Transplantation offers the opportunity for a relatively normal life and is the preferred form of treatment for children with ESRD. Primary or pre-emptive transplants maintain the greatest amount of normalcy in the family's life.

In terms of wait time for an available kidney for transplantation, discrepancies exist between various populations. Researchers from the Pediatric Renal Outcomes Canada Group found that the time from start of dialysis to the first kidney transplant was longer for Indigenous children than for non-Indigenous children. Further research is needed to investigate individual and system barriers that contribute to the difference in the wait times (Samuel et al., 2011).

Kidneys for transplant are available from two sources: a *living related donor*, from a family member, or a *cadaver donor*, a dead or patient with neurological determination of death, whose family consents to the donation of a healthy kidney. Retransplantation may be required if rejection occurs.

The primary goal in transplantation is the long-term survival of grafted tissue by securing tissue that is antigenically similar to that of the recipient and by suppressing the recipient's immune mechanism. The immunosuppressant therapy of choice has been corticosteroids (prednisone) in conjunction with cyclosporine or

tacrolimus and mycophenolate mofetil. Other therapies include antilymphoblast globulin or monoclonal antibodies. New immunosuppressant medications are rapidly coming into clinical trials and into use in large transplant centres. It is important for nurses to learn about the medications used in the antirejection protocol(s) and about their adverse effects. Because the immunosuppressant medications are taken indefinitely, transplant patients experience many adverse effects of the medications, including hypertension, growth restriction, cataracts, risk of infection, obesity, characteristics of Cushing syndrome, and hirsutism (McDonald, 2021).

! NURSING ALERT

The child with a kidney transplant who exhibits any of the following symptoms should be evaluated immediately for possible rejection, as this the most common cause of transplant failure:

- Fever
- Swelling and tenderness over graft area
- Diminished urine output
- Elevated blood pressure
- Elevated serum creatinine

Rejection of the transplanted kidney is the most common cause of transplant failure. Rejection is treated aggressively with immunosuppressant medications and can often be reversed. Some patients do not respond or develop chronic rejection and must eventually return to dialysis or undergo another kidney transplant.

KEY POINTS

- Common inflammatory disorders of the genitourinary tract include UTI, nephrotic syndrome, and AGN.
- Management of UTIs is directed at eliminating infection, detecting and correcting functional or anatomical abnormalities, preventing recurrences, and preserving renal function.
- VUR is the retrograde flow of urine from the bladder into the ureters or kidneys.
- Obstructive uropathy is a result of structural or functional abnormalities of the urinary system that obstruct the normal flow of urine.
- The more common defects of the genitourinary tract include phimosis, cryptorchidism, inguinal hernia, hydrocele, and hypospadias.
- Body image concerns may arise in children with anomalies in the genital area.
- Nephrotic syndrome is characterized by increased glomerular permeability to protein, with massive urinary loss of protein resulting in hypoproteinemia and edema.
- Management of nephrotic syndrome is aimed at reducing excretion of protein, reducing or preventing fluid retention by tissues, and preventing infection and other complications.
- Common features of AGN are oliguria, edema, hypertension, circulatory congestion, hematuria, and proteinuria.
- Therapeutic management of AGN involves maintenance of fluid balance, treatment of hypertension, and antibiotic therapy.
- Management of HUS is aimed at control of complications and hematological manifestations of renal failure.
- Wilms tumour is the most common malignant neoplasm of the kidney in infants and children.
- In AKI, management is directed at determining treatment of the underlying cause, managing complications of renal failure, and providing supportive therapy.
- Abnormalities in CKD are waste product retention, water and sodium retention, hyperkalemia, acidosis, calcium and phosphorus disturbance, anemia, and growth disturbances.
- The types of dialysis used in ESRD are peritoneal dialysis and hemodialysis.
- The major concerns in kidney transplantation are tissue matching and prevention of rejection; psychological concerns involve self-image related to possible body changes as a result of the effects of corticosteroid therapy.
