Iron-Deficiency Anemia. Iron-deficiency anemia is by far the most common anemia of pregnancy, accounting for approximately 75% of cases. Most of the time, anemia in patients of childbearing age is due to low or absent iron stores, which makes iron-deficiency anemia the world's most common dietary-related deficiency (Auerback & Landy, 2021). Patients with iron deficiency may be at risk for developing iron-deficiency anemia during pregnancy, when the demand for iron increases. Certain conditions such as nausea and vomiting of pregnancy, inflammatory bowel disease, and bariatric surgery (e.g., gastric bypass) may impair iron absorption and increase the risk of developing iron deficiency during pregnancy (Auerback & Landy, 2021).

Routine screening of at-risk pregnant patients for iron-deficiency anemia is recommended. There is a physiological demand for iron requirements in pregnancy resulting from increases in maternal blood volume and support for the development of the fetus and placenta. While ferritin levels are the primary screening test used to diagnose iron-deficiency anemia, patients' hemoglobin and hematocrit levels should also be checked. *Iron deficiency* is defined as serum ferritin less than 12 mcg/L, and iron-deficiency anemia is a combination of anemia (hemoglobin less than 110 g/L) and low serum ferritin less than 12 mcg/L (Blackburn, 2018). An association has been found between maternal iron-deficiency anemia, especially severe anemia, and preterm birth and low-birth-weight infants (Drukker et al., 2015). Iron stores in the fetus of an anemic patient seem to meet fetal needs when mothers were very iron deficient, even at the cost of further depleting the mother's iron level (Blackburn, 2018).

Generally, iron-deficiency anemia is prevented by having pregnant patients take prenatal vitamins that contain a 30 mg/day iron supplement to provide the increased amounts of iron needed for fetal development and maternal stores (Auerback & Landy, 2021; Blackburn, 2018). If prenatal vitamins do not provide enough iron supplementation, iron-deficiency anemia can develop and increased iron dosages are recommended (elemental iron, 60 to 120 mg/day) (Auerback & Landy, 2021). Diet alone cannot replace gestational iron losses. Inadequate nutrition without therapy will certainly mean iron-deficiency anemia during late pregnancy and the puerperium. It is important to teach the pregnant patient about the significance of iron therapy (see Table 12.1 and Chapter 12, Patient Teaching box: Iron Supplementation). In addition, the patient should be instructed in how to decrease the gastrointestinal adverse effects of iron therapy through diet. Those pregnant patients who cannot tolerate the prescribed oral iron because of nausea and vomiting should receive parenteral iron, such as iron sucrose (Venofer) (Perelló et al., 2014). Iron sucrose has been shown to be well absorbed and IV iron is associated with a higher hemoglobin level following therapy (Auerback & Landy, 2021). Blood transfusions should be considered for the patient with severe anemia to prevent fetal and maternal complications of decreased oxygen delivery.

Folic Acid–Deficiency Anemia. Folate is a water-soluble vitamin found naturally in dark green leafy vegetables, citrus fruits, eggs, legumes, and whole grains. Even in well-nourished patients, folate deficiency is common. Poor diet, cooking with large volumes of water, home canning of food (especially vegetables), and increased alcohol intake may contribute to folate deficiency. The need for folate increases during pregnancy because of fetal demands and because folate is less well absorbed from the gastrointestinal tract during gestation. Folic acid deficiency during conception and early pregnancy increases the incidence of neural tube defects, cleft lip, and cleft palate (see Chapter 12).

During pregnancy, the recommended daily intake is 0.4 mg per day of folic acid, although patients who have a deficiency may need 1 mg or more per day (see Box 12.1). Patients at particular risk for folate deficiency include those who have significant hemoglobinopathies, take anticonvulsant medication, are pregnant with a multifetal gestation, or have frequent pregnancies. These patients require larger than usual doses of folic acid (Samuels, 2017).

Folate deficiency is the most common cause of megaloblastic anemia during pregnancy, but a vitamin B_{12} deficiency must also be considered. Vitamin B_{12} deficiency in pregnant patients is seen much more often now than in the past because of the increasing numbers of patients who become pregnant after undergoing bariatric surgery (Maxwell et al., 2019; Samuels, 2017). Other patients at risk for developing vitamin B_{12} deficiency are those with gastrointestinal disease such as Crohn disease or who take the medication metformin (Samuels, 2017).

Patients with megaloblastic anemia caused by folic acid deficiency have the usual presenting symptoms and signs of anemia: pallor; fatigue; lethargy; and glossitis and skin roughness, which are associated specifically with megaloblastic anemia (Kilpatrick & Kitahara, 2019). Folate deficiency usually improves rapidly with folic acid therapy. It rarely occurs in the fetus and is not a significant cause of perinatal morbidity. Iron deficiency often occurs along with folate deficiency (Auerback & Landy, 2021; Samuels, 2017).

Sickle Cell Hemoglobinopathy. Sickle cell hemoglobinopathy is a disease caused by the presence of abnormal hemoglobin in the blood. Sickle cell trait (SCT) occurs when one sickle cell gene and one normal gene are inherited from each parent. Patients with SCT usually do not have any of the symptoms of sickle cell disease (SCD), but they can pass the trait during pregnancy to their children. There is sickling of the RBCs, but with a normal RBC lifespan, this usually causes only mild clinical symptoms. Patients with SCT require genetic counselling and partner testing to determine their risk of producing children with SCT or SCD. Patients with SCT usually do well in pregnancy, although they are at increased risk for painful crises during pregnancy, fetal growth restriction, antepartum hospital admission, and postpartum infection (Kilpatrick & Kitahara, 2019; Vichinsky, 2020).

SCD occurs when the RBCs form into a C-shape (called "sickle"). The sickle cells do not live long, which results in a constant shortage of RBCs. These cells are prone to increased breakdown, which causes hemolytic anemia, as well as vaso-occlusion in the small blood vessels, leading to pain and other serious health issues for the patient, such as acute and chronic organ dysfunction involving the spleen, brain, lungs, and kidneys. Pain and swelling of the hands and feet usually are the first symptoms of SCD. This swelling, often along with a fever, is caused by the sickle cells getting stuck in the blood vessels and blocking the flow of blood in and out of the hands and feet. The resulting hemolysis leads to chronic anemia and predisposes the patient to aplastic crises (Langlois et al., 2008). Crises are usually triggered by dehydration, hypoxia, or acidosis (Samuels, 2017).

There are two types of SCD. HbSS occurs when patients inherit two sickle cell genes (S), one from each parent. This is commonly called *sickle cell anemia* and is usually the most severe form of the disease. HbSC occurs when a person inherits a sickle cell gene (S) from one parent and an abnormal hemoglobin called *C* from the other parent. This is usually a milder form of SCD (Vichinsky, 2020). SCD affects those of African or Mediterranean descent. Anemia and vaso-occlusive or acute painful episodes occur more often in late pregnancy and postpartum and are the most common maternal complications, occurring in over 50% of pregnant patients with SCD. Patients with SCD are at increased risk for IUGR, gestational hypertension, pre-eclampsia, preterm labour, placental abruption, antepartum bleeding, and postpartum infection (Vichinsky, 2020). Patients may also be at increased risk for UTI and may be deficient in iron (Kilpatrick & Kitahara, 2019; Samuels, 2017). Patients in impending sickle cell crisis experience painful joints (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Sickle Cell Hemoglobinopathy

Latasha is a 23-year-old G1 T0 P0 A0 L0 with sickle cell disease who is hospitalized with a crisis at 16 weeks of gestation. She says, "I've been in and out of the hospital all my life because of my sickle cell disease. I sure hope my baby won't have it!"

Questions

1. Evidence—Is there sufficient evidence to counsel Latasha regarding her baby's chance of having sickle cell disease?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. The chance that Latasha's baby will inherit either sickle cell trait or sickle cell disease
   b. Pregnancy risks related to sickle cell disease
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Latasha's care.

Pregnant patients with sickle cell anemia are at risk of developing pyelonephritis, leg ulcers, bone abnormalities, strokes, cardiomyopathy, heart failure, and pre-eclampsia (Vichinsky, 2020). Patients with SCD are encouraged to take a low-dose Aspirin following completion of the first trimester to reduce the risk of pre-eclampsia (Butalia et al., 2018; Magee et al., 2014). The patient is monitored carefully during pregnancy for the all potential complications of SCD. In addition, the patient will need serial ultrasound examinations to monitor fetal growth and will likely have antepartum fetal testing performed regularly during the third trimester. Infections are treated aggressively with antibiotics. If sickle cell crisis does occur, patients are managed with analgesia, oxygen, and hydration. Prophylactic blood transfusions, which replace the patient's sickle cells with normal RBCs, to improve oxygen-carrying capacity and suppress the synthesis of sickle hemoglobin, may be associated with reduced painful episodes and reduced lung complications (Malinowski et al., 2015). However, prophylactic transfusions pose a risk for isosensitization, viral infection, transfusion reactions, and hemochromatosis and therefore are not routinely recommended (Samuels, 2017). Pregnant patients with acute complications of SCD, such as acute multi-organ failure or acute symptomatic anemia, may benefit from RBC transfusion to correct the anemia and improve the maternal and newborn outcome (Vichinsky, 2020).

If no complications occur, pregnancy can continue until term. Patients with SCD should be encouraged to labour in a side-lying position. They may require supplemental oxygen. Adequate hydration should be maintained while preventing fluid overload. Regional anaesthesia (e.g., epidural or combined spinal epidural anaesthesia) is recommended because it provides excellent pain relief. Caesarean birth is warranted only for obstetrical indications. In the postpartum period, patients with sickle cell anemia must be counselled that oral contraceptives are contraindicated because of the increased risk of thromboembolus.

SAFETY ALERT

Patients with sickle cell anemia are not iron deficient. Therefore, routine iron supplementation, even that found in prenatal vitamins, should be avoided because these patients can develop iron overload (Samuels, 2017; Vichinsky, 2020).

Thalassemia. Thalassemia is a relatively common anemia in which an insufficient amount of hemoglobin is produced to fill the RBCs. It is a hereditary disorder that involves the abnormal synthesis of the alpha or beta chains of hemoglobin. Beta thalassemia is the more common variety in North America and usually occurs in persons of Mediterranean, Middle Eastern, or Asian descent (Kilpatrick & Kitahara, 2019; Royal College of Obstetrics & Gynecology [RCOG], 2014).

Beta thalassemia minor is the heterozygous form of this disorder and has different forms of expression. Some patients with this disorder are asymptomatic, while others have splenomegaly and significant anemia. They may require numerous transfusions during pregnancy (Samuels, 2017). Patients with pregnancies complicated by beta thalassemia minor generally do not experience associated maternal or infant complications if their condition is stable (Blackburn, 2018; RCOG, 2014). These patients are managed similarly to patients with SCD during pregnancy. Iron therapy should only be prescribed for patients who are iron deficient, although folic acid supplementation is recommended for all patients with beta thalassemia minor (Samuels, 2017).

The homozygous form of beta thalassemia is known as *thalassemia major*, or *Cooley's anemia*. Persons with this form of the disease usually have hepatosplenomegaly and bone deformities caused by massive marrow tissue expansion. Many people affected with thalassemia major die of infection or cardiovascular complications early in life. If patients live to reach childbearing age, infertility is common. If patients with this disorder do become pregnant, they usually experience severe anemia and heart failure, although successful full-term pregnancies have been reported. Patients with beta thalassemia major are managed much like those with SCD during pregnancy (Samuels, 2017).

If both partners are found to be carriers of thalassemia they should be referred for genetic counselling. Ideally, this should take place before conception or as early as possible in the pregnancy. Additional molecular studies may be required to clarify the carrier status of the parents and thus the risk to the fetus (Langlois et al., 2008). Patients with the thalassemia trait usually have an uncomplicated pregnancy.

Pulmonary Disorders

As pregnancy advances and the enlarged uterus presses on the thoracic cavity, any pregnant patient may experience increased respiratory difficulty. This difficulty is compounded by pulmonary disease.

Asthma. Asthma is a common, chronic lung disorder in which inflammation causes the bronchi to swell and narrow the tracheobronchial airways, resulting in breathing difficulties that may range from mild to life-threatening. Symptoms include shortness of breath, cough, wheezing, and chest tightness. Asthma is characterized by

periods of exacerbations and remissions. Exacerbations are usually triggered by stimuli such as allergens, medications, marked change in ambient temperature, or emotional tension. In many cases, the cause may be unknown, although a family history of allergy is common. In response to stimuli, there is widespread but reversible narrowing of the hyperreactive airways, making it difficult for the person to breathe. The clinical symptoms include some or all of the following: expiratory wheezing, productive cough, thick sputum, dyspnea, or any combination of these.

Approximately 4 to 8% of pregnant patients have diagnosed asthma, making it the most common pulmonary disease in pregnancy (Shedd & Hays, 2016; Whitty & Dombrowski, 2017). The effect of pregnancy on asthma is unpredictable. In one large study, 23% of women with asthma had fewer symptoms during pregnancy, whereas 30% had worse symptoms (Whitty & Dombrowski, 2017). Pregnant patients with severe asthma were much more likely than those with mild or moderate asthma to have exacerbations and require hospitalization. Asthma appears to be associated with preterm birth, pre-eclampsia, low birth weight, IUGR, and perinatal mortality (Shedd & Hays, 2016; Whitty & Dombrowski, 2017). While poorly controlled asthma greatly increases pregnancy risk, well-controlled asthma does not appear to adversely affect pregnancy.

The ultimate goal of asthma therapy in pregnancy is to maintain adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. Achieving this goal requires monitoring lung function objectively (e.g., peak expiratory flow rate [PEFR] and forced expiratory volume in 1 second [FEV1]), avoiding or controlling asthma triggers (e.g., dust mites, animal dander, pollen, wood smoke), educating patients about the importance of controlling asthma during pregnancy, and medication therapy (Shedd & Hays, 2016). Current medication therapy for asthma emphasizes treatment of airway inflammation to decrease airway hyperresponsiveness and prevent asthma symptoms. Decreasing airway inflammation through the use of inhaled corticosteroids is currently the preferred treatment for managing persistent asthma during pregnancy (Whitty & Dombrowski, 2017). Respiratory infections should be treated with appropriate antibiotics, and mist or steam inhalation should be used to aid the expectoration of mucus. Pharmacotherapy to control symptoms and treat airway inflammation is safer than exacerbation of symptoms during pregnancy.

During pregnancy, patients with poorly controlled asthma may benefit from ultrasound examinations and antenatal testing. Because asthma has been associated with IUGR and preterm birth, accurate pregnancy dating should be established by a first-trimester ultrasound, if possible. Evaluation of fetal growth by serial ultrasound examinations may be considered for patients who have suboptimally controlled asthma or moderate to severe asthma (beginning at 32 weeks of gestation) and after recovery from a severe asthma exacerbation. All patients with asthma should be encouraged to monitor fetal activity (see Chapter 13 for information on daily fetal movement counts) (Whitty & Dombrowski, 2019). Acute exacerbations may require treatment with albuterol, steroids, aminophylline, beta-adrenergic agents, and oxygen. Patients with severe exacerbations unresponsive to treatment should be cared for in a tertiary setting, as they may require intubation and mechanical ventilation (Whitty & Dombrowski, 2017).

Although asthma attacks during labour are rare, medications for asthma are continued during labour and the postpartum period. Patients who are currently taking or have received several short courses of systemic corticosteroids during pregnancy should be given stress doses of corticosteroids during labour and for the first 24 hours after birth to prevent adrenal crisis (Whitty & Dombrowski, 2017). Pulse oximetry should be instituted to assess oxygenation levels during labour. Epidural analgesia reduces oxygen consumption as a result of decreased pain and the need for breathing techniques for pain relief and is an effective strategy to help prevent complications from asthma while the patient is in labour. Fentanyl, a nonhistamine-releasing opioid, may also be used for pain control and is not associated with bronchospasm (Cunningham et al., 2018; Whitty & Dombrowski, 2019). If tocolytic medications are necessary, indomethacin (Indocin) should be avoided because it might induce bronchospasm in Aspirin-sensitive patients (Whitty & Dombrowski, 2017).

During the postpartum period, patients with asthma are at increased risk for hemorrhage. If excessive bleeding occurs, oxytocin should be given as a first-line medication. If a patient continues to hemorrhage, other uterotonics such as prostaglandin E_1 (misoprostol) can be given, although the patient's respiratory status should be monitored (Whitty & Dombrowski, 2017). Carboprost (15-methyl $PGF_{2\alpha}$ [Hemabate]) and ergonovine (ergometrine) and methylergonovine (Methergine) can cause bronchospasm, thus their use should be avoided (Cunningham et al., 2018). In general, only small amounts of asthma medications enter breast milk; therefore their use is not considered a contraindication to breastfeeding. However, in sensitive individuals, theophylline in breast milk can cause vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias in newborns (Whitty & Dombrowski, 2017). Patients are encouraged to breastfeed, as it may provide protection against respiratory infections in the newborn. The patient usually returns to their prepregnancy asthma status within 3 months after giving birth (Madappa & Sharma, 2018).

Cystic Fibrosis. Cystic fibrosis (CF) is an autosomal recessive genetic disorder characterized by the build-up of thick, sticky mucus that can damage many of the body's organs. The disorder's most common signs and symptoms include progressive damage to the respiratory system and chronic digestive system issues. Most people with CF have chronic obstructive pulmonary disease (COPD), pancreatic exocrine insufficiency, and elevated sweat electrolytes. The severity of each of these conditions can vary among affected individuals. Morbidity and mortality are usually caused by progressive chronic bronchial pulmonary disease (Whitty & Dombrowski, 2019).

Cystic Fibrosis Canada (2021) states that there are 4 370 people in Canada living with CF; the median age of survival is 50.9 years (Stephenson et al., 2017). In North America, approximately 4% of the White population are carriers of the CF gene. CF occurs in 1 in 3 200 White live births (Whitty & Dombrowski, 2019). People with CF live longer than in the past because of earlier diagnosis and intervention, along with advances in antibiotic therapy and nutritional support. Adults with CF experience health challenges affecting the respiratory, digestive, and reproductive systems.

According to the SOGC, if both potential parents are identified as carriers of the CF gene, CF carrier screening should be offered to couples who are planning a pregnancy, as the risk of inheriting the gene is 25% (Dahdouh et al., 2015). Infertility appears to relate to changes in cervical mucus. Although most men with CF are infertile, women with the disease are often fertile. The number of patients with CF who achieve pregnancy is steadily increasing (Whitty & Dombrowski, 2017). Patients with CF may experience complications in pregnancy.

Pregnancy is tolerated well in patients with good nutritional status, mild obstructive lung disease, and minimal impairment of lung function (Whitty & Dombrowski, 2017). In patients with severe disease, the pregnancy is often complicated by chronic hypoxia and frequent pulmonary infections. Risk factors that may predict a poor pregnancy outcome are poor prepregnancy nutritional status, significant pulmonary disease with hypoxemia, pulmonary hypertension, liver disease, and diabetes mellitus (Whitty & Dombrowski, 2019). Increased maternal and perinatal mortality rates are related to severe pulmonary infection.

There is an increased incidence of preterm births, IUGR, and uteroplacental insufficiency (Whitty & Dombrowski, 2019). Predictors of adverse effects to the fetus and newborn are maternal inadequate weight gain, dyspnea, and cyanosis.

Care of the pregnant patient with CF requires an interprofessional health team effort. Ideally, the patient should reach 90% of their ideal body weight before becoming pregnant. A weight gain of 11 to 12 kg (24 to 26 lb) is recommended during pregnancy. Patients who are unable to achieve the recommended weight gain through oral supplements may require nasogastric tube feedings at night. Pancreatic insufficiency puts the patient at risk for malnutrition because they cannot meet the increased nutritional requirements of pregnancy. If malnutrition is severe, total parenteral nutrition (TPN) may be necessary. Fat-soluble vitamins may not be well absorbed, resulting in deficiency in those nutrients. Throughout pregnancy, frequent monitoring of the patient's weight, blood glucose, hemoglobin, total protein, serum albumin, prothrombin time, and fat-soluble vitamins A and E is suggested. Pancreatic enzymes should be adjusted as necessary (Whitty & Dombrowski, 2019). Pregnant patients with CF also may have decreased insulin secretion and increased insulin resistance, resulting in a higher incidence of development of GDM. A glucose tolerance test should be done at 20 weeks of gestation.

Pregnant patients with CF are followed closely with serial pulmonary function testing. Test results are used both to guide management and to predict pregnancy outcome. Inhaled recombinant human deoxyribonuclease I may be given to improve lung function by decreasing sputum viscosity. Inhaled 7% saline is also beneficial (Cunningham et al., 2018). Early detection and treatment of infection are critical. Management of infection includes antibiotics along with chest physiotherapy and bronchial drainage (Whitty & Dombrowski, 2017).

Fetal assessment is essential, given that the fetus is at risk for uteroplacental insufficiency and IUGR. Maternal nutritional status and weight gain during pregnancy significantly affect fetal growth. Fundal height should be measured routinely, and ultrasound examinations should be performed regularly to evaluate fetal growth and amniotic fluid volume. Fetal movement counts are often recommended, starting at 26 to 32 weeks of gestation. NSTs should be initiated at 32 weeks of gestation or sooner if there is fetal compromise (Liston et al., 2018; Whitty & Dombrowski, 2019).

During labour, monitoring of fluid and electrolyte balance is required to assess for sodium loss and hypovolemia. The increased cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the patient with pulmonary hypertension or cor pulmonale. These patients are also more likely to develop right-sided heart failure. Epidural or local analgesia is the preferred analgesic for birth, with vaginal birth recommended. Caesarean birth should be reserved for obstetrical indications. If general anaesthesia is needed for Caesarean birth, anticholinergic medications should not be given before surgery because they may cause airway drying (Whitty & Dombrowski, 2019). Oxygen should be given freely during labour, and monitoring by pulse oximetry is recommended.

Mothers with pulmonary and pancreatic disease can breastfeed, and their infants do well. It is appropriate, however, to test milk samples occasionally for sodium, chloride, and total fat and to monitor the infant's growth pattern carefully (Lawrence & Lawrence, 2016). Breastfeeding can be exhausting and uses up calories; patients with CF may find it difficult to breastfeed exclusively. If patients are unable to maintain their weight, alternative methods of feeding should be discussed.

Integumentary Disorders

Dermatological disorders induced by pregnancy include melasma (chloasma), vascular "spiders," palmar erythema, and striae gravidarum (see Chapter 10). A number of chronic skin disorders may complicate pregnancy. These disorders may be present before pregnancy or appear for the first time during pregnancy. Their course varies during pregnancy. For example, acne may improve. Psoriasis is unpredictable during pregnancy, but postpartum flares are common. Lesions from neurofibromatosis may increase in size and number during pregnancy (Cunningham et al., 2018). Explanation, reassurance, and common-sense measures should suffice for normal skin changes. In contrast, disease processes during and soon after pregnancy may be extremely difficult to diagnose and treat.

! NURSING ALERT

Isotretinoin (Accutane), commonly prescribed for cystic acne, is highly teratogenic. Its use must be avoided under all circumstances in patients who are hoping to conceive a pregnancy and during pregnancy. The risk of birth defects among pregnant patients is extremely high. These defects include hydrocephaly (enlargement of the fluid-filled spaces of the brain) and microcephaly (small head), heart defects, facial deformities such as cleft lip and missing ears, and developmental delays. Breastfeeding mothers also should not use Accutane.

Pruritus Gravidarum. Pruritus is a major symptom in several pregnancy-related skin diseases. Pruritus gravidarum, generalized itching without the presence of a rash, develops in up to 14% of pregnant patients. It is often limited to the abdomen and is usually caused by skin distension and the development of striae. Pruritus gravidarum is associated with twin gestation, fertility treatment, diabetes, and nulliparity. It is not associated with poor perinatal outcomes. It is treated symptomatically with skin lubrication, topical antipruritics, and oral antihistamines. Ultraviolet light and careful exposure to sunlight can decrease itching. Pruritus gravidarum usually disappears shortly after birth but can recur in approximately one half of all subsequent pregnancies (Rapini, 2019).

Pruritic Urticarial Papules and Plaques of Pregnancy. Another common pregnancy-specific cause of pruritus is pruritic urticarial papules and plaques of pregnancy (PUPPP), also known as *polymorphic eruption of pregnancy* (Figure 15.3). PUPPP classically appears in primigravidas during the mid to late third trimester and occurs a bit more frequently in pregnant patients carrying male fetuses (Wang & Kroumpouzos, 2017). Other risk factors include obesity and

Fig. 15.3 Patient with pruritic urticarial papules and plaques of pregnancy (PUPPP). Lesions also are present on her arms, back, abdomen, and buttocks. (Courtesy Shannon Perry.)

hypertension. The disorder is commonly seen in multiple gestations, more than in singletons. PUPPP is associated with moderate to severe itching in up to 80% of patients (Rapini, 2019). It is not, however, associated with poor maternal or fetal outcomes. Therefore, the goal of therapy is simply to relieve maternal discomfort. Antipruritic topical medications, topical steroids, and oral antihistamines usually provide relief. Patients with severe symptoms may require oral prednisone. PUPPP usually resolves before birth or within several weeks after birth. PUPPP does not usually recur in subsequent pregnancies (Rapini, 2019; Wang & Kroumpouzos, 2017).

Intrahepatic Cholestasis of Pregnancy. **Intrahepatic cholestasis of pregnancy (ICP)** is the most common liver disease of pregnancy (Gabzdyl & Schlaeger, 2015). It is characterized by generalized pruritus that usually begins in the third trimester of pregnancy. The itching commonly affects the palms and soles but can occur on any part of the body and is usually worse at night. No skin lesions are present. ICP occurs more frequently during the winter months (Bergman et al., 2013; Cappell, 2017). Secondary skin lesions that develop are a result of the patient scratching their abdomen.

Patients with ICP have elevated serum bile acids caused by a disruption of hepatic bile flow. Liver function tests may be abnormal. Jaundice may or may not be present. As many as one half of patients with ICP develop dark urine and light-coloured stools. The cause of ICP is unknown, but approximately half of patients have a family history of the disorder. Other risk factors for ICP are multiple gestations and a history of ICP in a previous pregnancy (Bergman et al., 2013; Cappell, 2017).

Treatment consists of giving ursodeoxycholic acid, which effectively controls the pruritus and laboratory abnormalities associated with ICP, and continued monitoring of liver function tests and bile acid levels (Cappell, 2017). Antihistamines such as diphenhydramine (Benadryl) or chlorpheniramine may be prescribed. Other comfort measures that may provide relief from itching include cool baths, oatmeal products added to a bath, oatmeal cream or lotion, baking soda baths, or an aqueous cream containing 2% menthol (Gabzdyl & Schlaeger, 2015).

The major fetal complications associated with ICP are asphyxial events, meconium staining, meconium ileus, stillbirth, and preterm birth. The cause of these complications is likely related to increased levels of fetal serum bile acids (Cappell, 2017). Antepartum fetal assessment with twice-weekly NSTs will probably be performed (Cappell, 2017).

If fetal complications do not occur, birth should be considered at or near term after lung maturity has been documented. Symptoms usually disappear and laboratory abnormalities resolve soon after giving birth (Cappell, 2017). However, postpartum hemorrhage is more likely in patients who have had ICP, and they are also at risk of developing cholelithiasis after birth. ICP can recur in approximately two thirds of subsequent pregnancies, however, or with oral contraceptive use (Bergman et al., 2013; Cappell, 2017; Gabzdyl & Schlaeger, 2015).

Neurological Disorders

People with neurological disorders are choosing to become pregnant with increasing prevalence with the improvement of medications for treatment of these disorders. The pregnant patient with a neurological disorder must consider potential teratogenic effects of prescribed medications, changes of mobility during pregnancy, and impaired ability to care for the baby. The nurse should be aware of all medications the pregnant patient is taking, to discuss the associated potential for producing congenital anomalies. Nurses need to counsel the pregnant patient with a neurological condition that, as the pregnancy progresses, their centre of gravity shifts and causes balance and gait changes. The patient should be advised of these expected changes and provided safety measures as appropriate. Family and community resources should be explored to provide supervision for child care for the patient with neurological impairments.

Epilepsy. Epilepsy (often called *seizure disorder*) is a neurological disorder of the brain, resulting in abnormal brain activity and can lead to recurrent seizures, unusual behaviours, and loss of awareness. Epilepsy is the most common neurological disorder accompanying pregnancy, although less than 1% of all pregnant patients have a seizure disorder (Douglas & Aminoff, 2019). Seizure disorders are divided into *generalized* and *focal* epilepsies. Focal epilepsy is the most common type of epilepsy in adults. The cause of most focal epilepsies remains unknown (Gerard & Samuels, 2017). Patients who have epilepsy are at higher risk for complications during pregnancy; however, through comprehensive care by an interprofessional health care team that includes an obstetrician, neurologist, pharmacist, nurse, and social worker, most patients with a seizure disorder can have a successful pregnancy with minimal risk to mother and fetus (Gerard & Samuels, 2017).

Patients with epilepsy should receive preconception counselling if possible. A detailed history of medication use and seizure frequency should be obtained. If the patient has frequent seizures before conception, they are likely to continue this pattern during pregnancy; therefore, achieving effective seizure control is extremely important before conception, even if changing medications is required (Gerard & Samuels, 2017; RCOG, 2016).

Seizures differ in presentation, ranging from focal seizures (brief losses of awareness without loss of consciousness) to generalized seizures (involving muscle rigidity, violent muscle contractions, and loss of consciousness). Both types of seizures are related to abnormal electrical activity in the brain. Patients with tonic–clonic seizures may experience them more frequently or have more severe complications during pregnancy, such as edema, **alkalosis**, fluid–electrolyte imbalance, cerebral hypoxia, hypoglycemia, and hypocalcemia. Seizures can also be triggered by hormonal changes, fatigue, or sleep deprivation.

! NURSING ALERT

Anticonvulsants may decrease the effectiveness of oral contraceptive agents, increasing the risk of unplanned pregnancy.

The effects of pregnancy on epilepsy are unpredictable. Many patients experience increased seizure frequency during pregnancy as a result of sleep deprivation or self-imposed decreased dosing of their antiepileptic medication due to concerns about the teratogenic effects on the developing fetus (Douglas & Aminoff, 2019). It is important to emphasize the importance of adequate sleep, adherence to the medical regimen, and minimizing stress and other factors known to precipitate seizures. Seizure control is the primary goal in treating pregnant patients with epilepsy. These patients must be educated about the risks associated with uncontrolled seizures. Changes to current anticonvulsant medications may be made to reduce the risks of teratogenicity. The benefits of effective seizure control versus the risk of uncontrolled seizures must be discussed on an individual basis.

If anticonvulsant therapy must be adjusted or introduced as a new therapy, the lowest effective dose must be used, and monotherapy is preferable to polytherapy. Babies born to mothers exposed to certain anticonvulsant medications are at increased risk of congenital malformations, cognitive impairment, and fetal death (Gerard & Samuels, 2017). Congenital anomalies associated with anticonvulsant medications include cleft lip or palate, congenital heart disease, urogenital

defects, and neural tube defects. These anomalies are related to the dose, type, and number of anticonvulsant medications taken, not to epilepsy itself (Gerard & Samuels, 2017).

Several anticonvulsant medications have been developed for use during the past two decades. Lamotrigine (Lamictal) and levetiracetam (Keppra) are now the most commonly prescribed antiepileptic medications for patients of childbearing age. Both appear to have relatively low major malformation rates associated with their use. More research is needed, however, regarding the fetal effects of these medications. Carbamazepine (Tegretol) is also a reasonable choice for use in patients who plan to conceive, although its use is declining (Gerard & Samuels, 2017). However, any anticonvulsant medication required to achieve good seizure control in a patient with epilepsy should be used at the lowest effective dose, regardless of the increased risk of fetal anomalies, because the most important goal during pregnancy is the prevention of seizures (Gerard & Samuels, 2017; RCOG, 2016).

All patients of childbearing age who take an anticonvulsant medication are advised to take a folic acid supplement of 0.4 mg to 1 mg daily, which may decrease the incidence of neural tube defects in their children. More research is needed to determine the optimal dose of folic acid for patients with epilepsy. Many practitioners recommend a dose of 4 mg/day for patients with epilepsy who are trying to conceive or are already pregnant. Vitamin D deficiency is common in patients with epilepsy, because anticonvulsant medications can interfere with production of the active form of this vitamin. Therefore, pregnant patients with epilepsy are encouraged to take a supplemental dose of 1 000 to 2 000 IU of vitamin D daily, in addition to a prenatal vitamin (Douglas & Aminoff, 2019).

SAFETY ALERT

Valproic acid (Epival, Depakote) should be avoided, if possible, during pregnancy, especially during the first trimester, because the incidence of congenital anomalies is highest with this medication.

If possible, only one anticonvulsant medication—at the lowest dose level that is effective at keeping the patient seizure-free—should be prescribed during pregnancy. The increase in plasma volume that is a normal pregnancy change can affect drug metabolism and distribution. Therefore, blood levels of anticonvulsant medications should be monitored, and medication dosages adjusted as necessary. With close monitoring, most patients with epilepsy may experience no change or even have fewer seizures during pregnancy. Accurate assessment of seizure type and frequency is important to identifying any triggering factors so an effective management plan can be put in place (RCOG, 2016).

In addition to congenital anomalies, the fetus of a pregnant patient with epilepsy is also at risk for IUGR. Determining an accurate gestational age as early as possible is important. This information decreases any confusion later in pregnancy regarding fetal growth issues. If the patient's weight gain and fundal height appear appropriate, serial ultrasounds for fetal weight assessment are probably unnecessary. A specialized, detailed anatomical ultrasound examination should be performed at 18 to 22 weeks of gestation to determine whether congenital malformations, including neural tube defects, are present. Nonstress testing later in pregnancy is not necessary for all patients with epilepsy, but it should be considered for those who have seizures during the third trimester (Gerard & Samuels, 2017).

The risk for seizures during labour is small. Seizures are most likely to occur in patients who have had seizures during pregnancy. Parenteral administration of antiepileptic medications is desirable during labour because absorption of medications given orally can be unpredictable, due to a decrease in gastric motility and risk of vomiting. If a patient experiences tonic–clonic seizures during pregnancy or labour, they must be assessed for the presence of pre-eclampsia/eclampsia. It is recommended that magnesium sulphate be administered until additional laboratory assessment can rule out pre-eclampsia/eclampsia (Cunningham, 2018; RCOG, 2016). If is determined that the patient has had an epileptic seizure, treatment with IV phenytoin or midazolam can be administered as required. The patient's vital signs must be assessed frequently and their neurological status assessed after the seizure (level of sedation, orientation, headache, language deficits, coordination, weakness or paralysis, behaviour changes). It is important to ensure patient safety until they return to pre-seizure level of consciousness. Most patients with epilepsy successfully give birth vaginally (Gerard & Samuels, 2017).

After birth, the levels of anticonvulsant medications must be monitored frequently for the first few weeks because they can rise rapidly. If medication dose levels were increased during pregnancy, they need to be reduced within the first 3 weeks postpartum to slightly higher than or at prepregnancy levels (Douglas & Aminoff, 2019; Gerard & Samuels, 2017). While all of the major anticonvulsant medications are found in breast milk, use of these medications is not a contraindication to breastfeeding (RCOG, 2016).

Safety measures related to the new baby should be discussed with the patient and their family members. In addition to the safety measures that apply to all newborns, specific precautions should be observed with babies whose mothers have epilepsy. The sleep deprivation that can be associated with breastfeeding a newborn may put the patient at risk for seizures.

Contraceptive counselling is an important part of postpartum and preconception planning for patients with epilepsy. Medication–medication interactions are numerous between hormonal contraceptive methods and antiepileptic medications. The most reliable form of contraception is the IUD. The IUD, either the copper or the levonorgestrel type, is considered the contraceptive method of choice for most patients with epilepsy (Gerard & Samuels, 2017). In terms of planning for future childbearing, couples should be informed that their risk for passing epilepsy along to their children is higher than that of the general population, but still relatively low. Mothers with epilepsy appear to have a much greater chance of having a child with epilepsy than do fathers with epilepsy (Gerard & Samuels, 2017).

Sudden unexpected death in epilepsy. Sudden unexpected death in epilepsy (SUDEP) is the sudden, unexpected death of someone with epilepsy where no other cause of death is found on autopsy. The person with epilepsy is often found dead in bed and does not appear to have had a convulsive seizure. The number of pregnancy-related deaths in patients with epilepsy has been increasing in recent years, and most of these were preventable and attributable to poor seizure control (Leach et al., 2017). While prevention of seizures during pregnancy is important, a balance must be struck between seizure control and the teratogenic potential of antiepileptic medications. Over one-third of the time, there is a witnessed seizure or there are signs of a recent seizure close to the time of death. Researchers have found that people with all types of epilepsy that experience convulsive seizures can be at risk (Leach et al., 2017).

Most, but not all, cases of SUDEP occur during or immediately after a seizure. The exact cause is not known, but the following are possible factors (MacDonald et al., 2015):

- Breathing: A seizure may cause a person to have apnea. Prolonged apnea will reduce the oxygen in the blood to a life-threatening level. In addition, during a convulsive seizure a person's airway sometimes may get obstructed, leading to suffocation.

- Heart rhythm: Rarely, a seizure may cause a life-threatening heart rhythm or even heart failure.
- Other causes and mixed causes: SUDEP may result from more than one cause or a combination involving both breathing difficulty and abnormal heart rhythm.

Risk factors for SUDEP include the following (Edey et al., 2014):

- Uncontrolled or frequent seizures
- Generalized tonic–clonic seizures

Other possible risk factors may include:

- Seizures that begin at a young age
- Many years of living with epilepsy
- Missed doses of medicine
- Drinking alcohol

Possible steps to reduce the risk of SUDEP may include the following:

- Avoid seizure triggers, if these are known.
- Avoid drinking alcohol, especially in pregnancy.
- Establish seizure control as much as possible.
- Encourage patients to get enough sleep.
- Have family members trained in seizure first aid.

Multiple Sclerosis. Multiple sclerosis (MS) involves a patchy demyelinization of the spinal cord and CNS and may be of viral origin. Onset of symptoms, which include weakness of one or both lower extremities, visual disturbances, and loss of coordination, is subtle and usually occurs between the ages of 20 and 40 years. The disease is characterized by exacerbations and remissions. Pregnancy likely does not have any adverse long-term effect on the course of the disease (Gerard & Samuels, 2017).

Remissions during pregnancy are common. If an exacerbation occurs, it is more likely during the third trimester of pregnancy or postpartum. The mainstay of treatment for acute MS relapses is corticosteroids and, rarely, other immunosuppressive agents along with the promotion of rest. Several new disease-modifying agents (DMAs) are available for treating MS, but their use in pregnancy has been limited as no related controlled studies are available. Because MS exacerbations are rare during pregnancy and few data are available regarding the safety of DMA use during pregnancy, most experts recommend stopping DMA use prior to conception. A few studies have suggested that the use of DMAs prior to conception or during gestation decreases the risk for postpartum MS relapses. Postpartum relapses are also less likely to occur in patients whose MS activity had been well controlled in the year prior to pregnancy (Gerard & Samuels, 2017). Patients need to have an informed discussion with their neurologist regarding whether they should consider going off medication in pregnancy. Interferon is also sometimes used to treat MS relapses during pregnancy and postpartum. Its safety for use during pregnancy has not been established, although in theory it should not cross the placenta because of its large molecular size (Gerard & Samuels, 2017).

Patients with disturbances in bladder function are more likely to develop UTIs during pregnancy. Therefore, they should be screened routinely. If an acute and severe MS relapse occurs during pregnancy, it can be treated with corticosteroids or intravenous immunoglobulin (IVIG) (Gerard & Samuels, 2017).

Epidural anaesthesia can be used during labour (Gerard & Samuels, 2017). Caesarean birth is usually not indicated for patients with MS. Only rare cases of severe or active disease that affect the spinal cord prevent a patient with MS from labouring safely (Gerard & Samuels, 2017).

Depression is common among patients with MS; they should be assessed frequently for evidence of perinatal mood disorders. Breastfeeding is encouraged, although resumption of medications in the postpartum period must be assessed for breastfeeding safety. IVIG is considered safe for use during lactation; no adverse effects in infants have been reported. All hormonal contraceptives may be used by patients with MS (Stuart & Bergstrom, 2011).

Bell Palsy. Bell palsy is an acute idiopathic facial paralysis. The clinical manifestations of Bell palsy include the sudden development of a unilateral facial weakness, with maximum weakness within 48 hours after onset, pain surrounding the ear, difficulty closing the eye on the affected side, *hyperacusis* (abnormal acuteness of the sense of hearing), and occasionally a loss of taste (Cunningham et al., 2018). The cause is unknown, but it may be related to the reactivation of herpes virus infection or acute HIV type 1 (HIV-1) retroviral infections. Bell palsy occurs fairly often, especially in patients of reproductive age. Women are affected two to four times more often than men (Cunningham et al., 2018). Pregnant patients are affected three to four times more often than nonpregnant patients.

The incidence usually peaks during the third trimester and the puerperium. Patients who develop Bell palsy during pregnancy also have an increased risk for gestational hypertension (Cunningham et al., 2018).

No effects of maternal Bell palsy have been observed in infants. Maternal outcome is generally good unless a complete block in nerve conduction occurs. Steroid therapy is the only medical treatment that has been shown to influence the outcome of Bell palsy. To be effective, treatment should begin within the first 3 to 5 days after the paralysis develops (Douglas & Aminoff, 2019). Supportive care includes prevention of injury to the constantly exposed cornea, facial muscle massage, careful chewing and manual removal of food from inside the affected cheek, and reassurance. Most patients recover without treatment, and only about 10% of patients are not satisfied with their recovery because of permanent disfigurement (Douglas & Aminoff, 2019).

Autoimmune Disorders

Autoimmune disorders, also called *collagen vascular diseases*, make up a large group of diseases that disrupt the function of the immune system of the body. In these types of disorders, the immune system is unable to distinguish "self" from "nonself." As a result, antibodies develop that attack its normally present antigens, causing tissue damage. Symptoms of an autoimmune disease could improve, worsen, or remain unchanged when a patient becomes pregnant, depending on their specific autoimmune disease (Bermas & Smith, 2021). Autoimmune disorders of concern in pregnancy include systemic lupus erythematosus, myasthenia gravis, antiphospholipid syndrome, systemic sclerosis, and rheumatoid arthritis.

Systemic Lupus Erythematosus. Systemic lupus erythematosus (SLE) is a chronic autoimmune disease in which the body's immune system attacks and causes inflammation in its own tissues. Inflammation results in swelling, pain, and other symptoms. As a result of SLE, the skin, joints, kidneys, heart, lungs, blood vessels, nervous system, and almost any other organ can be affected. SLE varies in severity, from mild to very severe. A person may experience active periods (commonly known as *flares*) and periods when there is decreased activity or even complete remission. The exact cause of SLE is unknown, but it probably involves the interaction of several factors, including immunological, environmental, hormonal, and genetic factors. Most cases of SLE occur in adolescence or young adulthood (Carpenter & Ware Branch, 2017).

Common symptoms include muscle pain, fatigue, weight change, and fevers; these occur in nearly all patients with SLE at some time during the course of the disease. Although a diagnosis of SLE is suspected on the basis of clinical signs and symptoms, it is confirmed by laboratory testing that demonstrates the presence of circulating autoantibodies.

Patients with SLE ideally begin a pregnancy when their disease has been quiescent for at least 6 months prior to conception. Active SLE at the time of conception is a strong predictor of adverse maternal and obstetrical outcomes. In spite of these risks, the majority of pregnancies result in live births (Bermas & Smith, 2021). Other maternal risks include an increased rate of miscarriage, nephritis, and pre-eclampsia; a possible need to give birth at a preterm gestation; and an increased risk of Caesarean birth. Fetal risks include stillbirth, IUGR, and preterm birth (Carpenter & Ware Branch, 2017; Mehta et al., 2019).

Medical therapy during pregnancy is kept to a minimum in patients who are in remission or who have a mild form of SLE. Occasional doses of nonsteroidal anti-inflammatory drugs (NSAIDs) can be given to treat arthralgia. Health Canada advise against the use of NSIADS from 20 to 28 weeks gestation due to rare but serious kidney issues in the fetus, unless advised by a health care provider (Health Canada, 2021). Low-dose Aspirin is recommended in all patients with SLE, starting from before 16 weeks gestation, to reduce the risk of pre-eclampsia (Butalia et al., 2018; Magee et al., 2014). Glucocorticoids such as prednisone are often used to treat SLE during pregnancy, either as maintenance therapy or as short-term treatment for flares. The lowest possible dose of prednisone should be given. A small risk for fetal cleft lip and palate when glucocorticoids are used during early pregnancy has been reported; however, subsequent studies have failed to consistently demonstrate an increased risk of this malformation (Bermas & Smith, 2021). Prolonged use of this group of medications also increases the risk for maternal bone loss, gestational diabetes, hypertension and pre-eclampsia, and adrenal suppression. Given the significant risks associated with long-term glucocorticoid use, hydroxychloroquine (Plaquenil), an antimalarial drug, may be the best medication for maintenance SLE therapy during pregnancy. It significantly reduces SLE disease activity but appears to cause no adverse effects in the fetus (ACOG, 2019; Carpenter & Ware Branch, 2017).

Prenatal care focuses on close monitoring to detect common pregnancy complications such as hypertension, proteinuria, and IUGR. Ultrasound examinations are performed frequently to monitor fetal growth. Fetal assessment tests, including daily fetal movement counts and weekly or twice-weekly NSTs and amniotic fluid volume assessments or BPPs, are performed beginning at 32 weeks of gestation unless indicated earlier in the pregnancy with the presence of IUGR (Liston et al., 2018) (see Chapter 13). More frequent ultrasound examinations and fetal testing are necessary if the patient develops an SLE flare, antiphospholipid syndrome, hypertension, proteinuria, or evidence of IUGR (Bermas & Smith, 2021; Carpenter & Ware Branch, 2017).

Patients with SLE can develop a flare of disease during labour. Maintenance medications should be continued throughout the intrapartum period or resumed immediately postpartum at the last pregnancy dose. Even if a flare does not occur, all patients who have received chronic glucocorticoid therapy (20 mg or more of prednisone daily for at least 3 weeks) need larger (stress) doses of steroids during labour (Carpenter & Ware Branch, 2017). Vaginal birth is preferred, but Caesarean birth is common because of maternal and fetal complications.

Close monitoring of all patients with SLE should continue after birth. Patients who have more severe SLE manifestations or who had an SLE exacerbation during pregnancy are at greatest risk of experiencing a postpartum flare (Bermas & Smith, 2021; Carpenter & Ware Branch, 2017). During the postpartum period, the mother should rest as much as possible to prevent an exacerbation of SLE. Breastfeeding is encouraged unless the mother is taking immunosuppressive agents. It is usually recommended that the patient follow up with their rheumatologist within 1 to 3 months after giving birth (Carpenter & Ware Branch, 2017).

Neonatal lupus (NL) is an autoimmune disease that can occur from passive transfer of maternal autoantibodies to the fetus; therefore, newborns should be assessed to determine the presence of NL.

Patients with SLE should be counselled regarding pregnancy and family planning. Education should include the maternal complications associated with the illness and increased adverse perinatal outcomes (Andreoli et al., 2017). If a patient with SLE is considering permanent sterilization with tubal ligation, the safest time is when the disease is in remission. Estrogen-containing oral contraceptives may increase the risk of thromboembolism. Progestin-only implants and injections provide effective contraception with no known effects on lupus flares (Cunningham et al., 2018). Barrier methods, in addition to progestin-only contraceptive options, are the most desirable forms of contraception with the least risk for patients with SLE (Andreoli et al., 2017). Evidence does not support concerns regarding an increased risk of infection with IUDs.

Myasthenia Gravis. Myasthenia gravis (MG) is a chronic autoimmune neuromuscular disease that causes weakness in the skeletal muscles. Muscle weakness results, particularly in the eyes, face, tongue, neck, limbs, and respiratory muscles. In addition, patients may experience ptosis, diplopia, and dysphagia. Women are affected twice as often as men, and the incidence peaks between 20 and 30 years of age. Pregnancy should be avoided in patients who have a new diagnosis of MG as the greatest period of risk is during the first year after diagnosis (Cunningham et al., 2018). If MG is under good control before pregnancy there is a better chance of it remaining stable throughout pregnancy, although for some patients it may worsen in the postpartum period. For patients with active MG before pregnancy, flares are most likely to occur in the first trimester and the postpartum period (Bird et al., 2020). The response of patients with MG to pregnancy is unpredictable; remission, exacerbation, or continued stability during pregnancy can occur (Bird et al., 2020; Chaudhry et al., 2012). Optimal care for the pregnant patient with MG is best achieved through an interprofessional team approach.

Pregnancy does not appear to affect the overall course of MG, but as the uterus enlarges respirations may be compromised. In addition, the normal fatigue experienced by many pregnant patients may be tolerated poorly by those with MG (Cunningham et al., 2018). Treatment during pregnancy is the same as for nonpregnant patients. Usual medications include glucocorticoids (prednisone) and acetylcholinesterase inhibitors, such as pyridostigmine or mestinon, which are standard first-line treatment for MG (Bird et al., 2020). Monitoring blood glucose values is important because hyperglycemia may result from corticosteroid therapy. Thymectomy may result in remission of the disease but is best performed before or after pregnancy if at all possible. For severe weakness, plasmapheresis or IVIG therapy may be needed. Assessment of fetal well-being may consist of nonstress testing or regular BPP.

! NURSING ALERT

Magnesium sulphate must not be administered to patients with MG because it inhibits the release of acetylcholine and can trigger myasthenic crisis.

Because MG does not affect smooth muscle, most patients tolerate labour well. Vaginal birth is desired, but vacuum or forceps assistance may be required because of muscle weakness. Oxytocin may be given, but medications that cause muscular relaxation should be avoided if at all possible. Opioids must be used cautiously because they may cause respiratory depression, and patients with MG are already at risk for respiratory muscle weakness. Assessment for respiratory rate and pulse oximetry are important because stress and fatigue associated with

labour and birth may precipitate worsening of disease. Regional analgesia is preferred to general anaesthesia (Chaudhry et al., 2012; Cunningham et al., 2018; Douglas & Aminoff, 2019). After birth, patients must be carefully supervised because relapses often occur during the postpartum period.

Approximately 10 to 20% of infants born to mothers with MG will develop neonatal myasthenia (Bird et al., 2020). All newborns of mothers with MG should be observed and monitored in the neonatal intensive care unit for the first 48 to 72 hours of life for any evidence of weakness caused by transient neonatal MG. Symptoms of respiratory distress, poor feeding, and flaccid tone can appear within hours after birth (Bird et al., 2020). Neonatal myasthenia can be treated with anticholinesterase medications and usually resolves by 6 weeks after birth (Douglas & Aminoff, 2019).

Spinal Cord Injury

Patients with various types of disabilities are choosing to become pregnant with increasing frequency. Patients with spinal cord injury (SCI) are no different. More than half of all SCIs occur in persons between the ages of 16 and 30, with women representing approximately 18% of cases (ACOG 2002/2019). Chronic effects of SCI may include autonomic dysreflexia (AD), impaired pulmonary function, chronic pulmonary or genitourinary infections, anemia, osteoporosis, and decubitus ulcers. AD is a potentially dangerous clinical syndrome that results in acute, uncontrolled hypertension. Pregnant patients with SCI may also be at increased risk of deep vein thrombosis and pulmonary embolus (ACOG, 2002/2019). Collaboration among perinatal and disability-related providers as well as patients with physical disabilities is essential for meaningful care planning and is important for improving pregnancy experiences and care outcomes (Berndl et al., 2021).

Antepartum Care. Many patients with disabilities identify that it is difficult to find information on pregnancy and its effects on their disability (Tarasoff, 2015). A prepregnancy assessment is preferred for patients with SCI in order to determine the level of function and presence of associated medical complications. Once a patient is pregnant, it is important that antenatal visits be tailored to the patient's unique needs. Frequent urine cultures and skin examination for pressure injuries should be conducted in addition to routine antenatal care. Anemia may be associated with an increased risk of pressure injuries, thus additional iron supplementation during pregnancy may be required. Patients must make frequent position changes during pregnancy. Extra padding and/or refitting of wheelchairs may be necessary in later stages of pregnancy. An interprofessional approach is preferred for patients with SCI. Anaesthetic consultation is suggested because of the risk of AD during labour and the potential for impaired pulmonary function. Patients with spinal cord lesions may have high rates of UTI during pregnancy (Sterling et al., 2013). These patients must be carefully monitored for the risk of developing pyelonephritis, which could lead to preterm labour (Pannek & Bertschy, 2011). Urology consultation may be considered for those with in-dwelling or suprapubic catheters or with evidence of impaired renal function. Physiotherapy consultation may be helpful, as mobility may become more impaired as pregnancy progresses and to assist with prevention of decubitus ulcers. Occupational therapy consultation may be helpful to optimize the patient's ability to care for their infant at home. Rates of pre-eclampsia or congenital malformation are not increased in patients with SCI; however, patients with SCI related to myelomeningocele do have a risk of recurrence and should take 4.0 mg of folic acid daily for 3 months prior to conception (Wilson et al., 2011).

Collaboration among interprofessional team members is essential to ensure a positive perinatal experience for pregnant patients with disabilities and their families. Perinatal care providers and those who provide disability-specific care need to practice clear communication with one another (Berndl et al., 2021). An individualized advanced care plan should be developed to ensure good communication among team members to address potential adverse outcomes during labour and birth and to identify the patient's wishes for birth.

Intrapartum Care. Vaginal birth is preferred for patients with SCI; Caesarean birth should be reserved for obstetrical indications. Induction may be considered in patients who do not feel uterine activity or fetal movement, to prevent the risk of undiagnosed labour and a possible unattended birth at home. Patients should be instructed that symptoms such as increased spasticity or shortness of breath may be signs of uterine contractions.

Patients with spine lesions above T6 are at increased risk of AD during labour secondary to uterine contractions. Patients should be cared for in a hospital that is capable of invasive hemodynamic monitoring and able to provide medications for treatment of AD. The use of regional anaesthesia, such as epidural or combined spinal–epidural, preferably instituted at the onset of labour, may help to prevent or decrease the risk of AD. An in-dwelling catheter should be placed routinely in patients who do not normally have one, to avoid the need to self-catheterize during labour. Assisted vaginal birth may be necessary due to inadequate expulsive effort.

Postpartum Care. For postpartum patients with SCI, special attention must be paid to bladder elimination in order to avoid urinary retention, to minimize the risk of UTI and AD. Bowel regimens should be resumed postpartum. Breastfeeding is possible and encouraged in these patients, but individualized assessment is important. Patients may need assistance to gain independence with positioning and latching of the baby, using props to aid in their potentially limited use of gross and fine motor arm movements. Patients with SCI at or above T6 may lack the innervation to experience milk let-down reflex, causing a disruption in their ability for lactation. These patients may be at risk for experiencing AD as a result of breastfeeding. An individualized assessment of mothers with a high-level SCI is required (Holmgren et al., 2018).

Additional care must be provided to address mobility in patients who have undergone Caesarean birth. An assessment of home supports and the need for extra nursing once the patient returns home should be made. Insufficient evidence exists to support routine deep vein thrombosis prophylaxis in the puerperium in patients with SCI. Patients should be assessed on a case-by-case basis. It is important to be aware that mothers with SCI (particularly high-level SCI) may have increased risk of postpartum depression following birth (Lee et al., 2021).

Human Immunodeficiency Virus and Acquired Immunodeficiency Syndrome

In Canada in 2018, the percentage of patients with HIV who are women, with HIV was 23.4% (Public Health Agency of Canada, 2020). Females aged 30 to 39 were the highest age group for new HIV diagnoses in women (Haddad et al., 2018). Most of these patients were and continue to be of childbearing age. Data from the Canadian Perinatal HIV Surveillance Program indicate that, in 2017, 240 infants were born to mothers with HIV. Only three of these infants were confirmed HIV positive; 97% of HIV-positive pregnant females received HIV antiretroviral treatment (ART), which significantly reduces the risk of HIV transmission from mother to child and the progression of AIDS-related complications. This section addresses the management of the pregnant patient who is HIV positive. See Chapter 7 for more information about the diagnosis and management of nonpregnant patients with HIV, and see Chapter 29 for a discussion of HIV infection in infants.

Preconception Counselling. At the present time in Canada, patients who are HIV positive are having successful pregnancies, resulting in non-infected, healthy newborns (Haddad et al., 2018; Money et al., 2014). The key to optimal perinatal outcomes for patients is preconception pregnancy counselling and planning. Preconception pregnancy planning should include consultation with providers specialized in the area of HIV infections and pregnancy. This assessment should include a review of the patient's HIV history, current physical status, and prenatal and HIV-specific laboratory results. A critical component of preconception counselling is to carefully assess for the presence of high-risk behaviour and develop a plan to decrease the risk of transmission to the fetus and reduce the pregnancy, intrapartum, and postnatal risks (Keenan-Lindsay & Yudin, 2017).

Pregnancy Risks. Pregnant patients who are HIV positive require specialized prenatal care that involves physicians, nurses, pharmacists, nutrition counsellors, social workers, and community support to ensure healthy outcomes for both the mother and infant. Care includes strict adherence to an antiretroviral medication regime, following through with regular HIV-specific blood-level monitoring (viral plasma levels and immunological functioning), and being well informed of management during labour, birth, and postpartum. Patients at risk for HIV and who have an unknown status should be offered screening whenever they present for care at any stage, even late in pregnancy or during the intrapartum period, as treatment with antiretroviral medications can be offered to decrease the risk of perinatal transmission (Keenan-Lindsay & Yudin, 2017).

HIV-positive patients should be encouraged to seek prenatal care immediately if they suspect pregnancy, in order to maximize chances for a positive outcome. Pregnancy itself does not appear to significantly accelerate the progression of HIV infection. One of the most overwhelming situations for a pregnant patient is when they are newly diagnosed with a positive HIV result. This situation must be supported with intensive counselling and support for the patient and often for their partner (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

The Pregnant Patient Who Is HIV Positive

Betsy is being seen in the prenatal clinic at 34 weeks of gestation. She has been positive for HIV for 2 years and has a past history of using intravenous cocaine and heroin for over 5 years. She has been substance-free for the last 18 months. This is Betsy's first baby and it is an unplanned pregnancy. During your nursing assessment, she tells you that she was started on medication for her HIV when she was 3 months pregnant. Betsy does not seem to know the names of the pills she is taking and says she tries to remember to take them daily but sometimes misses some doses.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about the type of continued care, treatment, and support for Betsy and her infant?
2. What implications and priorities for nursing care can be determined at this time related to the following:
   a. Reinforcing the importance of adherence to Betsy's antiretroviral medication treatment, comprehensive prenatal care, and planning throughout her pregnancy
   b. Prevention of maternal and child HIV transmission via antiretroviral medication prophylaxis regime
   c. Ongoing risk factors for Betsy
   d. Review of perinatal HIV transmission prevention as you plan to provide care for Betsy and her infant
3. What implications and priorities for nursing care can be drawn at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to Betsy.

BOX 15.4 Factors Increasing Risk of Mother-to-Child Perinatal HIV Transmission

- Lack of maternal and infant treatment with antiretroviral medications and prevention
- Maternal plasma viral level greater than 1 000 copies per millilitre
- Maternal vaginal infections during pregnancy
- Amniocentesis, chorionic villus sampling, or both
- Ruptured membranes
- Presence of chorioamnionitis
- Fetal scalp monitoring and venous scalp sampling
- Interventions such as forceps, vacuum, and external cephalic version
- Breastfeeding

Perinatal transmission. Perinatal transmission may occur to the fetus through the maternal circulation as early as the first trimester of pregnancy, to the newborn during labour and birth, or to the infant through breast milk. Factors that increase the likelihood of perinatal viral transmission are listed in Box 15.4.

Identification of the HIV-positive pregnant patient is especially important because antepartum and intrapartum antiviral medication therapy has been shown to greatly decrease the risk of viral transmission to the fetus. With optimal maternal child HIV-prevention treatment available throughout Canada, the percentage of infected newborns has decreased dramatically to less than 2% (Moore, D. L., et al., 2019). The likelihood of transmission from an untreated mother to fetus is 15 to 40% (Keenan-Lindsay & Yudin, 2017). Currently, almost all HIV-positive childhood diagnoses not attributed to mother-to-child transmission were in children from endemic countries (Forbes et al., 2012).

Obstetrical complications. A comprehensive nursing assessment is required for all pregnant patients with HIV. Patients who are HIV positive may have multiple risks for obstetrical complications based on the other lifestyle issues such as substance use, mental health issues, poverty, poor nutrition, limited access to prenatal care, or concurrent sexually transmitted infection (STI). As a result, HIV-positive patients are at increased risk for preterm labour and birth, premature rupture of membranes, perinatal loss, and IUGR. The mode of birth for patients who are HIV positive depends on the patient's plasma viral level and their status of labour upon admission. If a patient's plasma level is less than 1 000 copies per millilitre and they have received ART, they can proceed with a vaginal birth. In patients positive for HIV who have not received antiretroviral medications and have a plasma load greater than 1 000, an unknown plasma level, or antepartum bleeding, a Caesarean birth is recommended (Money et al., 2014). The postpartum period for the patient infected with HIV may be notable for infection, hemorrhage, or both. Patients without symptoms may have an unremarkable postpartum course; alternatively, immunosuppressed patients with symptoms may be at increased risk for postpartum UTIs, vaginitis, postpartum endometritis, and poor wound healing. HIV-related thrombocytopenia may also increase the risk of hemorrhage. It is critical that patients remain on their antiretroviral medication throughout their pregnancy and into the postpartum period.

Nursing Care. HIV testing is recommended for all pregnant patients in Canada when they initially enter prenatal care. Patients engaging in ongoing high-risk behaviour should be offered repeated HIV testing at each trimester of their pregnancy. Any patient whose HIV status is unknown at the time of labour or birth should be screened with a rapid HIV test.

Patients with HIV infection should receive standard testing in pregnancy for the presence of STI, such as gonorrhea, syphilis, and

chlamydia. Vaccination and immune status should be documented, and chicken pox (varicella) and rubella titres should be determined (Money et al., 2014). Patients who are HIV positive should be vaccinated against hepatitis B, pneumococcal infection, haemophilus B influenza, and viral influenza because of their risk of immunocompromise. If the patient has not had a recent tuberculin skin test, it should be performed; a positive test necessitates a chest X-ray film to identify any active pulmonary disease. A Papanicolaou (Pap) test should also be done if not completed recently.

All patients with HIV should be treated with ART during pregnancy, regardless of their CD4 counts. ART includes three medications:

1. Zidovudine (ZDV) is an antiretroviral drug that slows the growth of the HIV virus. It has been shown in a large randomized, multicentre study to decrease the rate of perinatal transmission of HIV when it is taken by the mother during pregnancy and at birth and by the infant for up to 6 weeks after birth. The use of ZDV has greatly reduced the risk of the infant becoming infected with HIV; however, it does not prevent all HIV infections. IV ZDV is administered to the HIV-positive patient during the intrapartum period. A loading dose is initiated upon the patient's admission in labour, followed by a continuous maintenance dosage throughout labour (Money et al., 2014).
2. Nevirapine is an antiretroviral drug that slows the growth of the HIV virus. In the absence of maternal ART, nevirapine has been shown to decrease the risk of a mother passing the HIV virus to the newborn when it is taken by the mother as a single oral dose at birth followed by administration of nevirapine to the newborn (current dosing recommendation is to administer three oral doses to the infant). Nevirapine can reduce the risk of the infant being infected; however, it does not prevent all infections.
3. Lamivudine is an antiretroviral drug that slows the growth of the HIV virus. Lamivudine-zidovudine (Combivir) prevents the emergence of HIV drug resistance in mothers and babies who received either the single-dose or three-dose nevirapine regimen, respectively.

The major adverse effect of these medications is bone marrow suppression. Periodic hematocrit, white blood cell count, and platelet count assessments should be performed. Patients with CD4 counts of less than 200 cells/mm^3 should receive prophylactic treatment for *Pneumocystis carinii* pneumonia with daily trimethoprim-sulphamethoxazole. Any other opportunistic infections should be treated with medications specific for the infection; often dosages must be higher for patients with HIV infection (Money et al., 2014).

The patient who is HIV positive requires nutritional support and counselling. Weight gain or maintenance in pregnancy can be a challenge. Patients need to be supported and counselled regarding safer sex practices to reduce risks for themselves and their partner. Use of condoms and a spermicide is encouraged to minimize exposure of the partner to HIV.

Every effort should be made during the birthing process to decrease the newborn's exposure to infected maternal blood and secretions if Caesarean birth is not scheduled and the patient goes into labour. If feasible, the membranes should be left intact until the birth. Increased duration of ruptured amniotic membranes has been associated with increased perinatal transmission. If rupture of membranes occurs before labour, induction of uterine contractions with oxytocin may be appropriate. Fetal scalp electrode and scalp pH sampling should be avoided because these procedures may result in inoculation of the virus into the fetus (Money et al., 2014). Operative vaginal birth (forceps or vacuum extractor) and episiotomy should also be avoided, when possible.

Immediately after birth, infants should be wiped free of all body fluids. Prior to blood testing or any injections, the skin area should be cleansed well with soap and water. All staff working with the mother or infant must adhere to routine precautions for exposure to blood and other body fluids. The infant can be placed skin-to-skin with the mother after birth, but breastfeeding is not recommended, in developed countries due to safe alternatives, because of the risk of HIV transmission through breast milk. Oral ZDV treatment for the infant is initiated within 6 hours of life and continues for up 6 weeks. In the postpartum period, it is critical that patients who are HIV positive be assessed for postpartum infections. Patients and their newborns require close postpartum follow-up by providers specialized in HIV in the hospital and upon discharge. This will ensure that ART and maternal and infant blood work are maintained and monitored. Counselling regarding postpartum contraception should be part of the nurse's and provider's discussion with the patient prior to discharge from the hospital.

SUBSTANCE USE

Substance use among people in Canada is recognized as an increasing concern from both a public health and a social perspective (Abrahams et al., 2010). Childbearing patients are using a variety of substances, the most common being alcohol, tobacco, cannabis, and mood-altering and pain-relieving prescribed medications, as well as illicit drugs such as cocaine, heroin, **crack**, crystal methamphetamine, and **opioids**. *Substance use* or *problematic use* can be defined as compulsive drug use and loss of control over use, resulting in physical, social, and psychological consequences. Symptoms of withdrawal and tolerance can be seen in patients who use substances (Ordean et al., 2017). Patients who use substances tend to have an increased incidence of unplanned pregnancies.

The damaging effects of alcohol and illicit drugs on pregnant patients and their unborn babies are well documented (Ordean et al., 2017; Wisner et al., 2017). Alcohol and other drugs easily pass from a mother to the baby through the placenta. Smoking during pregnancy has serious health risks, including bleeding complications, miscarriage, stillbirth, prematurity, low birth weight, and sudden unexplained infant death (Ordean et al., 2017; Wisner et al., 2017). Substance use in pregnancy may result in a lack of prenatal care for the pregnant patient. The safest pregnancy is one in which the patient is drug- and alcohol-free, although this is not always possible for some patients. For patients addicted to opioids, the current standard of care during pregnancy is treatment with opioid agonist therapy (OAT) with methadone or buprenorphine (Ordean et al., 2017; Wisner et al., 2017).

Barriers to Treatment

Patients who use substances and are pregnant often do not seek prenatal care, for many reasons. The most notable of these are guilt, stigma, and shame, as well as the fear of losing custody of a child. Patients who use substances may have difficulties forming relationships with prenatal care providers, based on traumatic and judgemental previous experiences with the health care system (British Columbia [BC] Centre on Substance Use, 2018). Pregnant patients who use substances may have little understanding of the ways in which these substances affect them, their pregnancies, and their newborns. They may even delay seeking prenatal care until labour begins. Substance use treatment programs for patients may not be able to meet the social needs of pregnant patients to enable them to effectively participate in such programs, such as concurrent need for obstetrical care and child care for other children. Long waiting lists and lack of women-only recovery spaces present further barriers to treatment.

Legal Considerations

Nurses who care for patients who use substances in pregnancy must use a nonjudgemental and person-centred approach based on a harm-reduction model of care (Abrahams et al., 2010; Ordean et al., 2017). Patients should be encouraged to attend prenatal care that has flexible

scheduling and a welcoming and nonjudgemental approach to care. Addressing a patient's substance use in pregnancy is a key opportunity to provide support and guidance for patients who want to make a change in their lives. Participation in counselling and treatment may be achieved through brief interventions, which are short counselling or education sessions. This form of intervention may be more effective when providing care to patients who use substances when offered as part of clinical care than during routine prenatal care appointments (Ordean et al., 2017). A flexible interprofessional team is invaluable when caring for patients who are pregnant and using substances. It is critical that patients experiencing substance use receive accessible and consistent care and support with a strong focus on their individual physical and psychosocial needs (Abrahams et al., 2010; Ordean et al., 2017). Throughout Canada, communities must strive to support policies that strengthen harm-reduction practices and substance use prevention programs designed for women and the provision of women-only treatment and recovery programs.

Drug Testing During Pregnancy. There is no legal requirement in Canada for a health care provider to test either the mother or the newborn for the presence of drugs, unless the provincial child agency requests this. Police and legal requirements for the drug testing of newborns vary by province; health care providers must be aware of the regulations in their location (Ordean et al., 2017). In both hospitals and community health centres, it is best to consult with the facility's social workers regarding drug testing, following informed consent from the patient.

Nursing Care

The care of the patient who is pregnant and using substances should be based on self-disclosure of their present and past use, prenatal health history, physical findings, and laboratory results. Screening questions for alcohol, tobacco, prescribed and nonprescribed medications, and illicit substance use should be included in the overall assessment of all patients, regardless of socioeconomic status, at their first prenatal visit (Ordean et al., 2017). Patients need to be assessed for a history of violence, abuse, and mental health concerns, as well as the impact of determinants of health on their well-being, such as poverty and lack of housing and social supports that put patients at risk and can increase their substance use. Patients must be assured that the confidentiality of the information they disclose is respected; they should be informed that there is no legal obligation to report substance use and risks to the fetus during the course of pregnancy (BC Centre on Substance Use, 2018).

It is critical for nurses and other providers to use a nonjudgemental and trauma-informed interview and questioning technique when gathering substance-use information from patients (BC Centre on Substance Use, 2018) (see Chapter 1: Trauma and Violence-Informed Care). Urine and toxicology testing is not recommended as a clinical screening tool for pregnant patients. Testing of maternal hair and newborn meconium is also not recommended for clinical use. Maternal serum toxicology or urine testing is helpful to support a patient's self-reporting of their current substance use status. When drug testing is ordered clinically or requested by the provincial child protection agency, informed consent from the patient is mandatory (Ordean et al., 2017). When testing is ordered in the newborn, parental or guardian informed consent is also required.

Following the initial prenatal assessment, serial ultrasound studies should be performed to confirm gestational age. Some patients may have had amenorrhea as a result of substance use or may not know when their last menstrual period occurred. There is an increased risk of stillbirth and of small-for-gestational-age infants as well as the potential for perinatal hypoxia. If concerns are detected, regular ultrasound examination and fetal surveillance with nonstress testing should be arranged.

In planning care for a pregnant patient who uses substances, the perinatal nurse must individualize the approach, taking the patient's past history and expressed needs into consideration. Although the ideal long-term outcome is total abstinence, in Canada a harm-reduction philosophy of care is practised, supporting a patient's desire to stop using, as well as assisting the patient in reducing risks. There is strong evidence that the use of a harm-reduction approach results in a significant reduction in substance use–related harms for the patient and has been associated with improved newborn outcomes, such as fewer preterm births, higher birth weights, and increased likelihood of babies being discharged from hospital with their mothers following birth (BC Centre on Substance Use, 2018).

An interprofessional team model is essential when planning care for pregnant patients who use substances. Major issues that must be addressed in treatment for these patients that generally are not part of treatment include low self-esteem, stigmatization, high probability of sexual abuse and physical abuse, lack of social support, need for social services and child care, need for individualized health services, and need for support and education in the mothering role. Safe housing or residential supervised communities may offer an ideal route toward stabilization in a safe environment. Recovery and treatment for patients must demonstrate cultural sensitivity and recognition of diversity and ethnicity as an important part of their identity. Other needs of many of these patients include relationship counselling, coping skills training, and vocational and legal assistance (Ordean et al., 2017).

Interventions with pregnant patients who use substances need to begin with trust and communication. Patients are often very receptive to learning how they can keep their growing fetus safe and healthy by stopping or reducing substance use. Patients are often more receptive to making lifestyle changes during pregnancy than at any other time in their lives. The casual, experimental, or recreational drug user is often able to achieve and maintain abstinence from substances when they receive education, support, and continued monitoring throughout their pregnancy. Pregnancy presents a window of opportunity for motivating patients to stop their use of substances (Abrahams et al., 2010; Ordean et al., 2017).

Stabilization and treatment for patients who use substances should be individualized for each patient, depending on the type of drug used and the frequency and amount of use. Detoxification, short-term inpatient or outpatient treatment, long-term residential treatment, aftercare services, and self-help support groups are all possible options. Newborn outcomes are improved among newborns whose mothers received an integration of substance use treatment with prenatal care. In most communities in Canada, treatment options are limited for patients, especially facilities that allow children to be with their mothers. Some patients find organizations such as Alcoholics Anonymous or Narcotics Anonymous, based on the 12-step program, very helpful, and meetings can be found in almost every community. A caution for some patients using the 12-step program is that the program's emphasis is on powerlessness over addiction and avoidance of codependency, which some patients might find disempowering and isolating.

OAT with methadone or buprenorphine is the standard of pharmacological care for pregnant individuals with opioid use disorder, as it has been effective at eliminating or reducing the use of opioids during and after pregnancy, which leads to improved maternal and newborn outcomes (BC Centre on Substance Use, 2018; Jones et al., 2012; Ordean et al., 2017). Buprenorphine is a semisynthetic opioid derivative used to treat opioid addiction at higher dosages and to control moderate acute pain in non–opioid-tolerant individuals at lower dosages. Use of buprenorphine has been shown to result in fewer instances

of neonatal abstinence syndrome (Minozzi et al., 2013). Methadone and buprenorphine therapy, along with patient-focused psychosocial and behavioural counselling, has been shown to decrease the use of opiates and other drugs, reduce high-risk activity, improve birth weight, and decrease the rates of pre-eclampsia and exposure to HIV. Disadvantages of methadone therapy include fetal heart rate changes (e.g., fewer accelerations, decreased rate and variability), a decrease in fetal breathing episodes, and increased need for treatment for neonatal abstinence syndrome after birth (BC Centre on Substance Use, 2018; Jones et al., 2012).

Cocaine and crystal methamphetamine use during pregnancy has increased dramatically in the last few years. A number of maternal and fetal complications can occur, including placental abruption, stillbirth, prematurity, and small-for-gestational-age infants.

The legalization of cannabis occurred in Canada in October of 2018. Patients who use cannabis need to be educated on the effects of cannabis use in pregnancy. Research has shown that there are neurodevelopmental and cognitive delays seen in children with cannabis exposure in pregnancy (Porath-Waller et al., 2015). Health care providers, including nurses, must advise patients to reduce or stop cannabis use to avoid fetal exposure and adverse long-term outcomes for the child.

Patients who use substances may have increased exposure to STIs and HIV infection. STI monitoring for gonorrhea and chlamydia infection and antibody determinations for hepatitis B and HIV counselling and testing should be offered frequently to substance-using pregnant patients (BC Centre on Substance Use, 2018; Ordean et al., 2017). A chest X-ray may be taken to assess for pulmonary issues such as hilar lymphadenopathy, pulmonary edema, bacterial pneumonia, and foreign-body emboli. A skin test to screen for tuberculosis may also be ordered.

Nurses must understand the reasons why patients use substances, the barriers to stopping use, and their life experiences. Planning the best care for patients who are pregnant and use substances must involve a person-focused framework (Box 15.5). Mother–infant attachment should be encouraged by identifying the patient's strengths and reinforcing positive maternal response and interactions. Promoting skin-to-skin contact immediately following birth and keeping mothers and their newborns together has been proven to be beneficial for both the mother and newborn (Abrahams et al., 2010).

Advice regarding breastfeeding must be individualized. Although all substances appear in breast milk, some in greater amounts than others, breastfeeding has many benefits. Breastfeeding should be encouraged in mothers who are stable on OAT (BC Centre on Substance Use, 2018). Frequent access to the breast and instructing and supporting patients in hand expression and breast pumping can be helpful for patients in their breastmilk production. Patients should be encouraged to remain substance-free if they are breastfeeding. Patients should be advised to abstain from cannabis use during lactation or reduce consumption if abstinence is not possible. Furthermore, patients should be advised to avoid breastfeeding within 1 hour of inhaled use to reduce exposure to the highest concentration of cannabis in breast milk (Ordean & Kim, 2020). Some patients have no desire to breastfeed, whereas others find it provides a strong motivation to achieve and maintain their substance-free status.

Before discharge, the patient needs to have an effective and resourceful discharge plan, which should be made with the assistance of nursing and other health care providers. If the patient is unable to provide care for their newborn or has chosen not to care for their newborn, the newborn may be placed with their own family or in foster care. Support and counselling for this mother are extremely beneficial, and planning for future visits with their infant is often helpful.

Most patients who have a history of substance use will require assistance in planning for hospital discharge with their newborn. Adequate and safe housing, food and formula provisions, transportation supports, and recovery and parenting supports are essential services for the patient to be successful as a new parent. The hospital or community social worker, along with the provincial child agency worker, will often be involved in assessing the patient's needs and in assisting the patient to ensure that supports and resources are put in place before discharge. Often family members or friends will be asked to become actively involved with the patient and their newborn before discharge. The public health nurse may be asked to make home visits to assist and support the patient and their newborn. Postpartum doula support may also be helpful at this time. Community providers need to encourage the patient to follow up with them soon after discharge for regular postpartum visits for themselves and their infant. Primary care providers must follow up with patients soon after discharge to establish regular postpartum visits for the patient and the newborn.

BOX 15.5 Perinatal Care for Patients Who Use Substances

- Realize that the decision to stop using substances and engage in recovery can only be made by the patient themselves.
- Understand that the nurse's role can be that of an advocate and facilitator for positive change in a patient's life using trauma-informed and nonjudgemental techniques.
- Provide education for nurses on the reasons why patients use substances and the barriers to recovery in pregnancy. Know that violence, trauma, and mental health history can contribute to a patient's substance use and their ability to ask for help.
- Review the effects of perinatal substance use in pregnancy, intrapartum, and on the newborn.
- Patient-centred and harm-reduction practices are critical in caring for patients who use substances. Respect, understanding, and choices should be key components in nursing care and planning.
- Be familiar with community resources for patients, including accessible health clinics and providers; housing services, both emergency and long term; counselling and mental health supports; and substance recovery and treatment centres. Contact numbers for community services should be available in the hospital and clinic for patients and their providers.

KEY POINTS

- Careful monitoring of blood glucose levels, insulin administration, and dietary counselling are instrumental in creating a normal intrauterine environment for fetal growth and development in the pregnancy complicated by pregestational diabetes mellitus.
- Poor maternal glycemic control prior to conception and in the first trimester of pregnancy may be responsible for fetal congenital malformations and maternal complications such as miscarriage, infection, pre-eclampsia, and dystocia (difficult labour) caused by macrosomia.
- Maternal insulin requirements increase as the pregnancy progresses and may quadruple by term as a result of insulin resistance created by placental hormones, insulinase, and cortisol.
- Thyroid dysfunction during pregnancy requires close monitoring of thyroid hormone levels to regulate therapy and prevent fetal insult.
- The stress of the normal maternal adaptations to pregnancy on a patient with heart disease may cause further cardiac decompensation.

- Obesity in pregnancy is associated with risk factors for both mother and fetus and requires increased surveillance.
- Anemia, the most common medical disorder of pregnancy, affects at least 20% of pregnant patients.
- Patients in their reproductive years have an increased prevalence of autoimmune disorders (e.g., systemic lupus erythematosus and myasthenia gravis); therefore, it is important for care providers to be familiar with the effects of these disorders on pregnancy.
- Patients with spinal cord injuries do become pregnant and nurses need to understand the specific needs of these clients.
- Perinatal administration of ART is recommended to decrease perinatal transmission of HIV from mother to child. HIV testing for all pregnant patients is critical, and preconception counselling is the best practice for patients who are HIV positive.
- Patients who use substances and are pregnant need a harm-reduction care approach, with support from a variety of sources. These supports can come from partners, family, health care providers, and the community.
- Understanding why patients use substances and the barriers to recovery will assist in a patient's success with stabilization and treatment.

Labour and Birth Processes

Lisa Keenan-Lindsay
Originating US chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Explain five major factors that affect the labour process.
2. Describe the anatomical structure of the bony pelvis.
3. Describe the normal measurements of the diameters of the pelvic inlet, cavity, and outlet.
4. Explain the significance of the size and position of the fetal head during labour and birth.
5. Describe factors thought to contribute to the onset of labour.
6. Summarize the cardinal movements of labour for a vertex presentation.
7. Examine the maternal anatomical and physiological adaptations to labour.
8. Describe fetal adaptations to labour.

During late pregnancy, the pregnant patient and fetus prepare for the labour process. The fetus has grown and developed in preparation for extrauterine life. The pregnant patient has undergone various physiological adaptations during pregnancy that prepare them for birth and to become a new parent. Labour and birth represent the end of pregnancy, the beginning of extrauterine life for the newborn, and a change in the lives of the family members. This chapter discusses the factors affecting labour, the processes involved, the normal progression of events, and the adaptations made by both the labouring patient and fetus.

FACTORS AFFECTING LABOUR

At least five factors affect the process of labour and birth. These are easily remembered as the five P's: **p**assenger (fetus and placenta), **p**assageway (birth canal), **p**owers (contractions), **p**osition of the labouring patient, and **p**sychological response. The first four factors are presented here as the basis of understanding the physiological process of labour. Other factors can influence the patient's labour and birth experience, including place of birth, preparation, presence of continuous labour support, type of provider (e.g., obstetrician or family medicine physician, midwife), nursing care, and procedures. These factors are discussed generally in Chapter 17 as they relate to nursing care during labour.

Passenger

The movement of the passenger, or fetus, through the birth canal is determined by several interacting factors: the size of the fetal head, fetal presentation, fetal lie, fetal attitude, and fetal position. Because the placenta also must pass through the birth canal, it can be considered a passenger along with the fetus; however, the placenta rarely impedes the process of labour in normal vaginal birth. An exception is the case of placenta previa (see Chapter 14).

Size of the Fetal Head. Because of its size and relative rigidity, the fetal head has a major effect on the birth process. The fetal skull is composed of two parietal bones, two temporal bones, the frontal bone, and the occipital bone (Figure 16.1, *A*). These bones are united by connective tissue sutures: sagittal, lambdoidal, coronal, and frontal (see Figure 16.1, *B*). The areas where more than two bones meet are called *fontanels*. During labour, after the rupture of the membranes, palpation of the fontanels and sutures during vaginal examination reveals fetal presentation, position, and attitude.

The two most important fontanels are the anterior and posterior (see Figure 16.1, *B*). The larger of these, the anterior fontanel, is diamond shaped, about 3 cm × 2 cm, and lies at the junction of the sagittal, coronal, and frontal sutures. It closes by 18 months after birth. The posterior fontanel lies at the junction of the sutures of the two parietal bones and the one occipital bone, is triangular, and is about 1 cm × 2 cm. It closes 6 to 8 weeks after birth.

Sutures and fontanels make the skull flexible to accommodate the newborn brain, which continues to grow for some time after birth. However, because the bones are not firmly united, slight overlapping of the bones, or moulding of the shape of the head, occurs during labour. This capacity of the bones to slide over one another also permits adaptation to the various diameters of the maternal pelvis. Moulding can be extensive, but the heads of most newborns assume their normal shape within 3 days after birth.

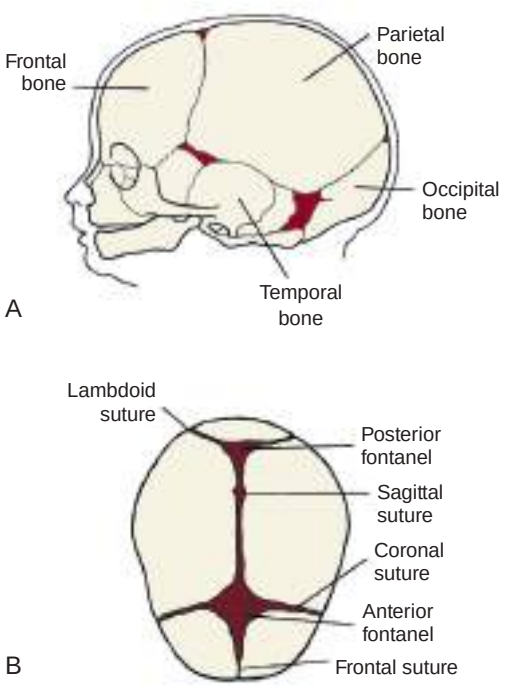

Fig. 16.1 Fetal head at term. **A:** Bones. **B:** Sutures and fontanels.

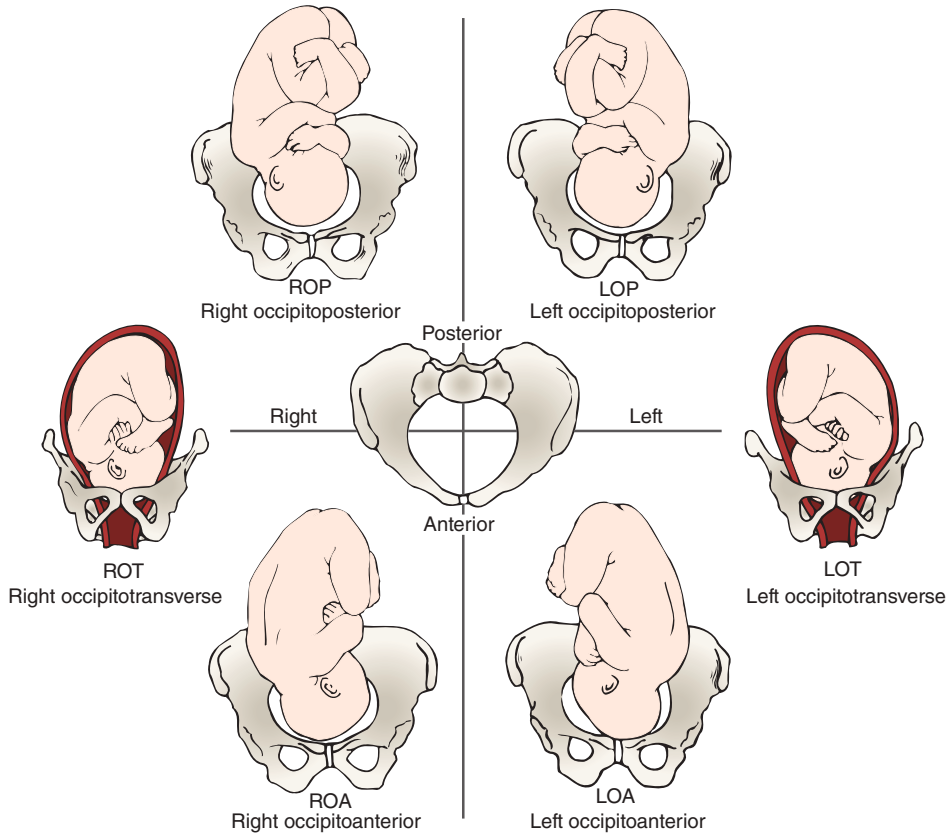
Although the size of the fetal shoulders may affect passage, their position can be altered relatively easily during labour so that one shoulder may occupy a lower level than the other. This creates a shoulder diameter that is smaller than the skull, facilitating passage through the birth canal. After the birth of the head and shoulders, the rest of the body usually emerges quickly.

Fetal Presentation. **Presentation** refers to the part of the fetus that enters the pelvic inlet first and leads through the birth canal during labour at term. The three main presentations are *cephalic presentation* (head first), occurring in 96% of births (Figure 16.2); *breech presentation* (buttocks, feet, or both first), occurring in 3 to 4% of births (Figure 16.3, *A–C*); and shoulder presentation, seen in less than 1% of births (see Figure 16.3, *D*). The *presenting part* is that part of the fetus that lies closest to the internal os of the cervix. It is the part of the fetal body first felt by the examining finger during a vaginal examination. In a cephalic presentation, the presenting part is usually the occiput; in a breech presentation it is the sacrum; in the shoulder presentation it is the scapula. When the presenting part is the occiput, the presentation is noted as vertex (see Figure 16.2). Factors that determine the presenting part include fetal lie, fetal attitude, and extension or flexion of the fetal head.

Fetal Lie. **Lie** is the relation of the long axis (spine) of the fetus to the long axis (spine) of the mother. The two primary lies are *longitudinal*,



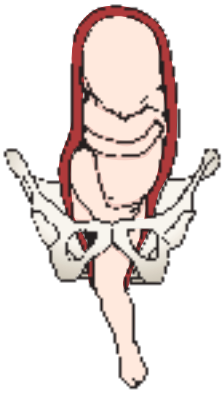


Fig. 16.2 Examples of fetal vertex (occiput) presentations in relation to front, back, or side of the maternal pelvis.

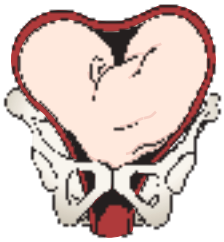
Frank breech

Lie: Longitudinal or vertical
Presentation: Breech (incomplete)
Presenting part: Sacrum
Attitude: Flexion, except for legs at knees

A

Single footling breech

Lie: Longitudinal or vertical
Presentation: Breech (incomplete)
Presenting part: Sacrum
Attitude: Flexion, except for one leg extended at hip and knee



B

Complete breech

Lie: Longitudinal or vertical
Presentation: Breech (sacrum and feet presenting)
Presenting part: Sacrum (with feet)
Attitude: General flexion

C

Shoulder presentation

Lie: Transverse or horizontal
Presentation: Shoulder
Presenting part: Scapula
Attitude: Flexion

D

Fig. 16.3 Fetal presentations. **A** to **C:** Breech (sacral) presentation. **D:** Shoulder presentation.

or vertical, in which the long axis of the fetus is parallel with the long axis of the mother (see Figure 16.2), and *transverse*, horizontal, or oblique, in which the long axis of the fetus is at a right angle diagonal to the long axis of the mother (see Figure 16.3, *D*). Longitudinal lies are either cephalic or breech presentations, depending on the fetal structure that first enters the mother's pelvis. Vaginal birth cannot occur when the fetus stays in a transverse lie. An *oblique lie*, one in which the long axis of the fetus is lying at an angle to the long axis of the mother, is less common and usually converts to a longitudinal or transverse lie during labour (Cunningham et al., 2018).

Fetal Attitude. **Attitude** is the relation of the fetal body parts to one another. The fetus assumes a characteristic posture (attitude) in utero partly because of the mode of fetal growth and partly because of the way the fetus conforms to the shape of the uterine cavity. Normally, the back of the fetus is rounded so that the chin is flexed on the chest, the thighs are flexed on the abdomen, and the legs are flexed at the knees. The arms are crossed over the thorax, and the umbilical cord lies between the arms and the legs. This attitude is termed *general flexion* (see Figure 16.2).

Deviations from the normal attitude may cause challenges for the labour and birth process. For example, in a cephalic presentation, the fetal head may be extended or flexed in a manner that presents a head diameter that exceeds the limits of the maternal pelvis, leading to prolonged labour, forceps- or vacuum-assisted birth, or Caesarean birth.

Certain critical diameters of the fetal head may be measured. The **biparietal diameter**, which is about 9.25 cm at term, is the largest transverse diameter and an important indicator of fetal head size (Figure 16.4, *B*). In a well-flexed cephalic presentation, the biparietal diameter is the widest part of the head entering the pelvic inlet. Of the several anteroposterior diameters, the smallest and the most critical one is the suboccipitobregmatic diameter (about 9.5 cm at term) (see Figure 16.4, *A*). When the head is in complete flexion, this diameter allows the fetal head to pass through the true pelvis easily (Figure 16.5, *A*). As the head is more extended, the anteroposterior

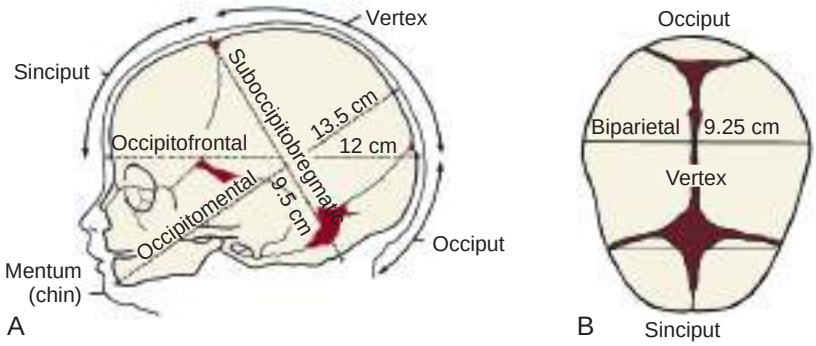


Fig. 16.4 Diameters of the fetal head at term. **A:** Cephalic presentations: occiput, vertex, and sinciput; and cephalic diameters: suboccipitobregmatic, occipitofrontal, and occipitomental. **B:** Biparietal diameter.

diameter widens, and the head may not be able to enter the true pelvis (see Figure 16.5, *B* and *C*).

Fetal Position. The presentation or presenting part indicates the portion of the fetus that overlies the pelvic inlet. **Position** is the relationship of a reference point on the presenting part (occiput, sacrum, mentum [chin], or sinciput [deflexed vertex]) to the four quadrants of the mother's pelvis (see Figure 16.2). Position is denoted by a three-letter abbreviation. The first letter of the abbreviation denotes the location of the presenting part in the right (R) or left (L) side of the mother's pelvis. The middle letter stands for the specific presenting part of the fetus (O for occiput, S for sacrum, M for mentum [chin], and Sc for scapula [shoulder]). The third letter stands for the location of the presenting part in relation to the anterior (A), posterior (P), or transverse (T) portion of the maternal pelvis. For example, ROA means that the occiput is the presenting part and is located in the right anterior quadrant of the maternal pelvis (see Figure 16.2). LSP means that the sacrum is the presenting part and is located in the left posterior quadrant of the maternal pelvis (see Figure 16.3, *A–C*).

Station is the relationship of the presenting fetal part to an imaginary line drawn between the maternal ischial spines and is a measure of the degree of descent of the presenting part of the fetus through the birth canal. The placement of the presenting part is measured in centimetres above or below the ischial spines (Figure 16.6). For example, when the lowermost portion of the presenting part is 1 cm above the spines, it is noted as being minus (−) 1. At the level of the spines, the station is referred to as 0 (zero). When the presenting part is 1 cm below the spines, the station is said to be plus (+) 1. Birth is imminent when the presenting part is at +4 to +5 cm. The station of the presenting part should be determined when labour begins so that the rate of descent of the fetus during labour can be accurately determined.

Engagement is the term used to indicate that the largest transverse diameter of the presenting part (usually the biparietal diameter) has passed through the maternal pelvic brim or inlet into the true pelvis and usually corresponds to station 0. Engagement often occurs in the weeks just before labour begins in nulliparas and may occur before or during labour in multiparas. Engagement can be determined by abdominal or vaginal examination.

Passageway

The *passageway*, or birth canal, is composed of the mother's rigid bony pelvis and the soft tissues of the cervix, pelvic floor, vagina, and introitus (the external opening to the vagina). Although the soft tissues, particularly the muscular layers of the pelvic floor, contribute to vaginal birth of the fetus, the patient's pelvis plays a far greater role in the labour process because the fetus must successfully accommodate itself to this relatively rigid passageway.

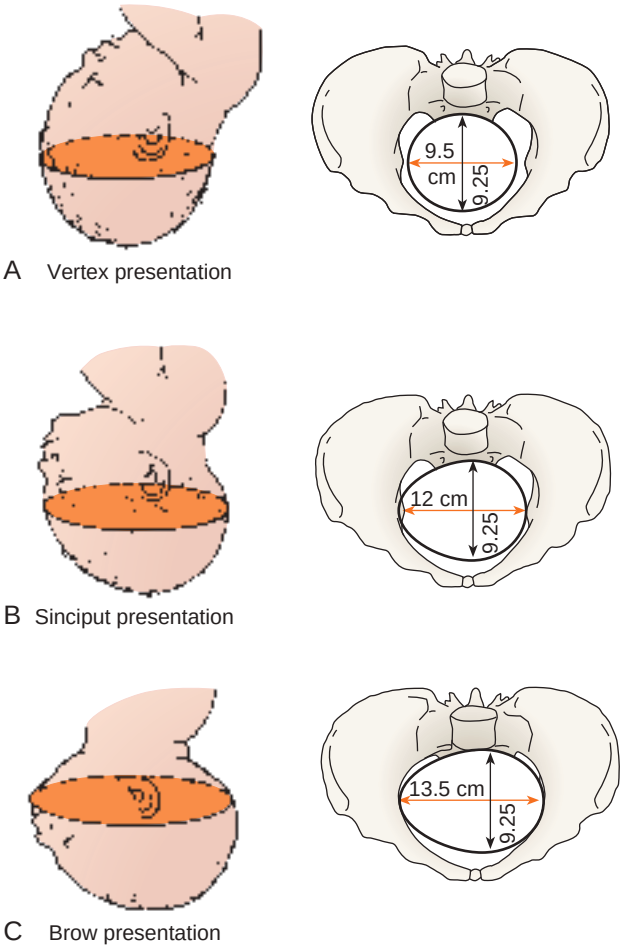

Fig. 16.5 Head entering pelvis. Biparietal diameter is indicated with shading (9.25 cm). **A:** Suboccipitobregmatic diameter: complete flexion of head on chest so that smallest diameter enters. **B:** Occipitofrontal diameter: moderate extension so that large diameter enters. **C:** Occipitomental diameter: marked extension (deflection) so that the largest diameter, which is too large to permit head to enter pelvis, is presenting.

Bony Pelvis. The anatomy of the bony pelvis is described in Chapter 7. The following discussion focuses on the importance of pelvic configurations as they relate to the labour process. (It may be helpful to refer to Figures 7.5 and 7.6.)

The *bony pelvis* is formed by the fusion of the ilium, ischium, pubis, and sacral bones. The four pelvic joints are the symphysis pubis, the

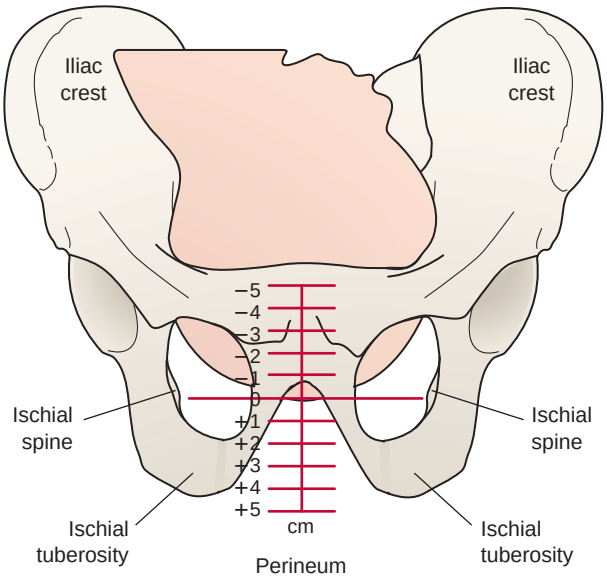

Fig. 16.6 Stations of presenting part, or degree of descent. Lowest portion of presenting part is at level of ischial spines, station 0.

right and left sacroiliac joints (Figure 16.7, *A*), and the sacrococcygeal joint (see Figure 16.7, *B*). The bony pelvis is separated by the brim, or inlet, into two parts: the false pelvis and the true pelvis. The *false pelvis* is the part above the brim and plays no part in childbearing. The *true pelvis*, the part involved in birth, is divided into three planes: the inlet, or brim; the midpelvis, or cavity; and the outlet.

The *pelvic inlet*, which is the upper border of the true pelvis, is formed anteriorly by the upper margins of the pubic bone, laterally by the iliopectineal lines along the innominate bones, and posteriorly by the anterior, upper margin of the sacrum and the sacral promontory.

The *pelvic cavity*, or midpelvis, is a curved passage with a short anterior wall and a much longer concave posterior wall. It is bounded by the posterior aspect of the symphysis pubis, the ischium, a portion of the ilium, the sacrum, and the coccyx.

The *pelvic outlet* is the lower border of the true pelvis. Viewed from below, it is ovoid, somewhat diamond shaped, and bounded by the pubic arch anteriorly, the ischial tuberosities laterally, and the tip of the coccyx posteriorly (see Figure 16.7, *B*). In the latter part of pregnancy, the coccyx is movable unless it has been broken (e.g., in a fall) and has fused to the sacrum during healing.

The pelvic cavity varies in size and shape at various levels. The diameters at the plane of the pelvic inlet, midpelvis, and outlet, plus the axis of the birth canal (Figure 16.8), determine whether vaginal birth is possible and the manner by which the fetus may pass down the birth canal.

The subpubic angle, which determines the type of pubic arch, together with the length of the pubic rami and the intertuberous diameter, is of great importance. Because the fetus must first pass beneath the pubic arch, a narrow subpubic angle is less accommodating than a rounded wide arch.

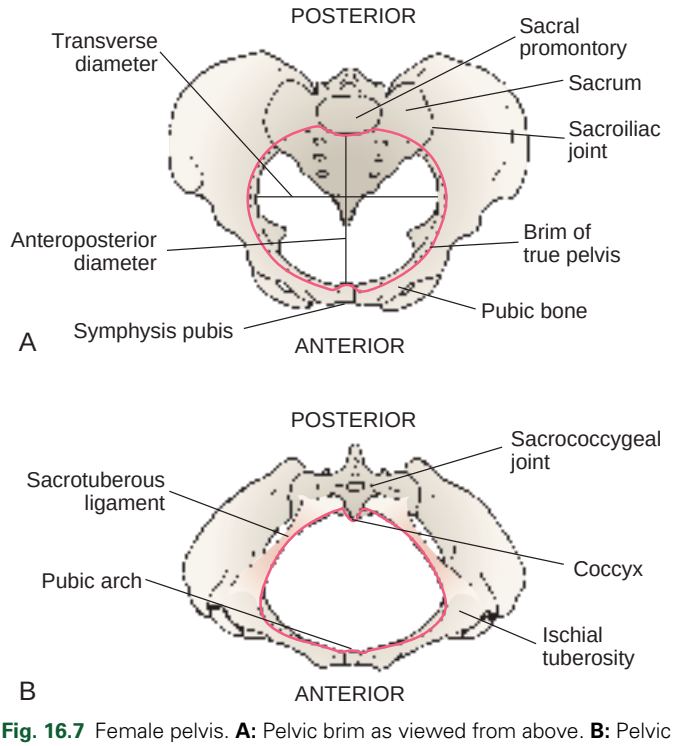

Fig. 16.7 Female pelvis. **A:** Pelvic brim as viewed from above. **B:** Pelvic outlet from below, as seen by health care provider when the patient is lying supine.

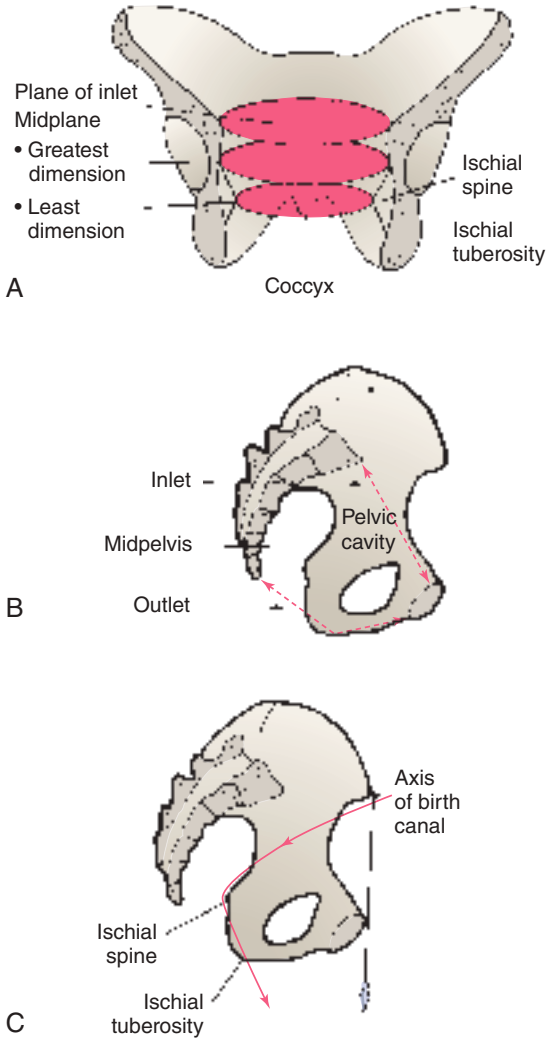

Fig. 16.8 Pelvic cavity. **A:** Inlet and midplane. Outlet not shown. **B:** Cavity of true pelvis. **C:** Note curve of sacrum and axis of birth canal.

The four basic types of pelves are classified as follows:

1. Gynecoid (the classic female type)
2. Android (resembling the male pelvis)
3. Anthropoid (resembling the pelvis of anthropoid apes)
4. Platypelloid (the flat pelvis)

The gynecoid pelvis is the most common type, with major gynecoid pelvic features present in 50% of all females. Anthropoid and android features are less common, and platypelloid pelvic features are least common. Mixed types of pelves are more common than are pure types (Kilpatrick & Garrison, 2017). Examples of pelvic variations and their effects on the mode of birth are given in Table 16.1.

Assessment of the bony pelvis can be performed during the first prenatal evaluation by health care provider and need not be repeated if the pelvis is of adequate size and suitable shape. In the third trimester of pregnancy, the examination of the bony pelvis may be more thorough and the results more accurate because there is relaxation and increased mobility of the pelvic joints and ligaments as a result of hormonal influences. Widening of the joint of the symphysis pubis and the resulting instability may cause pain in any or all of the pelvic joints.

Because the examiner does not have direct access to the bony structures and because the bones are covered with varying amounts of soft tissue, estimates of size and shape are approximate. Precise bony pelvis measurements can be determined by use of radiographic computed tomography (CT) or magnetic resonance imaging (MRI). However, these procedures are rarely performed for this purpose because evidence is lacking that they are beneficial. Indeed, some data show possible harm associated with their use because of an increase in Caesarean birth rates (Kilpatrick & Garrison, 2017). Even precise measurements do not always predict a patient's ability to give birth vaginally because of the many ways the fetus can negotiate the pelvis and the accommodation of maternal soft tissues. Therefore, pelvimetry results rarely contraindicate an attempt at labour.

Soft Tissues. The soft tissues of the passageway include the distensible lower uterine segment, cervix, pelvic floor muscles, vagina, and introitus. Before labour begins, the uterus is composed of the uterine body (corpus) and cervix (neck). After labour has begun, uterine contractions cause the uterine body to have a thick and muscular upper segment and a thin-walled, passive, muscular lower segment. *A physiological retraction ring* separates the two segments (Figure 16.9). The lower uterine segment gradually distends to accommodate the intrauterine contents as the wall of the upper segment thickens and its accommodating capacity is reduced. The contractions of the uterine body thus exert downward pressure on the fetus, pushing it against the cervix.

The cervix effaces (thins) and dilates (opens) sufficiently to allow the first fetal portion to descend into the vagina. As the fetus descends, the cervix is actually drawn upward and over this first portion.

The *pelvic floor* is a muscular layer that separates the pelvic cavity above from the perineal space below. This structure helps the fetus rotate anteriorly as it passes through the birth canal. As noted earlier, the soft tissues of the vagina develop throughout pregnancy until at term the vagina can dilate to accommodate the fetus and facilitate its passage to the external world.

Powers

Involuntary and voluntary powers combine to expel the fetus and the placenta from the uterus. Involuntary uterine contractions, called the *primary powers*, signal the beginning of labour. Once the cervix has dilated, voluntary bearing-down efforts by the labouring patient, called the *secondary powers*, augment the force of the involuntary contractions.

Primary Powers. The involuntary contractions originate at certain pacemaker points in the thickened muscle layers of the upper uterine segment. From the pacemaker points contractions move downward over the uterus in waves, separated by short rest periods. Terms used to describe these involuntary contractions include *frequency* (the time from the beginning of one contraction to the beginning of the next), *duration* (length of contraction), and *intensity* (strength of contraction at its peak).

The primary powers are responsible for the effacement and dilation of the cervix and descent of the fetus. **Effacement** means the shortening and thinning of the cervix during the first stage of labour. The cervix, normally 2 to 3 cm long and about 1 cm thick, is obliterated or "taken up" by a shortening of the uterine muscle bundles during the thinning of the lower uterine segment that occurs in advancing labour. Only a thin edge of the cervix can be palpated when effacement is complete. Effacement generally is advanced in first-time term pregnancy before more than slight dilation occurs. In subsequent

TABLE 16.1 Comparison of Pelvic Types

	Gynecoid (50% of Patients)	Android (23% of Patients)	Anthropoid (24% of Patients)	Platypelloid (3% of Patients)
Brim	Slightly ovoid or transversely rounded	Heart shaped, angulated	Oval, wider anteroposteriorly	Flattened anteroposteriorly, wide transversely
	◯ Round	♡ Heart	⬯ Oval	⬭ Flat
Depth	Moderate	Deep	Deep	Shallow
Side walls	Straight	Convergent	Straight	Straight
Ischial spines	Blunt, somewhat widely separated	Prominent, narrow interspinous diameter	Prominent, often with narrow interspinous diameter	Blunt, widely separated
Sacrum	Deep, curved	Slightly curved, terminal portion often beaked	Slightly curved	Slightly curved
Subpubic arch	Wide	Narrow	Narrow	Wide
Usual mode of birth	Vaginal Spontaneous Occipitoanterior position	Caesarean Vaginal Difficult with forceps	Vaginal Forceps/spontaneous Occipitoposterior or occipitoanterior position	Vaginal Spontaneous

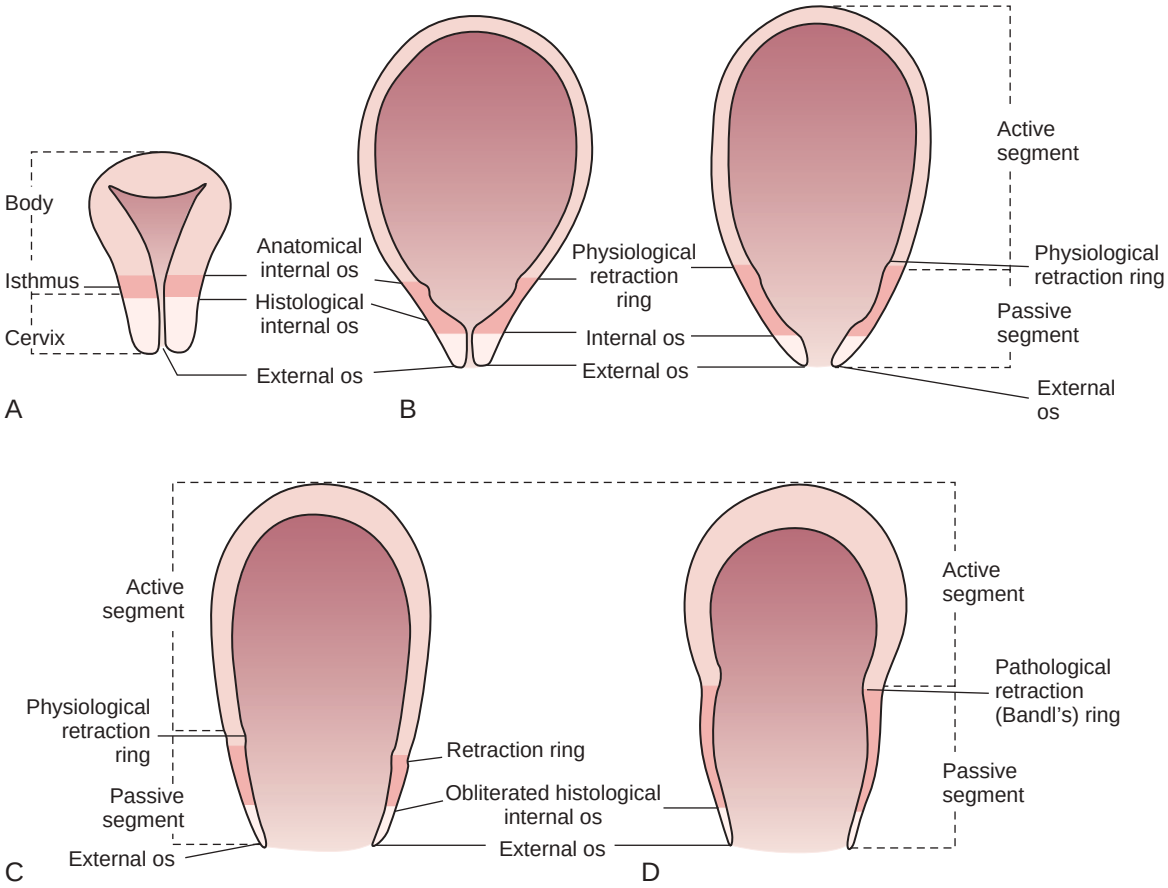

Fig. 16.9 Uterus. **A:** Nonpregnant uterus. **B:** Uterus in early first stage. **C:** Uterus in second stage. Passive segment is derived from lower uterine segment (isthmus) and cervix, and physiological retraction ring is derived from anatomical internal os. **D:** Uterus in abnormal labour in second-stage dystocia. Pathological retraction (Bandl's) ring that forms under abnormal conditions develops from the physiological ring.

pregnancies, effacement and dilation of the cervix tend to progress together. The degree of effacement is expressed in percentages, from 0 to 100% (e.g., a cervix is 50% effaced) or in length in centimetres (Figure 16.10, *A–C*).

Dilation of the cervix is the enlargement or widening of the cervical opening and the cervical canal that occurs once labour has begun. The diameter of the cervix increases from less than 1 cm to full dilation (approximately 10 cm) to allow birth of a term fetus. When the cervix is fully dilated (and completely retracted), it can no longer be palpated (see Figure 16.10, *D*). Full cervical dilation marks the end of the first stage of labour.

Dilation of the cervix occurs by the drawing upward of the musculofibrous components of the cervix, caused by strong uterine contractions. Pressure exerted by the amniotic fluid while the membranes are intact or by the force applied by the presenting part can promote cervical dilation. Scarring of the cervix as a result of prior infection or surgery may slow cervical dilation.

In the first and second stages of labour, increased intrauterine pressure caused by contractions exerts pressure on the descending fetus and the cervix. When the presenting part of the fetus reaches the perineal floor, mechanical stretching of the cervix occurs. Stretch receptors in the posterior vagina cause the release of endogenous oxytocin that triggers the maternal urge to bear down, or the *Ferguson reflex*.

Uterine contractions are usually independent of external forces. For example, labouring patients who are paralyzed because of spinal cord lesions above the twelfth thoracic vertebra have normal but painless uterine contractions (Dawood et al., 2014). However, uterine contractions may decrease temporarily in frequency and intensity if opioid analgesic medication is given early in labour. In addition, use of epidural analgesia during labour does not decrease the frequency or intensity of contractions (Cunningham et al., 2018).

Secondary Powers. As soon as the presenting part reaches the pelvic floor, the contractions change in character and become expulsive. The labouring patient experiences an involuntary urge to push. The patient uses secondary powers (bearing-down efforts) to aid in expulsion of the fetus as they contract their diaphragm and abdominal muscles and pushes. These bearing-down efforts result in increased intra-abdominal pressure that compresses the uterus on all sides and adds to the power of the expulsive forces.

The secondary powers have no effect on cervical dilation, but they are of considerable importance in the expulsion of the newborn from the uterus and vagina after the cervix is fully dilated.

When and how a patient pushes in the second stage of labour is a much-debated topic. Studies have investigated the effects of spontaneous bearing-down efforts, directed pushing, delayed pushing, Valsalva manoeuvre (closed glottis and prolonged bearing down), and open-glottis pushing. The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends that the method of pushing, spontaneous or directed with Valsalva manoeuvre, should be chosen by the patient's own preference. Directed pushing may assist with the final expulsion of the head (Lee et al., 2016). See Chapter 17 for further discussion regarding pushing during the second stage of labour.

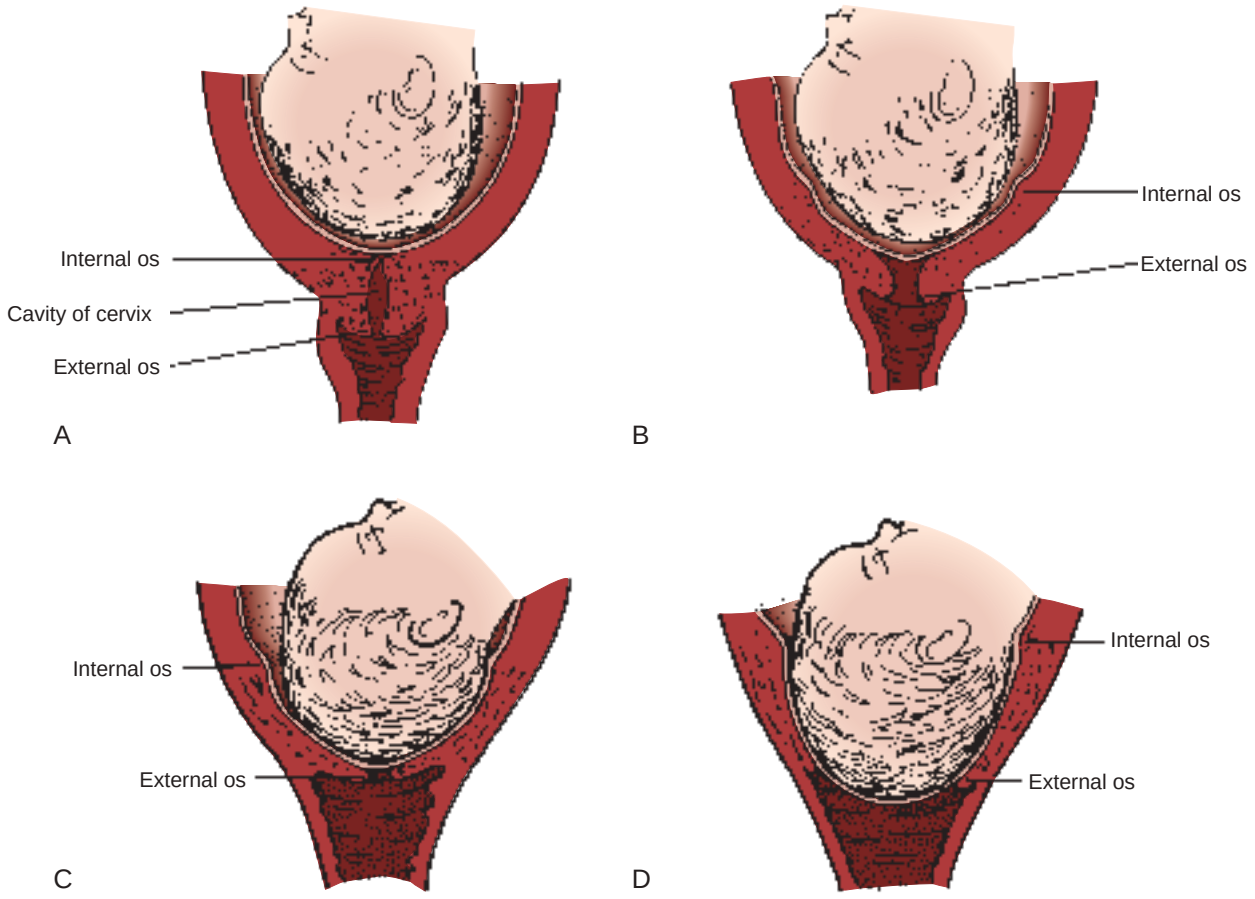

Fig. 16.10 Cervical effacement and dilation. Note how cervix is drawn up around presenting part (internal os). Membranes are intact, and head is not well applied to cervix. **A:** Before labour. **B:** Early effacement. **C:** Complete effacement (100%). Head is well applied to cervix. **D:** Complete dilation (10 cm). Cranial bones overlap somewhat, and membranes are still intact.

Position of the Labouring Patient

Position affects the patient's anatomical and physiological adaptations to labour. Frequent changes in position relieve fatigue, increase comfort, and improve circulation. Therefore, a labouring patient should be encouraged to find positions that are most comfortable to them.

An upright position (walking, sitting, kneeling, or squatting) offers a number of advantages. Gravity can promote the descent of the fetus. Uterine contractions are generally stronger and more efficient in effacing and dilating the cervix, resulting in shorter labour.

An upright position also is beneficial to the labouring patient's cardiac output, which normally increases during labour as uterine contractions return blood to the vascular bed. The increased cardiac output improves blood flow to the uteroplacental unit and the maternal kidneys. If the labouring patient wishes to lie down, a lateral position is suggested. The "all fours" position (hands and knees) may be used to relieve backache if the fetus is in an occipitoposterior position and may assist in anterior rotation of the fetus and in cases of shoulder dystocia.

Positioning for second-stage labour may be determined by the patient's preference, but it is constrained by the condition of the patient or fetus, the environment, and the health care provider's confidence in assisting in a birth in a specific position. See Chapter 17 for further discussion of positioning during birth.

PROCESS OF LABOUR

The term *labour* refers to the process of moving the fetus, placenta, and membranes out of the uterus and through the birth canal. Various changes take place in the pregnant patient's reproductive system in the days and weeks before labour begins. Labour itself can be discussed in terms of the mechanisms involved in the process and the stages the patient moves through.

Signs Preceding Labour

In first-time pregnancies, the uterus sinks downward and forward about 2 to 4 weeks before term, when the fetus's presenting part (usually the fetal head) descends into the true pelvis. This settling is called *lightening*, or "dropping," and usually happens gradually. After lightening, pregnant patients breathe more easily, but usually more bladder pressure results from this shift, and consequently there is a return of urinary frequency. In a multiparous pregnancy, lightening may not take place until after uterine contractions are established and true labour is in progress.

The pregnant patient may state that they feel persistent low backache and sacroiliac distress as a result of relaxation of the pelvic joints. They may identify strong, frequent, but irregular uterine (Braxton Hicks) contractions.

The vaginal mucus becomes more profuse in response to the extreme congestion of the vaginal mucous membranes. Brownish or

BOX 16.1 Signs Preceding Labour

- Lightening
- Return of urinary frequency
- Backache
- Stronger Braxton Hicks contractions
- Weight loss of 0.5 to 1.5 kg
- Surge of energy (also called *nesting*)
- Flulike symptoms
- Increased vaginal discharge; bloody show
- Cervical ripening
- Possible rupture of membranes

blood-tinged cervical mucus may be passed (**bloody show**). The cervix becomes soft (ripens) and partially effaced and may begin to dilate. The membranes may rupture spontaneously.

Other phenomena are common in the days preceding labour: (1) loss of 0.5 to 1.5 kg in weight, caused by water loss resulting from electrolyte shifts that in turn are produced by changes in estrogen and progesterone levels; and (2) a surge of energy. Patients speak of having a burst of energy (*nesting*) that they often use to clean the house and put everything in order. Less commonly, some patients have diarrhea, nausea, vomiting, and indigestion. Box 16.1 lists signs that may precede labour (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

"I Think I'm in Labour"

Erica is a 15-year-old G1 T0 P0 A0 L0 at 39 weeks of gestation. She presents by ambulance to the triage area in your labour and birth unit and announces, "I'm here to have my baby. I think I'm in labour." Erica reports that she saw a thick brownish red vaginal discharge several days ago and noticed bright red vaginal spotting when wiping after peeing earlier today. She states that she has lower abdominal cramping ("It feels like the cramps I have with my periods") but denies leakage of vaginal fluid. Erica also reports active fetal movement. She says she is having difficulty coping with the pain, while alternating between texting on her phone and chatting with her mother, who accompanied her to the hospital.

1. Evidence—Is there sufficient evidence at this time to draw a conclusion about whether Erica is in labour?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Characteristics of prelabour
   b. Indications of true labour
   c. Basic teaching for Erica and her mother at this time
   d. Criteria necessary for discharging Erica from the labour and birth unit
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who would potentially be involved in Erica's care.

Onset of Labour

The onset of true labour cannot be ascribed to a single cause. Many factors, including changes in the maternal uterus, cervix, and pituitary gland, are involved. Hormones produced by the normal fetal hypothalamus, pituitary, and adrenal cortex probably contribute to the onset of labour. Progressive uterine distension and increasing intrauterine pressure seem to be associated with increasing myometrial irritability. This is a result of increased concentrations of estrogen, oxytocin, and prostaglandins and decreasing progesterone levels. The mutually coordinated effects of these factors result in the occurrence of strong, regular, rhythmic uterine contractions (Blackburn, 2018; Kilpatrick & Garrison, 2017). The outcome of these factors working together is normally the birth of the fetus and the expulsion of the placenta.

Stages of Labour

The course of normal labour, at or near term gestation in a patient without complications and a fetus in vertex presentation, consists of (1) regular progression of uterine contractions, (2) effacement and progressive dilation of the cervix, and (3) progress in descent of the presenting part. Four stages of labour are recognized. An overview of these stages is included here. They are discussed in greater detail, along with nursing care for the labouring patient and family, in Chapter 17.

The *first stage of labour* is considered to last from the onset of regular uterine contractions to full dilation of the cervix. Commonly, the onset of labour is difficult to establish because the patient may be admitted to the labour unit just before birth, and the beginning of labour may be only an estimate. The first stage is much longer than the second and third combined. However, great variability is the rule, depending on the factors discussed previously in this chapter. Parity has a strong effect on the duration of first-stage labour. Full dilation may occur in less than 1 hour in some multiparous pregnancies. In first-time pregnancy, complete dilation of the cervix can take 18 hours or longer. Variations may reflect differences in the patient population (e.g., risk status, age) or in clinical management of the labour and birth.

The *first stage of labour* is divided into two phases: *latent* (early) and *active* labour (Lee et al., 2016). During the latent phase, there is more progress in effacement of the cervix and little increase in descent. During the active phase, there is more rapid dilation of the cervix and increased rate of descent of the presenting part.

The *second stage of labour* lasts from the time the cervix is fully dilated to the birth of the fetus. It is composed of two phases: the latent phase (passive fetal descent) and the active pushing phase. During the latent phase the fetus continues to descend passively through the birth canal and rotate to an anterior position as a result of ongoing uterine contractions. The urge to bear down during this phase is not strong, and some labouring patients do not experience it at all. During the active pushing phase the patient has strong urges to bear down as the presenting part of the fetus descends and presses on the stretch receptors of the pelvic floor.

The *third stage of labour* lasts from the birth of the fetus until the placenta is delivered. The placenta normally separates with the third or fourth strong uterine contraction after the infant has been born. After it has separated, the placenta can be delivered with the next uterine contraction. Creating a warm environment, supporting skin-to-skin contact between mother and newborn, and reducing fear and anxiety contribute to decreased catecholamine production and increased oxytocin production, which facilitate placental separation. The duration of the third stage may be as short as 3 to 5 minutes, although up to 1 hour is considered within normal limits.

The *fourth stage of labour* begins with the delivery of the placenta and includes at least the first 2 hours after birth. It is the period of immediate recovery, when homeostasis is re-established. The fourth stage of labour is also the time when parent–child bonding and attachment begins and breastfeeding is initiated. It is an important period of observation for complications, such as abnormal bleeding (see Chapter 24).

Mechanism of Labour

As already discussed, the female pelvis has varied contours and diameters at different levels, and the presenting part of the passenger is large in proportion to the passage. Therefore, for vaginal birth to occur, the fetus must adapt to the birth canal during the descent. The turns and other adjustments necessary in the human birth process are termed the

mechanism of labour. The seven cardinal movements of the mechanism of labour that occur in a vertex presentation are engagement, descent, flexion, internal rotation, extension, external rotation (restitution), and, finally, birth by expulsion (Figure 16.11). Although these movements are discussed separately, in actuality a combination of movements occurs simultaneously. For example, engagement involves both descent and flexion.

Engagement. When the biparietal diameter of the head passes the pelvic inlet, the head is said to be engaged in the pelvic inlet (see Figure 16.11, *A*). In most nulliparous pregnancies, this occurs before the onset of active labour because the firmer abdominal muscles direct the presenting part into the pelvis. In multiparous pregnancies in which the abdominal musculature is more relaxed, the head often remains freely movable above the pelvic brim until labour is established.

Asynclitism. The head usually engages in the pelvis in a synclitic position (i.e., one that is parallel to the anteroposterior plane of the pelvis). Frequently, asynclitism occurs (the head is deflected anteriorly or posteriorly in the pelvis), which can facilitate descent because the head is being positioned to accommodate to the pelvic cavity (Figure 16.12). Extreme asynclitism can cause cephalopelvic disproportion, even in a normal-size pelvis, because the head is positioned so that it cannot descend (see Chapter 20 for further discussion).

Descent. *Descent* refers to the progress of the presenting part through the pelvis. Descent depends on at least four forces: (1) pressure exerted by the amniotic fluid, (2) direct pressure exerted by the contracting fundus on the fetus, (3) force of the contraction of the maternal diaphragm and abdominal muscles in the second stage of labour, and (4) extension and straightening of the fetal body. The effects of these forces are modified by the size and shape of the maternal pelvic planes and the size of the fetal head and its capacity to mould.

The degree of descent is measured by the station of the presenting part (see Figure 16.6). As mentioned earlier, little descent occurs during the latent phase of the first stage of labour. Descent accelerates in the active phase. It is especially apparent when the membranes have ruptured.

In a first-time labour, descent is usually slow but steady; in subsequent pregnancies, descent may be rapid. Progress in descent of the presenting part is determined by abdominal palpation and vaginal examination until the presenting part can be seen at the introitus.

Flexion. As soon as the descending head meets resistance from the cervix, pelvic wall, or pelvic floor, it normally flexes so that the chin is brought into closer contact with the fetal chest (see Figure 16.11, *B*). Flexion permits the smaller suboccipitobregmatic diameter (9.5 cm) rather than the larger diameters to present to the outlet.

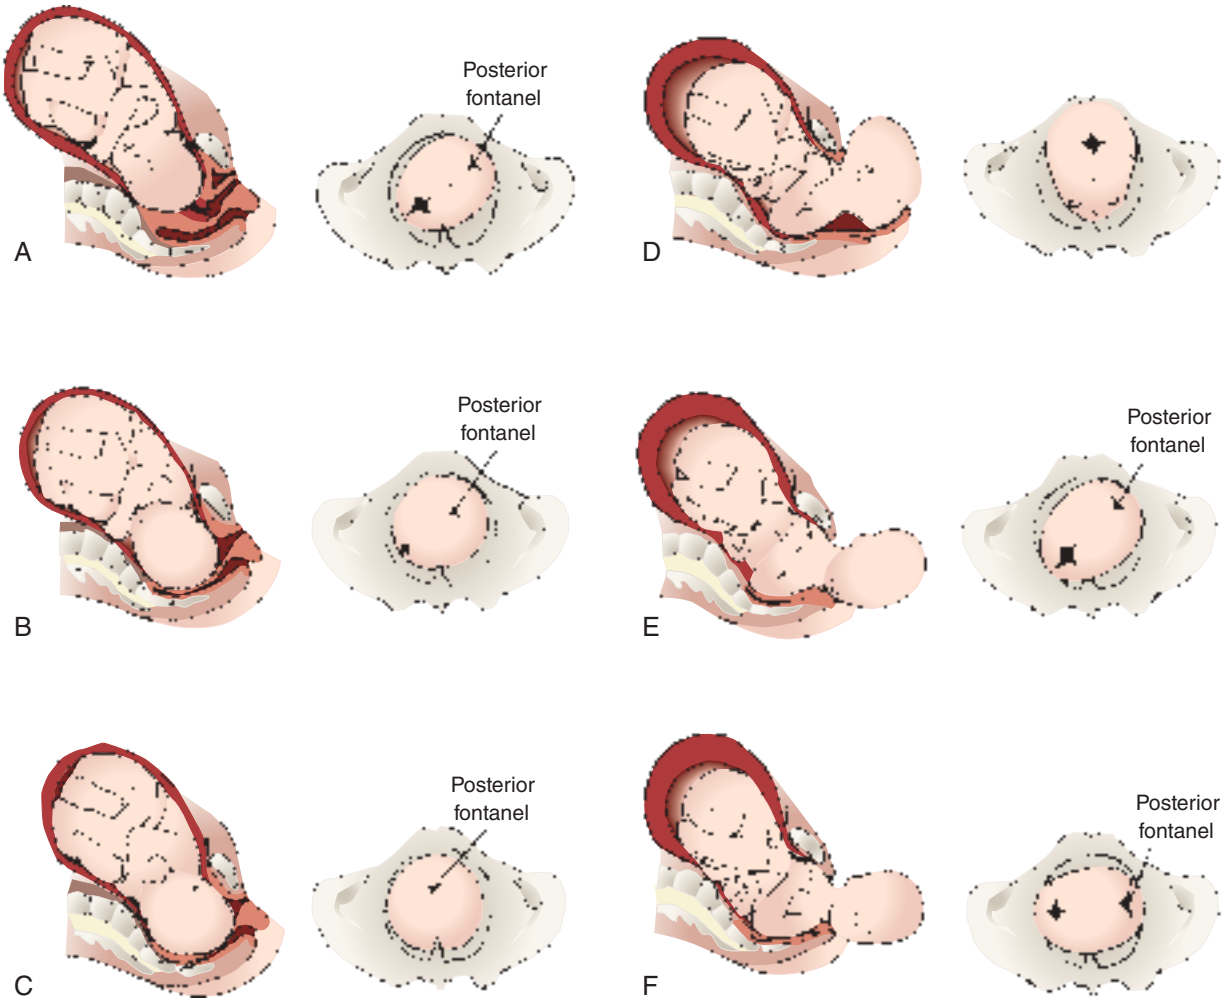

Fig. 16.11 Cardinal movements of the mechanism of labour. Left occipitoanterior (LOA) position. Pelvic figures show position of fetal head as seen by birth attendant. **A:** Engagement and descent. **B:** Flexion. **C:** Internal rotation to occipitoanterior position. **D:** Extension. **E:** External rotation beginning (restitution). **F:** External rotation.

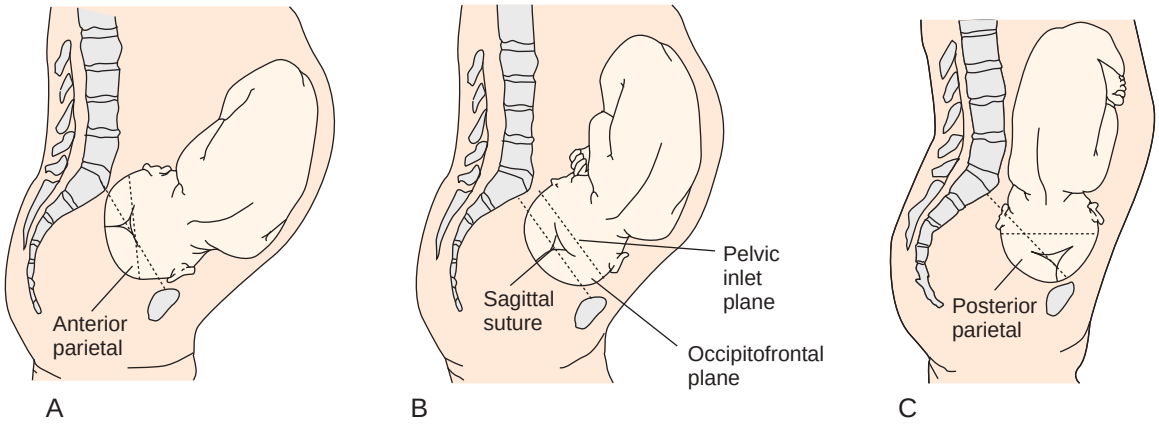

Fig. 16.12 Synclitism and asynclitism. **A:** Anterior asynclitism. **B:** Normal synclitism. **C:** Posterior asynclitism.

Internal Rotation. The maternal pelvic inlet is widest in the transverse diameter; therefore, the fetal head passes the inlet into the true pelvis in the occipitotransverse position. The outlet is widest in the anteroposterior diameter; in order for the fetus to exit, the head must rotate. Internal rotation begins at the level of the ischial spines but is not completed until the presenting part reaches the lower pelvis. As the occiput rotates anteriorly, the face rotates posteriorly. With each contraction the fetal head is guided by the bony pelvis and the muscles of the pelvic floor. Eventually, the occiput will be in the midline beneath the pubic arch. The head is almost always rotated by the time it reaches the pelvic floor (see Figure 16.11, *C*). Both the levator ani muscles and the bony pelvis are important for achieving anterior rotation. A previous childbirth injury or regional anaesthesia may compromise the function of the levator sling.

Extension. When the fetal head reaches the perineum for birth, it is deflected anteriorly by the perineum. The occiput passes under the lower border of the symphysis pubis first, and then the head emerges by extension: first the occiput, then the face, and finally the chin (see Figure 16.11, *D*).

Restitution and External Rotation. After the head is born, it rotates briefly to the position it occupied when it was engaged in the inlet. This movement is referred to as *restitution* (see Figure 16.11, *E*). The 45-degree turn realigns the newborn's head with their back and shoulders. The head can then be seen to rotate further. This external rotation occurs as the shoulders engage and descend in manoeuvres similar to those of the head (see Figure 16.11, *F*). As noted earlier, the anterior shoulder descends first. When it reaches the outlet, it rotates to the midline and is delivered from under the pubic arch. The posterior shoulder is guided over the perineum until it is free of the vaginal introitus.

Expulsion. After birth of the shoulders, the head and shoulders are lifted up toward the mother's pubic bone, and the trunk of the baby is born by flexing it laterally in the direction of the symphysis pubis. When the baby has completely emerged, birth is complete, and the second stage of labour ends.

PHYSIOLOGICAL ADAPTATION TO LABOUR

In addition to the maternal and fetal anatomical adaptations that occur during birth, physiological adaptations must occur. Accurate assessment of the labouring patient and fetus requires knowledge of these expected adaptations.

Fetal Adaptation

Several important physiological adaptations occur in the fetus. These changes occur in fetal heart rate (FHR), fetal circulation, respiratory movements, and other behaviours.

Fetal Heart Rate. Fetal health surveillance (FHS) provides information about the condition of the fetus related to oxygenation. The average FHR at term is 110 to 160 beats/min. Earlier in gestation the FHR is higher, with an average of approximately 160 beats/min at 20 weeks of gestation. The rate decreases progressively as the sympathetic nervous system in the fetus matures closer to term. However, temporary accelerations and slight early decelerations of the FHR can be expected in response to spontaneous fetal movement, vaginal examination, fundal pressure, uterine contractions, abdominal palpation, and fetal head compression. Stresses to the uterofetoplacental unit result in characteristic FHR patterns (see Chapter 19 for further discussion).

Fetal Circulation. Fetal circulation can be affected by many factors, including maternal position, uterine contractions, blood pressure, and umbilical cord blood flow. Uterine contractions during labour tend to decrease circulation through the spiral arterioles and subsequent perfusion through the intervillous space. Most healthy fetuses are able to compensate for this stress and exposure to increased pressure while moving passively through the birth canal during labour. Usually the umbilical cord moves freely in the amniotic fluid. However, it can be compressed during uterine contractions (Blackburn, 2018; Dore & Lehman, 2020).

Fetal Respiration. Certain changes stimulate chemoreceptors in the aorta and carotid bodies to prepare the fetus for initiating respirations immediately after birth (Blackburn, 2018). These changes include the following:

- Fetal lung fluid is cleared from the air passages as the newborn passes through the birth canal during labour and (vaginal) birth.
- Fetal oxygen pressure (P_{O_2}) decreases.
- Arterial carbon dioxide pressure (P_{CO_2}) increases.
- Arterial pH decreases.
- Bicarbonate level decreases.
- Fetal respiratory movements decrease during labour.

Adaptation of Labouring Person

As the patient progresses through the stages of labour, various body system adaptations cause the patient to exhibit both objective and subjective symptoms (Box 16.2). Accurate assessment of the mother and fetus during labour and birth depends on knowledge of these

BOX 16.2 Physiological Changes in Patient During Labour

- Cardiac output increases 10 to 15% in first stage; 30 to 50% in second stage.
- Heart rate increases slightly in first and second stages.
- Systolic and diastolic blood pressure increase during uterine contractions and return to baseline between contractions. Systolic values increase more than diastolic values.
- White blood cell count increases.
- Respiratory rate increases.
- Temperature may be slightly elevated.
- Proteinuria may occur.
- Gastric motility and absorption of solid food are decreased; nausea and vomiting may occur during the active phase to second-stage labour.
- Blood glucose level decreases.

expected adaptations so that appropriate interventions can be implemented.

Cardiovascular Changes. During each contraction, an average of 300 to 500 mL of blood is shunted from the uterus into the maternal vascular system. By the end of the first stage of labour, cardiac output during contractions is increased up to 51% above baseline pregnancy values at term. Cardiac output peaks about 10 to 30 minutes after both vaginal and Caesarean birth and returns to its prelabour baseline within the first postpartum hour. A drop in maternal heart rate accompanies this increase in cardiac output (Antony et al., 2017).

Changes in blood pressure also occur. Blood flow, which is reduced in the uterine artery by contractions, is redirected to peripheral vessels. As a result, peripheral resistance increases and blood pressure increases. In general, both systolic and diastolic pressures increase during contractions and return to baseline levels between contractions. Assessing blood pressure between contractions provides more accurate readings.

Supine hypotension (see Figure 17.3) occurs when the ascending vena cava and descending aorta are compressed. The labouring patient is at greater risk for supine hypotension if the uterus is particularly large because of multifetal pregnancy, hydramnios, or obesity or if the patient is dehydrated or hypovolemic. In addition, anxiety, pain, and some medications can cause hypotension.

! NURSING ALERT

The patient should be discouraged from using the Valsalva manoeuvre (holding one's breath and tightening abdominal muscles) for pushing during the second stage. This activity increases intrathoracic pressure, reduces venous return, and increases venous pressure. Cardiac output and blood pressure increase, and the pulse slows temporarily. During the Valsalva manoeuvre, fetal hypoxia may occur. The process is reversed when the patient takes a breath.

The white blood cell (WBC) count can increase (Blackburn, 2018). Although the mechanism leading to this increase in WBCs is unknown, it may be secondary to physical or emotional stress or tissue trauma. Labour is strenuous, and physical exercise alone can increase the WBC count.

Some peripheral vascular changes occur, perhaps in response to cervical dilation or compression of maternal vessels by the fetus passing through the birth canal. Flushed cheeks, hot or cold feet, and eversion of hemorrhoids may result.

Respiratory Changes. Increased physical activity with greater oxygen consumption is reflected in an increase in the respiratory rate. Hyperventilation may cause respiratory *alkalosis* (an increase in pH), hypoxia, and *hypocapnia* (decrease in carbon dioxide). In the unmedicated labouring patient in the second stage, oxygen consumption almost doubles. Anxiety also may increase oxygen consumption.

Renal Changes. During labour, spontaneous voiding may be difficult for various reasons: tissue edema caused by pressure from the presenting part, discomfort, analgesia, and embarrassment. Proteinuria up to +1 is a normal finding because it can occur in response to the breakdown of muscle tissue from the physical work of labour.

Integumentary Changes. The integumentary system changes are evident, especially in the great distensibility (stretching) in the area of the vaginal introitus. The degree of distensibility varies with the individual. Despite this ability to stretch, even in the absence of episiotomy or lacerations, minute tears in the skin around the vaginal introitus occur.

Musculoskeletal Changes. The musculoskeletal system is stressed during labour. Diaphoresis, fatigue, proteinuria (+1), and possibly an increased temperature accompany the marked increase in muscle activity. Backache and joint ache (unrelated to fetal position) occur as a result of increased joint laxity at term. The labour process itself and the patient's pointing their toes can cause leg cramps.

Neurological Changes. Sensorial changes occur as the patient moves through phases of the first stage of labour and from one stage to the next. Initially, the patient may be euphoric. Euphoria gives way to increased seriousness, to amnesia between contractions during the second stage, and finally to elation or fatigue after giving birth. Endogenous *endorphins* (morphine-like chemicals produced naturally by the body) raise the pain threshold and produce sedation. In addition, physiological anaesthesia of perineal tissues, caused by pressure of the presenting part, decreases the perception of pain.

Gastrointestinal Changes. During labour, gastrointestinal motility and absorption of solid foods are decreased, and stomach-emptying time is slowed. Nausea and vomiting of undigested food eaten after onset of labour are common. Nausea and belching also occur as a reflex response to full cervical dilation. The patient may state that diarrhea accompanied the onset of labour, or the nurse may palpate the presence of hard or impacted stool in the rectum. If stool is present in the rectum the patient often passes this as they push.

Endocrine Changes. The onset of labour may be triggered by decreasing levels of progesterone and increasing levels of estrogen, prostaglandins, and oxytocin. Metabolism increases, and blood glucose levels may decrease with the work of labour. Patients who are diabetic require close monitoring of glucose levels during labour (see Chapter 15, Pregestational Diabetes Mellitus, Intrapartum Care).

KEY POINTS

- Labour and birth are affected by the five P's: passenger, passageway, powers, position of the labouring patient, and psychological response.
- Because of its size and relative rigidity, the fetal head is a major factor in determining the course of birth.
- The diameters at the plane of the pelvic inlet, midpelvis, and outlet, plus the axis of the birth canal, determine whether vaginal birth is possible and the manner in which the fetus passes down the birth canal.

- Involuntary uterine contractions act to expel the fetus and placenta during the first stage of labour; these are augmented by voluntary bearing-down efforts during the second stage.
- The first stage of labour lasts from the time dilation begins to the time when the cervix is fully effaced and dilated.
- The second stage of labour lasts from the time of full dilation to the birth of the newborn.
- The third stage of labour lasts from the newborn's birth to the expulsion of the placenta.
- The fourth stage is approximately the first 2 hours after birth.
- The cardinal movements of the mechanism of labour are engagement, descent, flexion, internal rotation, extension, restitution and external rotation, and expulsion of the newborn.
- Although the events precipitating the onset of labour are unknown, many factors, including changes in the maternal uterus, cervix, and pituitary gland, are thought to be involved.
- A healthy fetus with an adequate uterofetoplacental circulation will be able to compensate for the stress of uterine contractions.
- As the patient progresses through labour, various body systems adapt to the birth process.

Nursing Care of the Family During Labour and Birth

Karen Pike
Originating US Chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter, the reader will be able to:

1. Review the factors included in the initial assessment of the childbearing person in labour.
2. Describe the ongoing assessment of progress during the first, second, third, and fourth stages of labour.
3. Recognize the physical and psychosocial findings that indicate progress during labour.
4. Identify risk factors for and signs of developing complications during labour and birth.
5. Incorporate evidence-informed nursing interventions into a comprehensive plan of care relevant to each stage of labour.
6. Recognize the importance of support (family, partner, doula, nurse) in fostering patient confidence and facilitating the progress of labour and birth.
7. Analyze the influence of cultural beliefs and practices as well as psychosocial factors on the process of labour and birth.
8. Evaluate research findings on the importance of support from the family, partner, doula, and nurse in facilitating the patient's progress during labour and birth.
9. Describe the role and responsibilities of the nurse during emergency childbirth.
10. Evaluate the impact of perineal trauma on the childbearing person's reproductive and sexual health.

The labour process can be an exciting and anxious time for the childbearing patient, their family, and support people. In a relatively short period, they experience one of the most profound changes in their lives, particularly with a first baby.

For most patients, labour begins with the first uterine contraction, continues with hours of work during cervical effacement and dilation, culminates in birth, and ends as the childbearing person and family begin the attachment process with the newborn. Nursing care management focuses on assessment and support of the childbearing patient and their support people throughout labour and birth, with the goal of ensuring the best possible outcome for all involved.

Although the majority of childbearing patients in Canada labour and give birth in a hospital under the care of a physician, others choose different settings and care providers. Midwifery care is available in hospitals, birth centres, or home, depending on the community (see Community Focus box and Chapter 11: Perinatal Care Choices).

COMMUNITY FOCUS

Availability of Alternative Childbirth Options in the Community

Consult the Internet to explore options for childbearing families in your community. Are registered midwives available? Is there an option for a home birth? For a water birth? Is there a birthing centre in your community? Prepare a patient handout listing the options for childbearing families in your community. Discuss the findings from your research with your clinical group.

FIRST STAGE OF LABOUR

The **first stage of labour** begins with the onset of regular uterine contractions that result in cervical change and ends with complete cervical effacement and dilation. *Effacement* means the shortening and thinning

of the cervix during the first stage of labour, and *dilation* of the cervix is the enlargement or widening of the cervical opening (see Chapter 16: Powers for further discussion). The Society of Obstetricians and Gynaecologists of Canada (SOGC) (2018) divides the first stage of labour into two phases: *latent* (or early) and *active*. For a nulliparous patient, the latent phase of labour is defined by a cervix that is found to be 0 to 3 cm dilated and less than 1 cm long. In a parous patient who has previously laboured, the latent phase of labour is defined by a cervix that is 0 to 4 cm dilated and less than 1 cm long. Active labour is defined as beginning when the cervix is 4 cm dilated in a nulliparous patient, and 4 to 5 cm dilated in a parous patient (SOGC, 2018).

Nursing Care During Prelabour and the First Stage of Labour

Nulliparous patients may seek admission to the hospital in the latent phase of labour because they have not experienced labour before and are unsure of the "right" time to come in. Multiparous patients may not come to the hospital until they are in the active phase.

Even though no two labours are identical, patients who have given birth before may appear less anxious about the process, unless their previous experience was negative. A patient often has lingering impressions of the childbirth experience. Satisfaction with childbirth depends on the labouring patient's ability to maintain a sense of control (World Health Organization [WHO], 2018). The WHO recommendations for providing intrapartum care in order to provide a positive childbirth experience are shown in Figure 17.1. It is important that caregivers actively involve patients in decision making about their care. In particular, caregivers who are respectful, supportive, available, protective, encouraging, kind, patient, professional, calm, and comforting (Registered Nurses Association of Ontario [RNAO], 2015) can positively impact a patient's memory of their childbirth experiences. A positive childbirth experience may contribute to a person's self-esteem and sense of accomplishment; this may in turn enhance the way they see themselves in their role as a parent.

Fig. 17.1 World Health Organization intrapartum care model.

Frustrations that a patient feels about their childbirth experience stem from unmet expectations, loss of control, lack of knowledge, or unsupportive behaviours of some caregivers. A patient who perceives childbirth to be unsatisfactory or traumatic could be at risk for post-traumatic stress disorder (PTSD) or a perinatal mood disorder and may struggle with parent–infant bonding, social and intimate relationships, and future family planning (Public Health Agency of Canada [PHAC], 2018; Simpson et al., 2018). The actions and interactions of the nurse or other care providers during labour can also influence a patient's experience of trauma during birth.

Nurses caring for the labouring patient must use an empathic approach when providing care, which may include the following:

- Establishing rapport with the patient and their support people
- Respecting the patient's individual needs, behaviours, and wishes
- Being kind, caring, and competent when performing necessary procedures
- Explaining procedures, using words the family can understand; repeating as necessary
- Being aware that pain and discomfort are as the patient describes them
- Carrying out appropriate comfort measures such as mouth and back care
- Including support people in the care as desired by the patient and the support people
- Recognizing that a patient's current childbirth experience and the actions of nurses and other health care providers can have a positive or negative impact on future childbirth experiences

Care during labouring should be based on research evidence such as that listed in Box 17.1. Promoting care that is based on these Healthy Birth Practices from Lamaze will help ensure that patients have improved birth outcomes.

BOX 17.1 Lamaze Healthy Birth Practices: Designed to Promote, Protect, and Support Normal Labour and Birth

- Allow labour to begin on its own: Encourage spontaneous labour rather than fostering elective labour inductions.
- Encourage freedom of movement throughout labour to facilitate the progress of labour and enhance patient's comfort and control of the labour process.
- Provide labour support beginning early in labour and continuing throughout the process of childbirth to relieve maternal anxiety and stress and decrease the risk for epidural anaesthesia and Caesarean birth; support should be provided by someone not employed by the hospital (e.g., doula).
- Avoid routine implementation of interventions (e.g., intravenous fluids, oral intake restrictions, continuous electronic fetal monitoring, labour augmentation measures such as amniotomy and oxytocin administration, and epidural anaesthesia).
- Support the practice of spontaneous, nondirected pushing in nonsupine positions (e.g., lateral, squatting, standing, kneeling, and semisitting) to facilitate the progress of fetal descent and shorten the second stage of labour.
- Avoid separation of the parent from the baby after birth by encouraging skin-to-skin contact of parent and baby to keep the newborn warm, prevent newborn infection, enhance the newborn's physiological adjustment to extrauterine life, and foster early breastfeeding.

Assessment. Assessment begins at the first contact with the patient, whether by telephone or in person. Patients may call the hospital or birthing centre first with questions or for validation that it is appropriate to come in for evaluation or admission or that they can remain at home. Nurses are required to collect data with specific questions and complete an assessment with the client, including when to come to hospital (College of Nurses of Ontario [CNO], 2020). Other options may include seeking help emergently or seeing their health care provider in the office. The details of the telephone conversation, including any advice or instructions given, should be documented in the patient's record (Baird et al., 2017; CNO, 2020).

A pregnant patient may come to the hospital while in prelabour or early in the latent phase of the first stage of labour. During the third trimester of pregnancy, patients should be instructed about the stages of labour and the signs indicating its onset. Most primiparous patients are instructed to come to the hospital when the contractions are 4 to 5 minutes apart, lasting 1 minute in length, occurring for approximately 1 hour, or when they are unable to cope at home anymore, no matter how far apart the contractions are. Multiparous patients are instructed to come to the hospital when the contractions are 5 minutes apart, or sooner if they are not able to cope with the contractions. Patients should be informed of the possibility that they may not be admitted if they are in latent labour (see Patient Teaching box: How to Distinguish True Labour From Prelabour).

PATIENT TEACHING

How to Distinguish True Labour From Prelabour

Prelabour

Contractions
- Occur irregularly or become regular only temporarily
- Often stop with walking or position change
- Can be felt in the back or abdomen above the navel
- Often can be stopped through the use of comfort measures

Cervix (by vaginal examination)
- May be soft, but there is no significant change in effacement or dilation, or evidence of bloody show
- Is often in a posterior position

True Labour

Contractions
- Occur regularly, become stronger, last longer, and occur closer together
- Become more intense with walking
- Usually felt in the lower back, radiating to the lower portion of abdomen
- Continue despite use of comfort measures

Cervix (by vaginal examination)
- Shows progressive change (softening, effacement, and dilation, which may be signalled by the appearance of bloody show)
- Moves to an increasingly anterior position

The labouring patient who arrives for assessment in the hospital is usually seen in a triage unit where there may be other patients present with other concerns. Nurses who work in triage need to be able to ask consistent questions of labouring patients to determine which patients are the highest priority in terms of initial medical assessment and nursing care and who will require immediate admission (Box 17.2). In many Canadian obstetrical units a priority scale called the Obstetrical Triage Acuity Scale (OTAS) is also used. The OTAS sets a national standard for determination of obstetrical patient acuity and timeliness of the initial nursing assessment and subsequent assessment by their care provider. It is based on the Canadian Triage and Acuity Scale (CTAS),

BOX 17.2 Questions to Ask All Patients Presenting to the Triage Unit

- When is your expected date of birth (EDB)?
- What is your GTPAL? Describe your obstetrical history. Are there any concerns during this pregnancy?
- Do you have any medical conditions?
- Are you having contractions? When did they start?
- Have your membranes ruptured? What time? What colour was it?
- Have you had any history of bleeding during pregnancy?
- How often is the fetus moving?
- Describe any pain you are having. Where is the pain?

Adapted from Gratton, R. J., Bazaracai, N., Cameron, I., et al. (2016). Acuity assessment in obstetrical triage. *Journal of Obstetrics and Gynaecology Canada, 38*(2), 125–133. https://doi.org/10.1016/j.jogc.2015.12.010.

and there is a version for early pregnancy (<20 weeks), pregnancy >20 weeks, and up to 6 weeks postpartum (Gratton et al., 2016). The obstetrical nurse who works in triage can be challenged by emergency presentations, as well as by caring for the labouring patient still in latent labour who would ideally go home until labour is more advanced.

The labouring patient may be encouraged to stay home or return home to allow labour to progress until the contractions are more frequent and intense. The ideal setting for low-risk persons in early labour is the familiar environment of their home. However, the labouring patient who lives at a considerable distance from the hospital, who lacks adequate support and transportation, or who has a history of rapid labours in the past may be admitted in the latent phase of labour. The same measures used by the labouring patient at home should be offered to the hospitalized patient during this stage of labour.

A warm shower or bath can be relaxing for the person in latent labour. Soothing back, foot, and hand massages or a warm drink of preferred liquids such as tea or milk can help the patient rest and even sleep, especially if prelabour or latent labour is occurring at night. Diversional activities such as walking, reading, watching shows, playing games, or talking with friends can reduce the perception of early discomfort, help the time pass, and reduce anxiety. Eating light meals is also recommended.

Admission to Labour Unit. When the patient arrives at the labour unit, assessment is the top priority (Figure 17.2). The nurse interviews the patient, performs a physical assessment, and reviews the patient records to determine their health status, as well as the status of the fetus

Fig. 17.2 Labouring patient assessment. (iStock.com/sturti)

and the progress of labour. The nurse also needs to notify the primary health care provider and, if the labouring patient is admitted, conduct a detailed systems assessment.

On admission, patients should receive an identification band and may be asked to change into a hospital gown or they may prefer to wear their own clothes. The practice of patients changing into hospital gowns should be abandoned, unless it is requested by the patient (PHAC, 2018). The nurse should orient the labouring person and support people to the layout and operation of the unit and room. This includes use of the call bell and telephone system, the location of personal storage areas, the unit kitchen, and how to adjust lighting in the room and positions of the bed. Any items to be used for comfort in labour should be unpacked and easily accessible, for example, tennis balls or rolling pins for counterpressure, a pillow for comfort and a reminder of home, and music. Anyone coming in the room should be introduced; labouring patients often express concern about the number of people intruding on their labour experience, especially if the role of the person and purpose for their presence is not clearly identified.

The family-centred care approach views labour and birth as a normal, healthy life event with the labouring patient and their support people being active participants (see Box 4.3). The patient is encouraged to have anyone they wish present for support. The nurse needs to develop a supportive, trusting relationship with the labouring patient and their support person or persons so that they feel comfortable to ask questions related to the patient's care and the status of the mother and fetus at any time. The nurse can minimize the labouring patient's anxiety by explaining terms commonly used during labour. The patient's interest, response, and prior experience will guide the depth of these explanations. It is most important that the nurse develop a therapeutic relationship with the labouring patient and their support people, as this will enable the nurse to truly meet the patient's needs.

Admission Data. Hospital admission forms in either paper or electronic format can provide guidelines for the acquisition of important assessment information when a patient in labour is being evaluated or admitted. Additional sources of data include the following: (1) antenatal record, (2) initial interview, (3) physical examination to determine baseline physiological parameters (e.g., vital signs), (4) laboratory and diagnostic test results, (5) expressed psychosocial and cultural factors, (6) clinical evaluation of labour status, and (7) the patient's birth plan (see Chapter 11).

Antenatal data. The nurse reviews the antenatal record to identify the patient's individual needs and risks. Copies of antenatal records are generally filed in the perinatal unit at some time during the pregnancy or accessed by computer so they are readily available on admission. If the labouring person has had no prenatal care or the antenatal record is unavailable, certain baseline information must be obtained. If the patient is having discomfort, the nurse should ask questions between contractions, when the person can concentrate more fully on the responses. At times, the support person or persons may need to be secondary sources of essential information.

Knowing the patient's age is important so that the nurse can individualize care to the needs of the patient's age group. For example, a 14-year-old and a 40-year-old have different but specific needs, and their ages place them at risk for different complications. Accurate height and weight measurements are important to determine because a weight gain greater than that recommended may place the patient at a higher risk for Caesarean birth. This is especially true for women who are petite and have gained 16 kg or more (Davies et al., 2018). A prepregnancy body mass index (BMI) greater than 30 is also a cause for concern. Other factors to consider are the patient's general health status and current medical conditions or allergies. Questioning about intimate partner violence and safety, mental health status, and history of substance use should form an integral part of the initial and ongoing assessment.

The nurse should review the antenatal records carefully, taking note of the obstetrical history, including gravidity; parity; and issues such as history of vaginal bleeding, gestational hypertension, anemia, pregestational or gestational diabetes, infections (e.g., bacterial, viral, sexually transmitted), and immunodeficiency status. Additionally, it is important to take note of any relevant medical, surgical, and anaesthetic history. The current gestational age and estimated date of birth (EDB) should be confirmed. Other important data found in the antenatal record may include patterns of weight gain; physiological measurements such as vital signs (blood pressure, temperature, pulse, respirations); symphysis fundal height (SFH); baseline fetal heart rate (FHR); and laboratory and diagnostic test results. See Table 11.1 for a list of common antenatal laboratory tests. Diagnostic and fetal assessment tests performed prenatally may include ultrasound examination, nonstress test (NST), biophysical profile (BPP), amniocentesis, and Doppler studies. See Chapter 13 for more information.

For patients who have had previous labour and birth experiences, it is important to note the characteristics of these experiences. This information includes the duration of previous labours, the type of anaesthesia used, the kind of birth (e.g., spontaneous vaginal, vacuum- or forceps-assisted, or Caesarean birth), any complicating factors (e.g., postpartum hemorrhage [PPH]), and the condition of the newborn. The patient's perception of previous labour and birth experiences should be explored because it may influence their attitude toward the current experience.

Group B streptococcus (GBS). A patient's group B streptococcus (GBS) status should be determined. GBS may be considered a normal vaginal flora in a patient who is not pregnant. However, GBS infection is associated with poor pregnancy outcomes and is present in 10 to 30% of healthy pregnant patients (Money & Allen, 2018). These infections are an important factor in perinatal and newborn morbidity and mortality, usually resulting from vertical transmission from the birth canal of the infected labouring patient to the newborn during birth. Risk factors for newborn GBS infection include positive culture for GBS in the current pregnancy, preterm birth of less than 37 weeks of gestation, prolonged rupture of membranes (ROM) (>18 hours), intrapartum fever higher than 38°C (100.4°F), and a positive history for early-onset neonatal GBS (Money & Allen, 2018).

To decrease the risk of newborn GBS infection, intravenous antibiotic prophylaxis (IAP) should be offered to all labouring patients who test positive. Also, if a culture is not available at the onset of labour and if risk factors are present, IAP should be offered (Money & Allen, 2018). Since the introduction of universal screening for GBS, which involves a vaginal-rectal swab at 35 to 37 weeks, the rate of GBS infection in newborns has decreased by about 70% (Money & Allen, 2018). IAP is not recommended before a Caesarean birth if labour or ROM has not occurred. The recommended treatment is penicillin G, 5 million units in an intravenous (IV) loading dose, and then 2.5 million units intravenously every 4 hours until birth. There are alternative therapies for use in the event of a penicillin allergy (Money & Allen, 2018). Therefore, the patient who is GBS positive will usually have IV access established shortly after admission to ensure that adequate antibiotics are administered. For a newborn to be considered adequately treated, one dose of antibiotics must be received 4 hours prior to the birth.

Herpes simplex virus (HSV). Neonatal herpes simplex virus (HSV) infection can be a devastating disease, so pregnant patients need to be screened for this during pregnancy and labour. Current recommendations include carefully examining and questioning all patients about symptoms at the onset of labour. If the labouring patient is free from

prodromal symptoms of an outbreak (e.g., itching, tingling, or pain without lesions) and active visible lesions when labour begins, vaginal birth is preferred. Caesarean birth within 4 hours after labour begins or membranes rupture is recommended if the patient is experiencing prodromal symptoms or has visible lesions (Money & Steben, 2017). Newborns who may have been exposed to the virus should be carefully observed and have blood tested for the presence of HSV. Some experts recommend presumptive treatment of newborns who were exposed to HSV during birth. Acyclovir and valacyclovir may be used, starting at 36 weeks of gestation, to decrease the risk of an active HSV outbreak at the time of birth and reduce the need for a Caesarean birth (Money & Steben, 2017) (see Table 7.3).

Interview. The patient's primary reason for coming to the hospital is determined in the interview. The primary reason may be that they are in labour; the bag of waters (i.e., amniotic membranes) have broken, with or without contractions; have concerns about any bleeding; or are unsure whether they are in labour.

Even the experienced person may have difficulty determining the onset of labour. The patient should be asked to describe the following:

- Time of onset of contractions and progress in terms of intensity, frequency, and duration
- Location and character of discomfort from the contractions (e.g., back pain, abdominal or suprapubic discomfort)
- Persistence of contractions despite changes in position and activity (e.g., walking or lying down)
- Presence and character of vaginal discharge or "bloody show"
- Status of amniotic membranes such as gush or leakage of fluid (spontaneous rupture of membranes [SROM]). If there has been a discharge that may be amniotic fluid, the patient should be asked about the **C**olour, **O**dour, **A**mount and the **T**ime (COAT) it was first noted. In many instances, a sterile speculum examination and a **nitrazine** (pH) or **ferning test** can confirm that the membranes are ruptured (Box 17.3).

These descriptions can help the nurse assess the degree of progress in labour. Bloody show is distinguished from vaginal bleeding in that it feels sticky because of its mucoid nature. There is typically very little bloody show in the beginning, but the amount increases with effacement and dilation of the cervix. A patient may report a small amount of brownish-to-bloody discharge that can be attributed to cervical

BOX 17.3 Procedure: Tests for Rupture of Amniotic Membranes

Nitrazine Test for pH*

Explain procedure to the labouring patient.

Procedure

Wash hands.

Use cotton-tipped applicator impregnated with Nitrazine dye or Nitrazine test paper, a dye-impregnated test paper for determining pH. (Nitrazine differentiates amniotic fluid, which is slightly alkaline, from urine and purulent material [pus], which are acidic.)

Wearing gloves, dip cotton-tipped applicator or test paper deep into vagina to pick up fluid. (The procedure may be performed during speculum examination.)

Provide perineal care as needed.

Remove gloves and wash hands.

Read Results

Membranes probably intact—Identifies vaginal and most body fluids that are acidic:

Yellow	pH 5.0
Olive–yellow	pH 5.5
Olive–green	pH 6.0

Membranes probably ruptured—Identifies amniotic fluid that is alkaline:

Blue–green	pH 6.5
Blue–grey	pH 7.0
Deep blue	pH 7.5

Realize that false test results are possible because of presence of bloody show, insufficient amniotic fluid, or semen.

Document Results

Results are positive or negative.

Test for Ferning or Fern Pattern

Explain procedure to the labouring person.

Wash hands, apply sterile gloves, obtain specimen of fluid (usually during sterile speculum examination).

Spread a drop of fluid from vagina on a clean glass slide with a sterile, cotton-tipped applicator.

Provide perineal care as needed.

Remove gloves and wash hands.

Allow fluid to dry.

Read Results

Examine slide under microscope. Observe for appearance of ferning (a frond-like crystalline pattern). (Do not confuse with cervical mucus test, when high levels of estrogen are responsible for causing the ferning.)

Observe for absence of ferning (alerts staff to possibility that amount of specimen was inadequate or that specimen was urine, vaginal discharge, or blood).

Note: the appearance of ferning may not be immediately obvious. The provider must thoroughly examine the microscope slide. Any evidence of ferning, however small, is considered to be a positive result.

Document Results

Results are positive or negative.

*In some settings, the specimen is collected by the nurse or primary health care provider and sent to the laboratory for interpretation of results.

trauma resulting from vaginal examination or intercourse within the previous 48 hours.

Assessing the patient's respiratory status is important in case general **anaesthesia** is needed in an emergency. The nurse should ask the patient if they have a cold or related symptoms (e.g., stuffy nose, sore throat, or cough). The nurse should also check the status of allergies, including allergies to latex and tape. Some allergic responses cause swelling of mucous membranes of the respiratory tract, which could interfere with breathing and the administration of inhalation anaesthetics. The nurse should record the type and time of the patient's last solid food and liquid intake before coming to the hospital, as vomiting and aspiration into the respiratory tract can be a complication during an operative birth.

Other pertinent data include the **birth plan**, the type of pain management preferred, the choice of newborn feeding method, and the name of the newborn's health care provider. The patient profile should indicate the support person or persons desired during childbirth and their availability, as well as cultural expectations and needs.

The nurse should review the birth plan (see Chapter 11: Birth Plans). If no written plan has been prepared, the nurse can help the labouring patient formulate a birth plan by describing options available and finding out the person's wishes and preferences. As caregiver and advocate, the nurse integrates the patient's desires into the nursing care plan as much as possible. The nurse needs to discuss with the patient the possibility that changes may be needed in the plan as labour progresses and assure them that information will be provided so that they can make informed decisions.

The nurse should provide information about the agency's policies regarding photography and recording of the birth and under what circumstances they are allowed. Protection of privacy and safety and infection control are major concerns for the expecting parents and the agency. To avoid future embarrassment and distress, the nurse should clarify with the patient exactly which parts of the childbirth they wish to have photographed as well as the degree of detail. It is important to remind patients and families that pictures should not be posted on social media sites without the knowledge and consent of every person who appears in the picture. The patient's record should reflect that the birth was recorded.

Psychosocial Factors. The patient's general behaviour (and that of the support persons) may provide clues to the type of supportive care needed during labour. However, the nurse should keep in mind that general appearance and behaviour may vary, depending on the stage and phase of labour (Table 17.1 and Box 17.4).

TABLE 17.1 Expected Progress During the First Stage of Labour

	PHASES MARKED BY CERVICAL DILATION*	
Criterion	**0–3 cm (Latent)**	**4–10 cm (Active)†**
Duration‡	About 6–8 hr	About 3–6 hr
Contractions		
Strength	Mild to moderate	Moderate to very strong
Rhythm	Irregular	More regular
Frequency	5–30 min apart	2–5 min apart
Duration	30–45 sec	40–90 sec
Descent		
Station of presenting part	Nulliparous: 0	Varies: +1 to +3 cm
	Parous: –2 cm to 0	Varies: +1 to +3 cm
Show		
Colour	Brownish discharge, mucous plug, or pale pink mucus	Pink-to-bloody mucus
Amount	Scant	Scant to copious
Behaviour and appearance§	Excited; thoughts centre on self, labour, and baby; may be talkative or silent, calm or tense; some apprehension; alert, follows directions readily; open to instructions	Becomes more serious, doubtful of pain control, more apprehensive; desires companionship and encouragement; attention more inner directed; fatigue evidenced; malar (cheeks) flush; has some difficulty following directions Later in active phase: Pain described as moderate to severe; backache common; frustration, fear of loss of control, and irritability may be voiced; expresses doubt about ability to continue; vague in communications; amnesia between contractions; writhing with contractions; nausea and vomiting, especially if hyperventilating; hyperesthesia; perspiration of forehead and upper lips; shaking tremor of thighs; feeling of need to defecate, pressure on rectum

*In the nullipara, effacement is often complete before dilation begins; in the multipara it occurs simultaneously with dilation.
†In the multipara, active labour is defined as starting at 4–5 cm.
‡Duration of each phase is influenced by such factors as parity, patient emotions, position, level of activity, fetal size, presentation, and position. For example, the labour of a nullipara tends to last longer, on average, than the labour of a multipara. Patients who ambulate and assume upright positions or change positions frequently during labour tend to experience a shorter first stage. Descent is often prolonged in breech presentations and occiput-posterior positions.
§Patients who have epidural analgesia for pain relief may not demonstrate some of these behaviours.

BOX 17.4 Psychosocial Assessment of the Labouring Patient

Verbal Interactions
- Does the patient ask questions?
- Can they ask for what they need?
- Do they talk to their support person or persons?
- Do they talk freely with the nurse, or respond only to questions?

Body Language
- Do they change positions, or lie rigidly still?
- Are they relaxed or tense?
- What is their anxiety level?
- How do they react to being touched by the nurse or support person?
- Do they avoid eye contact?
- Do they look tired? If they appear tired, ask them how much rest they have had in the past 24 hours.

Perceptual Ability
- Do they understand what the nurse says?
- Is there a language barrier?
- Are repeated explanations necessary because their anxiety level interferes with their ability to comprehend?
- Can they repeat what has been told or otherwise demonstrate their understanding?

Discomfort Level
- To what degree does the patient describe what they are experiencing, including their pain experience?
- How do they react to a contraction?
- How do they react to assessment and care measures?
- Are any nonverbal pain messages noted?
- Can they ask for comfort measures?

History of sexual abuse. Labour can trigger memories of sexual abuse, especially during intrusive procedures such as vaginal examinations. Monitors, IV lines, and epidurals can make the patient feel a loss of control or as if they were being confined to bed and "restrained." Being observed by students and having intense sensations in the uterus and genital area, especially during the second stage, can also trigger memories of abuse. Patients who are survivors of abuse may fight the labour process by reacting in panic or anger toward care providers, take control of everyone and everything related to their childbirth, surrender by being submissive and dependent, or retreat by mentally dissociating themselves from the sensations of labour and birth.

Patients with a history of abuse require supportive and nonjudgemental trauma-informed care. Trauma-informed care principles such as safety, trust, choice and control, compassion, and collaboration are key to a positive experience (PHAC, 2018) (see Box 1.2). It is also important that the childbearing experience does not retraumatize the person who has been exposed to violence in their life. It is imperative to wait for the patient to give permission before touching them and to accept their often extreme reactions to labour (Simpson & O'Brien-Abel, 2014).

The nurse can help the abuse survivor associate the sensations being experienced with the process of childbirth and not with the past abuse. The nurse can also help maintain the patient's sense of control by explaining all procedures and why they are needed, validating any needs, and paying close attention to requests. The nurse should avoid words and phrases that can cause the patient to recall the words of the abuser (e.g., "open your legs," "relax and it won't hurt so much"). The number of procedures that invade the body (e.g., vaginal examinations, urinary catheter, internal monitor, forceps or vacuum extractor) should be limited as much as possible. The patient should be encouraged to choose a person (e.g., doula, friend, family member) to be with them during labour to provide continuous support and comfort and act as an advocate. Nurses are advised to care for all labouring persons in this manner as it is not unusual for a patient to choose not to reveal a history of sexual abuse. These care measures can help the person perceive the childbirth experience in positive terms.

Stress in labour. The way in which labouring patients and their support person or family members approach labour may be related to the manner in which they have been socialized to the childbearing process. Their reactions reflect their life experiences regarding childbirth—physical, social, cultural, and religious. Likewise, society communicates its expectations of acceptable and unacceptable behaviours that occur during labour and birth. There are thus different cultural and societal perceptions of pain in labour; these may include the following:

- Pain in childbirth is inevitable and something to be endured.
- Pain in childbirth can be avoided completely.
- Pain in childbirth is punishment for sin.
- Pain in childbirth can be managed by the labouring person.

It is important for the nurse to determine what beliefs the labouring patient holds, as these expectations may be used by some patients as the basis for evaluating their own actions during childbirth. An idealized perception of labour and birth may be a source of guilt and a sense of failure if the patient finds the process less than joyous, especially when the pregnancy is unplanned or is the product of a dysfunctional or terminated relationship. Often patients have heard horror stories or seen friends or relatives go through labours that appeared anything but easy. **Multiparous** patients often base their expectations of the present labour on their previous childbirth experiences.

The nurse needs to encourage the patient to express their feelings about the pregnancy and any concerns and fears related to childbirth. This discussion is especially important if the patient is a primigravida who has not attended childbirth classes or a multiparous patient who had a previous negative childbirth experience. The ideal time to have this discussion is before labour begins, but if this has not occurred before labour starts then patients should be asked about their concerns, as they may not volunteer this on their own. Major fears and concerns relate to the process and effects of childbirth, patient and fetal well-being, and the attitude and actions of the health care staff. Unresolved fears can increase a patient's stress and can slow the process of labour as a result of the inhibiting effects of catecholamines associated with the stress response on uterine contractions.

The nurse's responsibilities to the patient in labour with regard to these concerns are to answer any questions, provide support to the patient and support persons and family, take care of the patient in partnership with the support team, and serve as the patient's advocate. One of the most important aspects of nursing care for the labouring patient is to develop a trusting relationship with the patient and support people, as this will help them feel more comfortable expressing their feelings and concerns. Patients can equate information giving with emotional support. Nurses are perceived as supportive when they explain things in detail by using positive terms and provide accurate information and specific directions. Patients will feel empowered when they are given information they can understand and that reflects support of their efforts. This feeling of empowerment contributes to a positive perception of the birth experience. In contrast, a patient's level of

anxiety and fear may increase when they do not understand what is being said or are not given adequate information.

The nurse needs to communicate to the labouring person that they are not expected to act in any particular way. Also, the patient's views and expectations regarding the nurse's role as caregiver should be determined. As labour progresses, the nurse–patient relationship will become increasingly important. Labouring persons need to trust in their own innate ability to give birth, and nurses need to support and protect each patient's efforts to achieve this outcome.

The support persons may also experience stress during labour. The nurse can assist and support these individuals by identifying their needs and expectations and helping to make sure these are met. The nurse can ascertain what role the support persons intend to fulfill and whether they are prepared for that role by making observations, such as the following: Are they nervous, anxious, aggressive, or hostile? Do they look hungry, tired, worried, or confused? Do they watch television, sleep, or stay out of the room instead of paying attention to the patient? Do they touch the labouring person and, if so, what is the character of the touch? The nurse can also ask the support person questions regarding attendance of childbirth classes and the role they expect to play during labour. The nurse should be sensitive to the needs of the support person and provide teaching and support, as appropriate. Often the support that this person is able to give to the labouring patient is in direct proportion to the support they receive from nurses and other health care providers.

Caring for Trans and Gender-Nonconforming Persons. Among the childbearing population, perinatal nurses may provide care for *trans men* (men who were assigned female at birth) or gender nonconforming people (people who do not subscribe to being either male or female (Wolfe-Roubatis & Spatz, 2015). If reproductive organs are still present, the person may be able to get pregnant, perhaps with the assistance of hormone treatment or assistive human reproduction. It is important that the nurse develop a relationship with the patient that is based on trust and respect. Health history forms and questions that nurses ask are often gender biased. Most importantly, the nurse needs to ask all patients open-ended questions, such as "How do you describe your gender identity?" (Wolfe-Roubatis & Spatz, 2015). The patient's preferred pronoun and gender identity must be documented (Duckett & Ruud, 2019). For example, the patient may prefer "they/them" pronouns or wish to be referred to as "dad" instead of "mom."

It is ideal if these patients can meet with a nurse prior to the birth in order to develop an individualized and comprehensive birth plan. The plan should include all aspects of care, from admission, to security, to intrapartum and postpartum care, and should include discussions of all ancillary departments that will contribute to the health care of the patient (Adams, 2010). Privacy must be respected, and it is imperative that staff working in the hospital are aware of the issues with accessing records of a patient for whom they are not providing care. Most importantly, the nurse should always ask for permission prior to touching or assessing the patient and be aware that the patient may have significant concerns about being seen during labour, since the person may be conflicted about gender identity in relation to what is actually happening to their body.

Cultural Factors. Nurses need to be committed to providing culturally safe care and developing an appreciation of and respect for cultural diversity (Callister, 2014; Canadian Nurses Association [CNA], 2018) (see Chapter 2). For the perinatal nurse, it is important to recognize a pregnant patient's cultural and religious values, beliefs, and practices in order to be able to anticipate nursing interventions that should be included in a mutually acceptable plan of care that fosters a sense of safety and control. The patient should be encouraged to request caregiving behaviours and practices that are important to them. Special requests should be accommodated, if possible. For example, in many cultures it is unacceptable to have a male caregiver examine a pregnant patient. Most health care providers will try to accommodate this request, if possible. In some cultures it is traditional to take the placenta home; in others, the labouring patient has only certain nourishments during labour and after birth. Some patients believe that cutting their body, as with an episiotomy, allows their spirit to leave the body and that rupturing the membranes prolongs, not shortens, labour. It is important that the rationale for recommended and required care measures be carefully explained, particularly if they conflict with the patient's beliefs.

Cultural beliefs and values can influence a patient's desire to participate in making decisions about the care they receive. For example, Indigenous patients believe childbirth is a community event, one that places a high value on relationships, respect, and the collective perspective. With limited access to birthing centres, Indigenous Canadians are often moved off reserve and away from their families in late pregnancy to await labour, causing a disruption of the balance and harmony that are critical for a positive birth experience. The National Council of Aboriginal Midwives is working to increase the number of Indigenous midwives to provide appropriate care to childbearing families in their own communities. Indigenous midwives can respond to the needs that are unique to Indigenous people and provide care in a culturally safe manner (see Chapter 4, Indigenous Women).

Immigrants who have personally experienced or been told stories about birthing practices in other countries may be anxious about unfamiliar practices they encounter in a Canadian centre. Health care providers should assess each patient's preferences for support and collaborate with them to meet these needs.

Within cultures, patients may learn the "right" way to behave in labour and thus react to the pain experienced in that way. These behaviours can range from total silence to moaning or screaming, but they do not necessarily indicate the degree of pain the person is experiencing. A patient who moans with contractions may not be in as much physical pain as a patient who is silent but winces during contractions. Women may be silent during labour for several reasons. They may be retreating from all that is going around them and "going inside" to get the resources to cope with labour, or they may also feel that the level of energy that is required to yell or call out may just be too great. Some patients believe that screaming or crying out in pain is shameful if a man is present. If the patient's support person is their mother, they may perceive the need to "behave" more strongly than if their support person is the father of the baby. They may perceive themselves as failing or succeeding, based on their ability to follow these "standards" of behaviour. Conversely, a patient's behaviour in response to pain may influence the support received from their support people. In some cultures, patients who lose control or cry out in pain may be scolded, whereas in other cultures, support people will be more helpful. It is important to reassure the patient that there is no "right" way to behave in labour; it is whatever is right for the woman.

Some patients may believe in the balance of yin and yang and view childbirth as a source of heat loss from the body. Thus, providing hot fluids and a warm shower to these patients during labour could be acceptable measures of restoring the heat that is being lost.

When assessing a patient's cultural and religious preferences, the nurse can ask questions regarding the following:

- The value and meaning placed on the childbirth experience
- The view of childbirth as a wellness or illness experience and as a private or social event

- Practices regarding diet, medications, activity, and emotional and physical support
- Appropriate parental behaviours
- Birth companions—who they should be and what they should do
- Views regarding newborn care immediately after birth

Culture and the partner's participation. A companion is an important source of support, encouragement, and comfort to a person during labour. The patient's cultural and religious background influences the choice of a birth companion, as do trends in the society in which one lives. For example, in Western societies, the partner is viewed as the ideal birth companion. For European–North American couples, attending childbirth classes together has become a traditional, expected activity. In some other cultures, a father may be involved, but their presence in the labour and birth room with the mother may not be considered appropriate, or they may be present but resist active involvement in the care of the labouring person. Such behaviour could be perceived by the nursing staff as a lack of concern, caring, or interest. Patients from many cultures prefer female caregivers and want to have at least one female companion present during labour and birth. They may also be very concerned about modesty. Islamic patients may be very modest (i.e., need to keep hair and body covered) and may not accept the presence of a man during childbirth, not even the father. In India, women are attended by other women and in rural areas by a local untrained midwife. For couples from these cultures who immigrate to Canada their roles may change. The nurse needs to discuss any concerns with the patient and their support people to determine the roles they will assume.

The non–English-speaking patient in labour. A patient's level of anxiety in labour increases when they do not understand what is happening to them or what is being said. Non–English-speaking patients are at risk of feeling a complete loss of control over their situation if there is no health care provider present who speaks their language. They can panic and withdraw or become physically abusive when someone tries to do something that they perceive might harm them or their baby. A support person is sometimes able to serve as an interpreter. However, caution is warranted in this situation because the interpreter may not be able to convey exactly what the nurse or others are saying or what the labouring person is saying, and this may increase the patient's stress level even more.

Ideally, a bilingual nurse would care for the patient. Alternatively, an interpreter may be contacted for assistance. Preferably, the interpreter is from the same culture as the patient. For some patients, a female interpreter may be more acceptable. If no one appropriate in the hospital is able to interpret, a translation service can be called so that an interpretation can take place over the telephone. See Chapter 2, Use of Interpreters on how to work with an interpreter. It is important to identify the need for an interpreter early during antenatal care in order to ensure adequate time to coordinate the availability of this service when the patient arrives for labour assessment. Even when the nurse has limited ability to communicate verbally with the patient, in most instances the patient appreciates the nurse's efforts to do so. Often the patient may understand English but may not be able to speak it. Speaking slowly and avoiding complex words and medical terms can help a patient and partner to better understand what is happening during labour and birth.

Physical Examination. The initial physical examination includes a general systems assessment and an assessment of fetal status. During the examination, uterine contractions are assessed and a vaginal examination is performed. The findings of the admission physical examination serve as a baseline for assessing the patient's progress from that point on and help determine whether the patient should be admitted and their ongoing plan of care. Expected progress of the labouring patient and minimal assessment guidelines during the first stage of labour are presented in Table 17.1 and Box 17.5. Throughout labour, accurate documentation following agency policy should be done as soon as possible after a procedure has been performed (Figure 17.3).

Birth is a time when nurses and other health care providers are exposed to a great deal of blood and body fluids. Therefore, routine precautions should guide all assessment and care measures (Box 17.6). Hand hygiene (e.g., washing hands with soap and water or applying an alcohol-based antibacterial solution) before and after assessing the patient and after providing care is a critical step in the prevention of infection transmission. The nurse should explain assessment findings to the patient and their partner.

General systems assessment. On admission the nurse should perform a brief systems assessment. This includes an assessment of the heart, lungs, and skin and an examination to determine the presence and extent of edema of the legs, face, and hands. It also includes testing of deep tendon reflexes and for clonus, if indicated. The patient's weight is also noted, as obesity can add complexity to nursing care during labour and birth and places the patient at risk for complications such as operative birth, infection, and blood clots (Davies et al., 2018). See Chapter 20: Obesity for further information.

Vital signs. Vital signs (temperature, pulse, respirations, blood pressure, and pulse oximetry) are assessed on admission, and initial values are used for comparison with subsequent values. If blood pressure is elevated, it should be reassessed at least 15 minutes later, between contractions, after the patient has relaxed (Magee et al., 2014). How a patient is coping with the pain of labour should also be assessed (see Chapter 18: Assessing Coping During Labour for further discussion).

If the patient is in bed, they should be encouraged to lie on their side to prevent supine hypotension and the resulting fetal hypoxemia (Figure 17.4). The nurse needs to monitor the patient's temperature

BOX 17.5 Nursing Assessments in First-Stage Labour

Latent Phase (if admitted to hospital)

- Assess blood pressure, pulse, respirations every 30 to 60 minutes, depending on risk status.
- Assess level of coping.
- Assess fetal heart rate (FHR) and pattern, uterine activity, vaginal fluids (show, amniotic fluid) every 30 to 60 minutes, depending on risk status.
- Assess temperature every 4 hours until membranes rupture and then every 2 hours.
- Perform vaginal examination as needed to identify progress.
- Observe every 30 minutes: changes in patient's appearance, mood, affect, and energy level and condition of support person.

Active Phase

- Assess blood pressure, pulse, and respirations every 30 to 60 minutes, depending on risk status.
- Assess level of coping and pain.
- Assess FHR and pattern, uterine activity, and vaginal show every 15 to 30 minutes, depending on risk status.
- Assess temperature every 4 hours until membranes rupture and then every 1 to 2 hours.
- Perform vaginal examination as needed to identify progress.
- Observe every 5 to 15 minutes: changes in patient's appearance, mood, affect, and energy level and condition of partner.

BOX 17.6 Routine Precautions During Childbirth

Routine precautions applicable to childbirth include the following:

- The 4 Moments of Hand Hygiene are implemented: (1) before initial patient/patient environment contact, (2) before aseptic procedure, (3) after body–fluid exposure risk, (4) after patient/patient environment contact. Wash hands with cleansing alcohol rub, unless visibly soiled, when soap and water are required.
- Wear gloves (clean or sterile, as appropriate) when performing procedures that require contact with the patient's genitalia and body fluids, including bloody show (e.g., during vaginal examination, amniotomy, hygienic care of the perineum, insertion of an internal scalp electrode and intrauterine pressure monitor, and urinary catheterization).
- Wear protective eyewear and cover gown when assisting with the birth. Masks, cap, and shoe covers are worn for Caesarean birth. Gowns worn by the primary health care provider who is attending the birth should have a waterproof front. A mask should be worn during spinal puncture or insertion of an epidural catheter.
- Wear gloves when handling the newborn immediately after birth until the first bath is completed.

to identify signs of infection or a fluid deficit (e.g., dehydration associated with inadequate intake of fluids).

! NURSING ALERT

During labour, blood pressure should be assessed with an appropriate-sized sphygmomanometer and stethoscope or a calibrated aneroid device to obtain the most accurate results. Automatic devices that measure blood pressure have been found to overestimate the systolic pressure and underestimate the diastolic pressure. Automated blood pressure machines need to be validated for use in pregnant patients and especially for use in patients with hypertensive disorders. These devices further restrict freedom of movement and can also increase the discomfort of the patient as the cuff inflates and deflates on a regular basis. The heart rate of the patient should be assessed by auscultation (i.e., apical rate) or palpation (i.e., radial pulse rate) rather than with a pulse oximeter.

Assessment of uterine activity (UA). A general characteristic of effective labour is regular uterine activity (UA) (i.e., contractions becoming more frequent and of increased duration); however, UA is not directly related to labour progress. Uterine contractions are the primary powers that act involuntarily to dilate the cervix and expel the fetus and placenta from the uterus. Several methods are used to evaluate the strength of uterine contractions: the labouring patient's subjective description, palpation and timing of the contraction by a health care provider, and internal electronic monitoring, when indicated.

Each contraction exhibits a wavelike pattern. It begins with a slow increment (the "building up" of a contraction from its onset) that gradually reaches an acme (peak) and then diminishes rapidly (decrement, the "letting down" of the contraction). An interval of rest ends when the next contraction begins. The outward appearance of the patient's abdomen during and between contractions and the pattern of a typical uterine contraction are shown in Figure 17.5.

Uterine contractions are described in terms of the following characteristics:

Frequency—Frequency is measured by determining the number of contractions in a 10-minute period averaged out over a 30-minute window (Dore & Ehman, 2020).

Intensity—The palpable strength of a contraction at its peak

Duration—The time that elapses between the onset and the end of a contraction (in seconds)

Resting tone—The tension in the uterine muscle between contractions; relaxation of the uterus

Uterine contractions are assessed by palpation or by using an external or internal electronic monitor (see Chapter 19 for further discussion). Frequency and duration can be measured by all three methods of UA monitoring. Intensity can only be assessed using palpation or internal electronic monitoring (see Table 19.1). Palpation is subjective but, along with the patient's report of the pain, is the best way to determine the intensity of uterine contractions.

Patients in labour tend to describe the pain of contractions in terms of their sensations in the lower abdomen or the back, which are sometimes unrelated to the firmness of the uterine fundus. The amount of discomfort reported is a valid assessment of the pain the patient is experiencing.

On admission, a 20-minute baseline monitoring of uterine contractions and of the FHR pattern via external fetal monitoring (EFM) is only recommended for patients with risk factors for adverse perinatal outcomes (see Table 19.3) and is not supported by evidence for healthy, term patients in labour (Dore & Ehman, 2020). Intermittent auscultation (IA) is the preferred method for healthy patients between 36 to 41 +3 weeks' gestation in spontaneous labour, in the absence of risk factors (Dore & Ehman, 2020; see Chapter 19 for more in-depth discussion).

The nurse's responsibility in monitoring uterine contractions is to ascertain whether they are powerful and frequent enough to accomplish the work of effacing and dilating the cervix and expelling the fetus and the placenta. The effect on the fetus must also be considered. Progress of labour can be verified effectively through the use of graphic charts (also called *partograms* or *labour graphs*) on which cervical dilation is plotted as labour progresses. This type of graphic charting helps in early identification of deviations from expected labour patterns. Figure 17.6 provides examples of a modern labour graph and partogram that incorporate new knowledge regarding the labour process in contemporary labouring patients. Birthing units may develop their

Fig. 17.4 Supine hypotension. Fig. 17.6 **A:** Modern labour graph. Characteristics of the average cervical dilation curve for nulliparous labour. **B:** Zhang labour partogram. The ninety-fifth percentiles of cumulative duration of labour from admission among singleton term nulliparous patients with spontaneous onset of labour. (From Gabbe, S. G., Niebyl, J. R., Simpson, J. L., et al. [Eds.]. [2017]. *Obstetrics: Normal and problem pregnancies* [7th ed.]. Elsevier.)

own assessment graphs that may include data not only on cervical dilation but also on vital signs of the labouring patient, FHR, and UA.

The findings that are expected as first-stage labour progresses are summarized in Table 17.1.

! NURSING ALERT

If the characteristics of uterine activity (UA) are found to be abnormal, either exceeding or falling below what is considered acceptable in terms of the standard characteristics, the nurse should document the finding and report this finding to the primary health care provider.

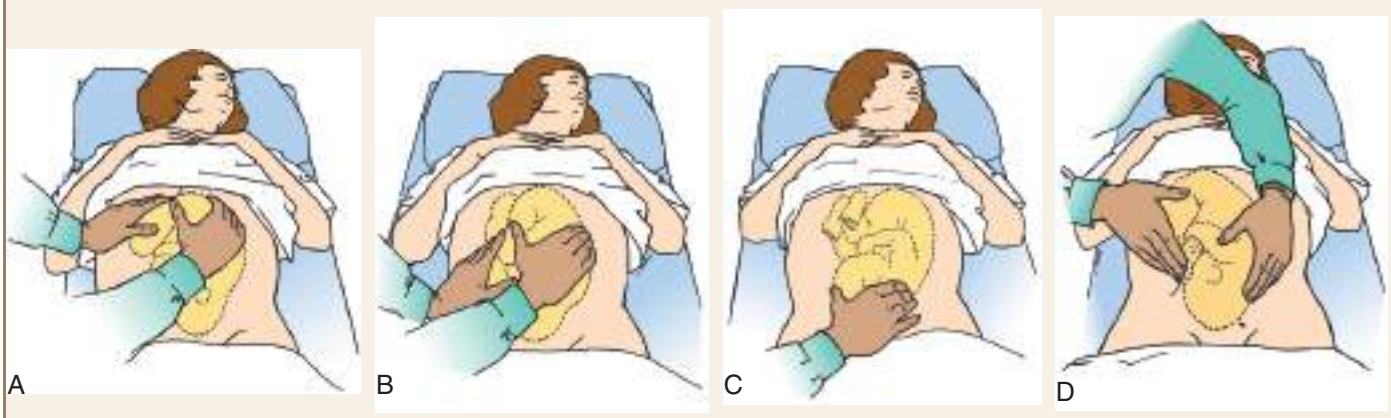
Leopold manoeuvres (abdominal palpation). Leopold manoeuvres are performed with the patient briefly lying on their back (Box 17.7). These manoeuvres help to identify the (1) number of fetuses; (2) presenting part, fetal lie, and fetal attitude; (3) degree of descent of the presenting part into the pelvis; and (4) expected location of the point of maximal intensity (PMI) of the FHR on the patient's abdomen.

Assessment of fetal heart rate and pattern. The PMI of the FHR is the location on the labouring patient's abdomen where the FHR is heard loudest and clearest. It is usually directly over the fetal back. In a vertex presentation, FHR is usually heard below the patient's umbilicus in either the right or left lower quadrant of the abdomen. In a breech presentation, the FHR is heard above the umbilicus (Figure 17.7, *A, C*). As the fetus descends and rotates internally, the FHR is heard lower and closer to the midline of the labouring patient's abdomen (see Figure 17.7, *B*).

The FHR and pattern must be assessed (1) immediately after ROM, due to an increased risk for the umbilical cord to prolapse, (2) after any change in the contraction pattern or patient status, and (3) before and after administering medication or performing a procedure. For a complete discussion of fetal health surveillance in labour see Chapter 19.

! NURSING ALERT

It is important for the nurse to recognize that active labour can last longer than the expected labour patterns. This finding should not be a cause for concern unless the fetus exhibits atypical or abnormal fetal heart rate (FHR) patterns or the labouring patient has a fever.



Vaginal examination. The vaginal examination reveals whether the patient is in true labour and enables the examiner to determine whether the membranes have ruptured (Figure 17.8). Vaginal examinations can be done by nurses who are given special training to do these, depending on an institution's policies. Because this examination is invasive and often uncomfortable for the patient, it should be performed only when indicated by the status of the patient or fetus. For example, a vaginal examination should be performed on admission, when significant change has occurred in UA, on patient perception of perineal pressure or the urge to bear down, when the labouring patient requests pain medication, or when abnormal FHR characteristics are noted. A full explanation of the examination and support of the patient are important factors in reducing the stress and discomfort associated with the examination. Vaginal examinations can reveal the amount of dilatation and effacement as well as the station and presentation of the presenting part (Box 17.8).

Laboratory and diagnostic tests

Analysis of urine specimen. A clean-catch urine specimen may be obtained to gather more data about the pregnant patient's health. Analysis of the specimen is a convenient and simple procedure that can provide information about hydration status (e.g., by specific gravity, colour, and amount), nutritional status (e.g., ketones), infection (e.g., leukocytes), or the status of possible complications such as pre-eclampsia, shown by finding protein in the urine. The results can be obtained quickly and help the nurse to determine appropriate interventions to implement.

BOX 17.7 Procedure: Leopold Manoeuvres

- Wash hands.
- Ask patient to empty bladder.
- Position patient supine with one pillow under the head and the knees slightly flexed.
- Place small rolled towel under patient's right hip to displace uterus off major blood vessels (prevents supine hypotension; see Figure 17.4, *D*).
- If right-handed, stand on patient's right, facing patient (if left-handed, stand on patient's left):
  1. Identify fetal part that occupies the fundus. The head feels round, firm, freely movable, and palpable by ballottement; the breech feels less regular and softer. This manoeuvre is used to identify fetal lie (longitudinal or transverse) and presentation (cephalic or breech) (Fig. A).
  2. Using palmar surface of one hand, locate and palpate the smooth convex contour of the fetal back and the irregularities that identify the small parts (feet, hands, elbows). This manoeuvre helps identify fetal presentation (Fig. B).
  3. With right hand, determine which fetal part is presenting over the inlet to the true pelvis. Gently grasp the lower pole of the uterus between the thumb and fingers, pressing in slightly (Fig. C). If the head is presenting and not engaged, determine the attitude of the head (flexed or extended).
  4. Turn to face the patient's feet. Using both hands, outline the fetal head (Fig. D) with the palmar surface of the fingertips. When the presenting part has descended deeply, only a small portion of it may be outlined. Palpation of the cephalic prominence helps identify the attitude of the head. If the cephalic prominence is bound on the same side as the small parts, this means that the head must be flexed and the vertex is presenting (Fig. D). If the cephalic prominence is on the same side as the back, this indicates that the presenting head is extended and the face is presenting.
  5. Document fetal presentation, position, and lie and whether presenting part is flexed or extended, engaged, or free floating. Use agency protocol for documentation (e.g., "Vtx, LOA, floating").

Blood tests. The blood tests performed vary with hospital protocol and according to the patient's health status. Blood can be obtained by a finger stick, venipuncture, or from the hub of a catheter used to start an IV line. A complete blood count (CBC) may be ordered for patients with a history of variances in pregnancy like infection, anemia, or gestational hypertension. Comprehensive assessments such as white blood cell count, red blood cell count, hemoglobin level, hematocrit, and platelet values are included in the CBC. Any patient whose human immunodeficiency virus (HIV) status is undocumented at the time of labour should be screened with a rapid HIV test unless the testing is declined by the patient.

Most hospitals require that a "type and screen" be performed on admission in order to determine the patient's blood type, Rh status, and the presence of any antibodies. Even if these tests have already been performed during pregnancy, the hospital laboratory or blood bank must verify the results in their own facility. If the patient had no prenatal care or if the prenatal records are not available, a prenatal screen is likely drawn on admission. The prenatal screen includes laboratory tests that would normally have been drawn at the initial prenatal visit (see Table 11.1).

Other tests. If the patient's GBS status is not known, a rapid test may be done on admission if this testing is available at the facility. The rapid test results are usually available within an hour and determine if the patient should be given prophylactic antibiotics during labour, although this test does not determine antibiotic susceptibility.

Assessment of amniotic membranes and fluid. Labour is initiated at term by SROM in approximately 8% of pregnant patients. Almost 90% of patients at term will go into spontaneous labour within 24 hours of spontaneous membrane rupture (Middleton et al., 2017). Membranes (the bag of waters [BOW]) can also rupture spontaneously at any time during labour, but do so most commonly later in the active phase of the first stage of labour. Box 17.3 explains how to determine if membranes are ruptured. If the membranes do not rupture spontaneously, the BOW may be ruptured artificially at some time during labour. Artificial rupture of membranes (AROM), called an **amniotomy**, is performed by the obstetrical health care provider using a plastic AmniHook (Figure 17.9) or a surgical clamp.

Regardless of whether the membranes rupture spontaneously or artificially, the time of rupture should be recorded. Other necessary documentation includes information regarding the colour (clear,

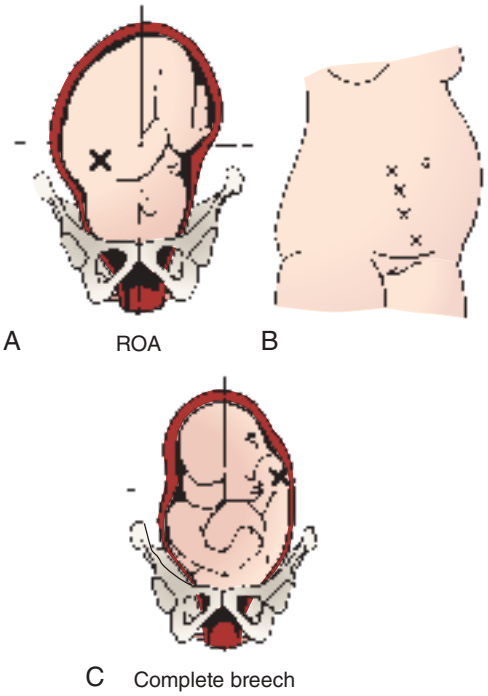


Fig. 17.7 Location of the fetal heart rate. **A:** With fetus in right occipito–anterior (ROA) position. **B:** Changes in location of point of maximal intensity of fetal heart tones as fetus undergoes internal rotation from ROA to OA position for birth. **C:** With fetus in left sacrum posterior position. (*A* and *C,* Courtesy Ross Laboratories.)

meconium-stained, or blood-tinged), estimated amount, and odour of the fluid (Table 17.2).

! NURSING ALERT

The umbilical cord may prolapse when the membranes rupture. The fetal heart rate (FHR) pattern should be monitored closely for several minutes immediately after rupture of membranes (ROM) to ascertain fetal well-being and the findings should be documented.

Infection. After membranes rupture, microorganisms from the vagina can ascend into the uterus and may cause **chorioamnionitis**. The rate of infection is low, at 2.3% after 24 hours of ruptured membranes (Pintucci et al., 2014), although maternal temperature and vaginal discharge should be assessed frequently (every 1 to 2 hours) to identify a developing infection. However, microorganisms may ascend despite intact membranes and cause premature ROM. Careful assessment is critical; if an infection is suspected, appropriate antibiotics should be administered.

Assessment findings serve as a baseline for evaluating the patient's progress during labour. Although some challenges of labour are anticipated, others may appear unexpectedly during the clinical course of labour (Box 17.9).

BOX 17.8 Procedure: Vaginal Examination of the Labouring Patient

- Encourage patient to empty bladder.
- Position patient to prevent supine hypotension. Drape to ensure privacy.
- Cleanse perineum and vulva if needed.
- Use sterile glove and antiseptic solution or soluble gel for lubrication.
- After obtaining the patient's permission to touch them, gently insert index and middle fingers into vagina.
- Determine:
  - Cervical dilation, effacement, and position (e.g., posterior or anterior)
  - Presenting part, position, and station; moulding of head with development of caput succedaneum (may affect accuracy of determination of station)
  - Status of membranes (intact, bulging, or ruptured)
  - Characteristics of amniotic fluid (e.g., colour, clarity, and odour) if membranes are ruptured
- Explain findings of examination to patient.
- Document findings and report to primary health care provider.

Physical Care. The physical nursing care given to a patient in labour is also an essential component of care. Evidence-informed practice is used to enhance the safety, effectiveness, and acceptability of the physical care measures chosen to support the patient during labour and birth (see Nursing Care Plan: Care of Patient in Labour, available on Evolve).

Hydrotherapy and hygiene. Nurses can offer labouring patients the use of showers or warm-water baths, if they are available, to enhance the feeling of well-being and minimize the discomfort of contractions. Water immersion during active labour may reduce the use of regional analgesia (Cluett et al., 2018) (see Chapter 18, Hydrotherapy for further information). Other hygiene measures can enhance comfort and improve morale and may include offering a toothbrush or mouthwash to maintain oral hygiene; offering washcloths; regularly cleansing the

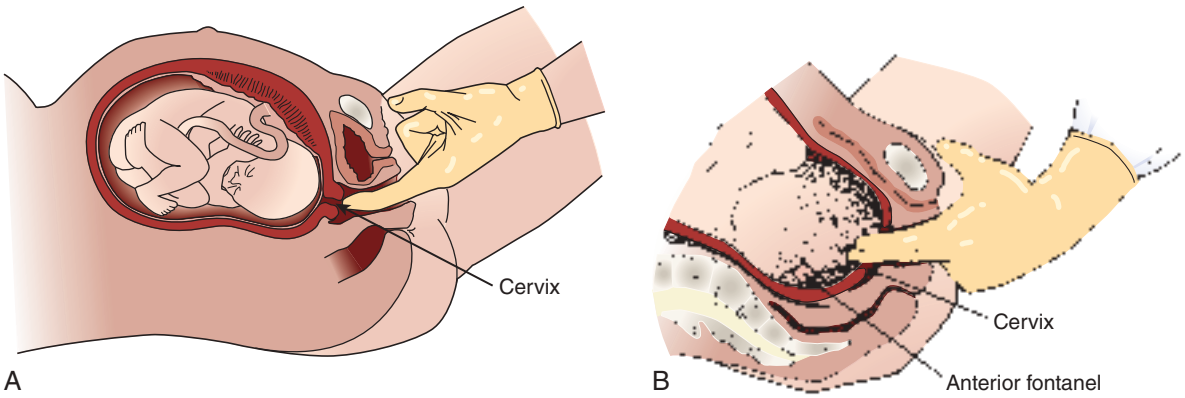

Fig. 17.8 Vaginal examination. **A:** Undilated, uneffaced cervix; membranes intact. **B:** Palpation of sagittal suture line. Cervix effaced and partially dilated.

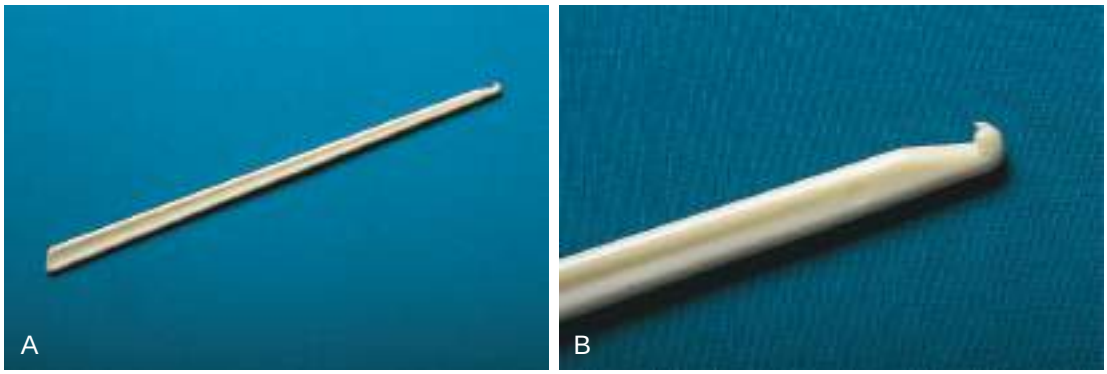

Fig. 17.9 **A:** Disposable plastic membrane perforator (Amnihook). **B:** Hook end of plastic membrane perforator.

TABLE 17.2 Assessment of Amniotic Fluid

Characteristic of Fluid	Normal Finding	Deviation From Normal Finding	Cause of Deviation From Normal
Colour	Pale, straw-coloured; may contain white flecks of vernix caseosa, lanugo, scalp hair	Greenish-brown colour	Meconium in fluid from hypoxic episode in fetus or post-term gestational age May be normal finding in breech presentation as pressure is exerted on fetal abdominal wall during descent
		Yellow-stained fluid	Fetal hypoxia ≥36 hr before ROM; fetal hemolytic disease; intrauterine infection
		Port wine–coloured	Bleeding associated with placental abruption
Viscosity and odour	Watery; no strong odour	Thick, cloudy, foul-smelling	Intrauterine infection Large amount of meconium can make fluid thick
Amount (normally varies with gestational age)	400 mL (20 wk of gestation) 1 000 mL (36–38 wk of gestation)	≥2 000 mL (32–36 wk of gestation)	Polyhydramnios; associated with congenital anomalies of the fetus when fetus cannot drink or fluid is trapped in the body (e.g., fetal gastrointestinal obstruction or atresias); increased risk with maternal pregestational or gestational diabetes mellitus
		≤500 mL (32–36 wk of gestation)	Oligohydramnios; associated with incomplete or absent kidney; obstruction of urethra; infant cannot secrete or excrete urine

ROM, Rupture of membranes.

BOX 17.9 Signs of Potential Labour Complications

- Contractions consistently lasting ≥90 seconds
- More than five contractions in a 10-minute period (occur more frequently than every 2 minutes)
- Relaxation between contractions lasting <30 seconds
- Intrauterine pressure of ≥80 mm Hg (determined by intrauterine pressure catheter monitoring) or resting tone of ≥20 mm Hg
- Fetal bradycardia or tachycardia; absent or minimal variability not associated with fetal sleep cycle or temporary effects of central nervous system depressant medications given to the patient; late, variable, or prolonged fetal heart rate decelerations (see Chapter 19)
- Irregular fetal heart rate; suspected fetal dysrhythmias
- Presence of atypical or abnormal fetal heart rate pattern (see Chapter 19)
- Appearance of meconium-stained or bloody fluid from the vagina
- Arrest in progress of cervical dilation or effacement, descent of the fetus, or both
- Temperature of 38°C or more in labouring patient
- Foul-smelling vaginal discharge
- Persistent bright-red or dark-red vaginal bleeding

perineum, especially once the membranes are ruptured and when show increases; and changing the gown and linens as needed.

Nutrient and fluid intake

Oral intake. Traditionally, the labouring patient was offered only clear liquids or ice chips or given nothing by mouth during the active phase of labour. This was to minimize the risk of anaesthesia complications and their sequelae should general anaesthesia be required in an emergency. These sequelae could include aspiration of gastric contents and resultant compromise in oxygen perfusion, which may endanger the lives of the labouring person and fetus. This practice is being challenged today because regional anaesthesia is used more often than general anaesthesia, even for emergency Caesarean births.

Patients are awake during regional anaesthesia and are able to participate in their own care and protect their airway.

A Cochrane database review of this topic concluded that there is no justification for restricting food or fluid intake during labour in patients at low risk for complications (Singata et al., 2013). Nurses should follow the orders of the primary health care provider and the desires of the labouring patient when offering the patient food or fluids during labour. However, as advocates, nurses can facilitate change by informing others of the current research findings that support the safety and effectiveness of the oral intake of food and fluid during labour and by initiating such research themselves.

Although gastric emptying is slowed as a result of labour, stress, and the use of opioids or sedatives, fasting does not cause gastric contents to be eliminated and may even cause them to be more acidic. In addition, fasting is identified by many labouring patients as a stressor with which they must cope and a source of frustration during labour, related to a loss of control in meeting their own nourishment needs.

An adequate intake of fluids and calories is required to meet the energy demands and fluid losses associated with childbirth. The progress of labour slows, and ketosis develops if these demands are not met and fat is metabolized for energy. Reduced energy for bearing-down efforts (pushing) increases the risk for a vacuum- or forceps-assisted birth. This is most likely to occur in patients who begin to labour early in the morning after a night without caloric intake. When labouring patients are permitted to consume fluids and food freely, they typically regulate their own oral intake, eating light foods (e.g., eggs, yogurt, ice cream, dry toast and jam, fruit) and drinking fluids during latent labour and then tapering off to an intake of clear fluid and sips of water or ice chips as labour intensifies and the second stage approaches. Patients who are allowed to eat may have an enhanced sense of control and level of comfort (Lee et al., 2016). Another benefit to drinking and eating during labour is that the person is provided with some nutrition and energy, which is important especially with long labours.

Herbal teas can provide not only hydration but also other beneficial effects. Chamomile tea can enhance relaxation, lemon balm or peppermint tea can reduce nausea, and teas of ginger or ginseng root may be energizing. A patient's culture may influence what they will eat and drink during labour. In addition, patients who use nonpharmacological pain-relief measures and labour at home or in birthing centres are more likely to eat and drink during labour.

Intravenous intake. Routine IV fluid therapy is a common practice in labour, although it decreases the patient's ability to stay mobile and increases the risk of fluid overload and is therefore not recommended as a routine practice. In addition, it does not meet the need for nutrition in labour, regardless of the type of solution used. It may also affect breastfeeding due to edema in the breasts postpartum (Kujawa-Myles et al., 2015; PHAC, 2018). Only certain medically indicated situations require IV fluid therapy, such as when the patient is unable to ingest a sufficient amount of fluid orally or if the patient is receiving epidural or intrathecal analgesia. Labouring patients may require IV access for medication administration, and the nurse may consider using a saline lock in these situations to allow for mobility.

In most cases, an electrolyte solution without glucose is adequate and does not introduce excess glucose into the bloodstream, which results in fetal **hyperglycemia** and fetal hyperinsulinism. After birth, the newborn's high level of insulin will then deplete their glucose stores and **hypoglycemia** will result. Infusions containing glucose can also reduce sodium levels in the labouring person and fetus, leading to transient newborn tachypnea. If ketosis occurs, the primary health care provider may order an IV solution containing a small amount of dextrose to provide the glucose needed to assist in fatty acid metabolism.

! NURSING ALERT

Nurses should carefully monitor the intake and output of IV fluids that labouring patients receive, because there is an increased danger of hypervolemia as a result of the fluid retention that occurs during pregnancy.

Elimination

Voiding. A person in labour should be encouraged to void a minimum of every 2 hours. A distended bladder may impede descent of the presenting part, slow or stop uterine contractions, and lead to decreased bladder tone or atony after birth. If epidural anaesthesia is administered there is an increased risk for retention of urine; therefore, the need to void should be assessed more frequently.

The labouring patient should be assisted to the bathroom to void unless the primary health care provider has ordered bed rest. In certain situations, the patient may be unable to get up to use the bathroom —for example, if experiencing a motor block while receiving epidural anaesthesia—or it may be the nurse's judgement that ambulation would compromise the status of the labouring patient or fetus. External monitoring can be interrupted for the patient to go to the bathroom for periods of up to 30 minutes if maternal–fetal condition is stable (Dore & Ehman, 2020). Nurses should offer the use of a bedpan if a patient is unable to weight-bear or ambulate to the bathroom, prior to urinary catheterization. When using a bedpan, the patient's safety needs to be ensured by putting up the side rails on the bed and placing the call bell within reach. To encourage voiding, the patient is provided privacy and tap water may be run or warm water poured over the vulva. The nurse can promote general hygiene following urination by offering a washcloth for the patient's hands and washing the vulvar area.

Catheterization. If the labouring patient is unable to void and the bladder is distended, there may be a need for catheterization. Many hospitals have protocols that rely on the nurse's judgement concerning the need for catheterization, but nurses must ensure that practice aligns with the health care provider's orders and hospital protocol. Before performing the catheterization, the vulva and perineum need to be cleaned because vaginal show and amniotic fluid may be present. The nurse inserts the catheter between contractions and needs to avoid force if resistance is noted on insertion. An obstacle preventing advancement of the catheter is most likely the fetal presenting part. If the nurse cannot advance the catheter, the procedure should be stopped and the primary health care provider notified of the difficulty. Based on research, intermittent catheterization is the preferred method of catheterization, when catheterization is necessary (DeSevo & Semeraro, 2010; Wilson et al., 2015)

Bowel elimination. Given an increase in prostaglandins associated with the beginning of labour, a labouring person may experience loose stools in early labour. Most patients do not have bowel movements during labour because of decreased intestinal motility. Stool that has formed in the large intestine often is moved downward toward the anorectal area by the pressure exerted by the fetal presenting part as it descends. This stool may be expelled during second-stage pushing and birth. However, the passage of stool with bearing-down efforts may embarrass the labouring person, thereby reducing the effectiveness of these efforts. To prevent these issues, the nurse should immediately cleanse the perineal area to remove any stool, while at the same time reassuring the patient that the passage of stool at this time is a normal and expected event because the same muscles used to expel the baby also expel stool. The routine use of an enema to empty the rectum is not recommended and should only be used if medically indicated or the labouring person requests an enema (PHAC, 2018).

When the presenting part is deep in the pelvis, even in the absence of stool in the anorectal area, the patient may feel rectal pressure and think they need to defecate. If the patient expresses the need to defecate, the nurse should perform a vaginal examination to assess cervical dilation and station. When a multiparous patient experiences the urge to defecate, this often means that birth will follow quickly. Following careful assessment, the nurse should assist the labouring person to the bathroom or offer them a bedpan if appropriate and safe to do so.

Ambulation and Positioning. Freedom of movement and choice of position should be encouraged throughout labour. Upright positions and mobility during labour have been associated with improved uterine contraction intensity and shorter labours, less need for pain medications, reduced rate of operative birth (e.g., Caesarean birth, vacuum- and forceps-assisted birth), increased autonomy and control in the patient, distraction from the discomforts of labour, and an opportunity for close interaction with the patient's partner and care provider as they help them assume upright positions and remain mobile (Kilpatrick & Garrison, 2017; PHAC, 2018).

Walking, sitting, or standing during early labour is more comfortable than lying down and facilitates the progress of labour. Encouraging the childbearing patient to select positions for labour and birth and encouraging them to try different positions involves few risks and has potential benefits (PHAC, 2018). The patient may find it comfortable to stand and lean forward on their partner, doula, or nurse for support at times during labour (Figure 17.10, *A*). At times, although rarely, ambulation is contraindicated because of the status of the labouring patient or fetus.

The increased use of epidurals during childbirth accompanied by multiple medical interventions (e.g., monitors, IV infusions) and reduced motor control interferes with a patient's freedom of movement and tends to confine the labouring person to bed. If EFM is required, many birthing areas now use wireless fetal monitors (known as **telemetry**) to allow the patient to remain mobile while continuous monitoring of the fetus takes place. Nurses can advocate for changes in this practice in their labour and birth units.

When the labouring patient lies in bed, they generally will change their position spontaneously as labour progresses. If they do not change their position every 30 to 60 minutes, the nurse can encourage them to try different positions. A variety of positions recommended for the labouring person are described in Box 17.10 and shown in Figure 17.11. The side-lying (lateral) position promotes optimal uteroplacental and renal blood flow and increases oxygen saturation (see Figure 17.10, *B*). If the labouring patient wants to lie supine, the nurse may place a pillow under one hip as a wedge to prevent the uterus from compressing the aorta and vena cava. Sitting is not contraindicated unless it adversely affects fetal status, which can be determined by checking the FHR and its pattern. As with patients without an epidural, patients with low-dose epidurals should be educated about the benefits and risks of different positions in labour and encouraged to try different positions depending on their clinical situation (PHAC, 2018).

A birth ball can be used to support a labouring patient's body as they assume a variety of labour and birth positions (Figure 17.12). The patient can sit on the ball while leaning over the bed, or can lean over the ball to support the upper body and reduce stress on the arms and hands when assuming a hands-and-knees position. Use of the birth ball can encourage pelvic mobility and pelvic and perineal relaxation when the labouring person rocks on the ball in rhythmic movements. Warm compresses applied to the perineum and back can maximize this relaxation effect. The birth ball should be large enough so that, when the patient sits, their knees are bent at a 90-degree angle and their feet are flat on the floor and approximately shoulder-distance apart.

Back labour. Back labour is often felt when the fetus is in the occiput-posterior position. The use of squatting during contractions may help encourage a fetus that is in the occiput-posterior position to rotate to a more anterior position because squatting increases the pelvic diameter (Figure 17.13, *A*). A hands-and-knees position during contractions is also recommended to facilitate the rotation of the fetal occiput from a posterior to an anterior position as gravity pulls the fetal back forward (see Figure 17.13, *B*). If epidural anaesthesia is being used, the patient may not be able to squat or assume a hands-and-knees position, depending on the degree of motor block resulting from the epidural.

A squatting or hands-and-knees position also provides access to the back for application of counterpressure. A support person may be taught to exert counterpressure against the sacrum. The back pain is caused by the occiput pressing on spinal nerves, and counterpressure lifts the occiput off these nerves, thereby providing some relief from pain. Once counterpressure is initiated, the labouring patient will usually ask the support person to continue doing this for each following contraction. However, the support person may need to be relieved after a while because exerting counterpressure is hard work. Application of

Fig. 17.10 **A:** Labouring patient standing and leaning forward. (iStock.com/chameleonseye) **B:** Lateral position. (iStock.com/Yuri_Arcurs)

BOX 17.10 Common Positions* During Labour and Birth

Semirecumbent Position (see Figure 17.11)

With the patient sitting with the upper body elevated to at least a 30-degree angle, place a wedge or small pillow under the hip to prevent compression of the vena cava and reduce the likelihood of supine hypotension (see Figure 17.4, *D*).

- The greater the angle of elevation, the more gravity or pressure is exerted, which promotes fetal descent, the progress of contractions, and the widening of pelvic dimensions.
- This position is sometimes more convenient for providing care measures and for external fetal monitoring.

Lateral Position (see Figure 17.10, *B*)

Have the patient alternate between left and right side-lying position and provide abdominal and back support as needed for comfort.

- Removes pressure from the vena cava and back; enhances uteroplacental perfusion and relieves backache
- Facilitates internal rotation of fetus in a posterior position to an anterior position (patient should lie on same side as fetal spine)
- Makes it easier to perform back massage or counterpressure
- Associated with less frequent but more intense contractions
- May be used as a birthing position
- Takes pressure off perineum, allowing it to stretch gradually
- Reduces risk for perineal trauma

Upright Position

The gravity effect enhances the contraction cycle and fetal descent. The weight of the fetus places increasing pressure on the cervix; the cervix is pulled upward, facilitating effacement and dilation; impulses from the cervix to the pituitary gland increase, causing more oxytocin to be secreted; and contractions are intensified, thereby applying more forceful downward pressure on the fetus, but they are less painful.

- The fetus is aligned with the pelvis, and pelvic diameters are widened slightly.
- Effective upright positions include the following:
  - Ambulation (see Figure 17.11)
  - Standing and leaning forward with support provided by a couch, end of bed, back of chair, or birth ball; relieves backache and facilitates application of counterpressure or back massage (see Figure 17.10, *A*)
  - Sitting up in bed, chair, or birthing chair, on toilet or bedside commode
  - Squatting (see Figure 17.13, *A*)

Hands-and-Knees Position

This position is ideal for occiput-posterior position of the presenting part (see Figure 17.13, *B*; Box 17.11). The patient assumes an "all-fours" position or leans over an object (e.g., birth ball) while on their knees in bed or on a covered floor; they can also place their knees on the seat section of the bed while leaning over the back of the raised head of the bed; this allows for pelvic rocking.

- Relieves backache characteristic of back labour
- Facilitates internal rotation of the fetus by increasing mobility of the coccyx, increasing the pelvic diameters, and using gravity to turn the fetal back and rotate the head

*Assess the effect of each position on the labouring patient's comfort and anxiety level, progress of labour, and fetal heart rate and pattern. Alternate positions every 30 minutes.

ice packs and heat also help relieve back labour. The nurse should always ask the patient if the massages are helpful. See Box 17.11 for other measures that assist when a fetus is in the occiput-posterior position. Sterile water injections may also be helpful if a patient is experiencing back labour. The presence of small blebs of sterile water in the intradermal space of the lower back activates the gate-control theory by interfering with the transmission of pain along the affected nerves (see Chapter 18 for further discussion).

Supportive Care During Labour and Birth

Support during labour and birth involves emotional support, comfort measures, and provision of information, along with physical care.

The value of the continuous presence of a support person (e.g., partner, doula, family member, friend, or nurse) during labour has long been known. Patients who have continuous support beginning in early labour are less likely to use pain medication or epidurals, more likely to have a spontaneous vaginal birth, and less likely to report dissatisfaction with their birth experience. There is also good evidence that labour support improves important health outcomes (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 2018; Bohren et al., 2017).

The labouring person should feel safe in the birthing environment and feel free to be themselves and use their preferred comfort and relaxation measures. To enhance relaxation, the lighting in the room should be kept low, if possible, and noise and intrusions kept to a minimum. The temperature should be controlled to ensure the labouring patient's comfort. The room should be large enough to accommodate ambulation and position changes in the labouring patient, a comfortable chair for the support persons, the monitoring equipment, and hospital personnel. Patients should be encouraged to bring their own pillows to make the hospital surroundings more homelike and to facilitate position changes. This type of an environment can help patients view their childbirth experience as normal and not related to illness. Environmental modifications should reflect the preferences of the labouring patient, including the number of visitors and availability of a telephone and music. Table 17.3 lists support person actions during the first stage of labour.

Labour Support by the Nurse. The nurse can alleviate a labouring patient's anxiety by communicating clearly, explaining unfamiliar terms, providing information and explanations without the patient having to ask and at a level that is understandable, and preparing the patient for sensations that will be experienced and procedures that will follow. By encouraging the labouring patient and the support persons to ask questions and by providing honest, understandable answers, the nurse can play a significant role in helping the patient achieve a satisfying birth experience.

Care that is not supportive can be traumatic for labouring patients. In research by Reed et al. (2017), labouring patients described how care providers prioritized their own agendas, disregarded embodied knowledge, used lies and threats related to the well-being of the baby to gain compliance, and sometimes felt violated them. These patients often experienced psychological trauma during birth that could also trigger memories of sexual assault. Nurses must provide care that prioritizes both the physical and emotional needs of labouring patients (Reed et al., 2017) (see Figure 17.1).

Supportive, empathic nursing care for a labouring patient includes the following:

- Helping the patient maintain control and participate to the extent they wish in the birth of their baby
- Providing continuity of care by the same nurse throughout the shift, if possible
- Providing care that is nonjudgemental and respectful of the cultural and religious values and beliefs of the patient
- Helping the patient meet their expected outcomes for labour
- Listening to concerns and encouragement to express their feelings
- Acting as an advocate, supportive of decisions and respecting choices as appropriate and relating the wishes of the patient as needed to other health care providers
- Helping conserve the patient's energy and cope effectively with pain and discomfort by using a variety of comfort measures that are acceptable to the patient
- Acknowledging the efforts during the patient's labour, including strength and courage, and those of the partner, and providing positive reinforcement
- Protecting the patient's privacy, modesty, and dignity

BOX 17.11 Back Labour—Occiput-Posterior Position

Measures to Reduce Back Pain During a Contraction

Counterpressure—Apply fist or heel of hand to sacral area

Heat or cold applications—Apply to sacral area

Double hip squeeze:

- Patient assumes a position with hip joints flexed, such as knee–chest position
- Support person or nurse places hands over gluteal muscles and presses with palms of hands up and inward toward centre of pelvis

Knee press:

- Patient assumes a sitting position with knees a few inches apart and feet flat on the floor or on a stool
- Support person or nurse cups a knee in each hand with heels of hands on top of the tibia and then presses the knees straight back toward the patient's hips while leaning forward toward the patient

Measures to Facilitate Rotation of Fetal Head (May Also Relieve Back Pain)

Lateral abdominal stroking—Stroke abdomen in direction that fetal head should rotate

Hands-and-knees position (all-fours)—Can also be accomplished by kneeling while leaning forward over a birth ball, padded chair seat, bed, or over-the-bed table

Squatting

Pelvic rocking

Stair climbing

Lateral position—Lie on side toward which the fetus should turn

Lunges—Widen pelvis on side toward which patient lunges

- Patient stands, facing forward, next to or alongside a chair so that they can lunge toward the side the fetal back is on or in the direction of the fetal occiput
- Patient places foot on seat of chair with toes pointed toward the back of the chair and then lunges
- Alternative position for lunge is kneeling

TABLE 17.3 Labouring Patient's Responses and Support Person's Actions During First Stage of Labour

Labouring Person's Responses	Nurse/Support Person's Actions*
Dilation of Cervix 0–3 cm (Latent) (Contractions: 30–45 sec Long, 5–30 min Apart, Mild to Moderate Intensity)	
Mood: alert, happy, excited, mild anxiety	Provides encouragement, feedback for relaxation, companionship
Labouring at home or settles into labour room if required; selects focal point	Helps to cope with contractions
Rests or sleeps if possible	Provides distractions
Uses breathing techniques if required	Encourages use of focusing techniques
Uses effleurage, focusing, and relaxation techniques	Helps to concentrate on breathing techniques if required
	Uses comfort measures
	Assists patient into comfortable position
	Informs patient of progress; explains procedures and routines
	Gives praise
	Offers fluids, ice chips as ordered
Dilation of Cervix 4–10 cm (Active)† (Contractions: 40–90 sec Long, 2–5 Minutes Apart, Moderate to Strong in Intensity)	
Admitted to hospital when required by patient	Stays with patient; limits assessment techniques to between contractions
Mood: seriously labour oriented, concentration and energy needed for contractions, alert, more demanding, becomes more irritable in later stages often with intense concentration required to relax	Provides constant support
	Assists with contractions
	Encourages patient as needed to help maintain breathing techniques
Nausea and vomiting common	• Reminds, reassures, and encourages patient to re-establish breathing pattern and concentration as needed
Continues relaxation, focusing techniques	• Alerts patient to begin breathing pattern before contraction becomes too intense
Uses breathing techniques when required and continues to use breathing techniques that are working	Uses comfort measures
Uses panting to overcome urge to push	Assists with frequent position changes (every 30 min), emphasizing side-lying and upright positions
	Encourages voluntary relaxation of muscles of back, buttocks, thighs, and perineum; effleurage
	Applies counterpressure to sacrococcygeal area; accepts irritable response to helping such as counterpressure
	Encourages and praises
	Keeps patient aware of progress
	Accepts patient's inability to follow instructions
	Assists with administration of analgesics if requested by patient (nurse only)
	Checks bladder; encourages patient to void
	Gives oral care; offers fluids, ice chips as ordered
	Supports patient who has nausea and vomiting; gives oral care as needed
	Gives reassurance regarding signs of end of first stage
	Prompts panting respirations if patient begins to push prematurely

*Provided by nurses and support people.
†Active labour is identified as 4–5 cm in a multiparous patient.

Labouring patients and their support people who have prepared for birth through reading or childbirth education programs will know something about the labour process, supportive techniques, and comfort measures. In this context the nurse should play a supportive role and keep the patient informed of their progress.

Even when expectant parents have not attended childbirth education classes, the nurse can teach them simple breathing and relaxation techniques during the early phase of labour. In this case, the nurse may provide more of the coaching and supportive care, as some support persons may not feel able to fulfill this role.

Comfort measures vary with the situation. The nurse can draw on the couple's repertoire of comfort measures and relaxation techniques learned during the pregnancy and through life experiences. Such measures include maintaining a comfortable, calm, supportive atmosphere in the labour and birth area; using touch therapeutically (e.g., massage, heat or cold applied to the lower back in the event of back labour, a cool cloth applied to the forehead); foot or hand massage; providing nonpharmacological measures to relieve discomfort (e.g., hydrotherapy); administering analgesics when necessary; and, most importantly, being continuously present (see Table 17.1). See Chapter 18 for a full discussion of both pharmacological and nonpharmacological comfort measures.

While most people in labour respond positively to touch, permission should be obtained before using any measure involving touch.

The patient's perception of the soothing qualities of touch may change as labour progresses. Some patients may become more sensitive to touch (*hyperesthesia*) as labour progresses; this is a typical response during the active phase (see Table 17.1). They may tell their support person to leave them alone or to not touch them. The partner who is unprepared for this normal response may feel rejected and react by withdrawing active support. The nurse can reassure them that this response is a positive indication that the first stage is ending and the second stage is approaching. The labouring patient may have a positive response when touched on surfaces of the body where hair does not grow, such as the forehead, palms of the hands, and soles of the feet. Touch is often more therapeutic and comforting when it is firm or confident and not light and repetitive.

Labour Support by the Partner. The partner is often able to provide the comfort measures and touch that the labouring patient needs. When the labouring person becomes focused on the pain, sometimes the partner can encourage them with nonpharmacological variations of comfort measures. In addition, the partner may be able to interpret the labouring patient's needs and desires to staff members.

The feelings of a first-time parent change as labour progresses. Although the partner may be calm at the onset of labour, feelings of fear and helplessness can begin to take over as labour becomes more active and the partner may feel unable to help their labouring partner without support from the nurse. In one study, first-time fathers who were interviewed described childbirth as truly life-changing for them, in part because it was a new experience in an unfamiliar environment. Four factors were identified that affected their childbirth experience: preparing for childbirth, feeling vulnerable in a new situation, feeling recognized as a contributing part of a unit with the person giving birth, and meeting their child for the first time. The study found that first-time fathers need information and support in order to participate more fully in the process and experience a positive childbirth experience (Ledenfors & Bertero, 2016).

Nurses should assure the partner that their presence is helpful and encourage them to be involved in the care to the extent to which they and the labouring person are comfortable (Figure 17.14). The partner should be reassured that they are not assuming the responsibility for observation and management of their partner's labour but that their role is to provide support as the labour progresses. The nurse can suggest alternative comfort measures when those being used are no longer helpful or are rejected by the labouring patient. The nurse may need to show the partner what provides comfort to the labouring patient so that they feel more confident in providing this care.

Fig. 17.14 Partner providing comfort measures. (Courtesy Loma Linda University Medical Center.)

The first-time partner may feel excluded as birth preparations begin later during the active phase. Once the second stage begins and birth nears, the partner's focus will change from being on the labouring person to being on the baby who is about to be born. The partner will be exposed to many sights and smells that they may never have experienced before. Therefore, the nurse needs to explain to the partner what to expect and make them comfortable about leaving the room to regain composure should something occur that is unexpected, but make sure that someone else is available to support the labouring patient during the partner's absence.

Nursing actions that support the partner convey several important concepts: first, that they are a person of value; second, that they are a partner in the patient's care; and third, that childbearing is a team effort. Box 17.12 details ways in which the nurse can support the partner and any support person. A well-informed partner can make an important contribution to the health and well-being of the childbearing person and child, their family interrelationship, and their self-esteem.

Labour Support by Doulas. Continuity of care has been cited by patients as a critical component of a satisfying childbirth experience. This need can be met by a specially trained, experienced labour attendant called a *doula*. The doula provides a continuous, one-on-one caring presence throughout the labour and birth process of the patient they are attending. Some hospitals employ doulas to work in the labour and birth unit, others have volunteer doula programs, although the majority of labouring persons who use a doula pay for the service privately. The primary role of the doula is to focus on the labouring patient and their partner and provide physical and emotional support by using soft, reassuring words and physical touch. The doula also administers comfort measures to reduce pain and enhance relaxation, walks with the patient, helps with position changes, and provides encouragement during bearing-down efforts. Doulas provide information and explain procedures and events. They advocate for the patient's right to participate actively in the management of their labour. These forms of caring help to reduce a person's level of anxiety and fear, make the labouring patient more confident and calm, and reduce the stress response that could inhibit the progress of labour.

The doula also supports the partner, who may feel unqualified to be the sole labour support and may find it difficult to watch someone they care about experience pain. The doula can encourage and praise the partner's efforts, create a partnership as caregivers, and provide respite care. The doula in no way takes away from the role of the partner, but rather enables them to be involved at their own comfort level. The doula recognizes that birth is a shared experience with long-term implications for families (PHAC, 2018). Doulas also facilitate communication between the labouring patient and their partner and between the couple and the health care team (Simkin, 2012).

Doula support during labour is associated with decreased use of analgesia, decreased incidence of operative birth, increased incidence of spontaneous vaginal birth, and increased satisfaction with the childbirth experience (Bohren et al., 2017; PHAC, 2018). Long-term benefits of doula care are reflected in greater success with breastfeeding, more positive feelings about parenting ability, and lower rates of perinatal mood disorders.

The roles of the nurse and the doula are complementary. They should work together as a team, recognizing and respecting the role each plays in supporting and caring for the labouring patient and

BOX 17.12 Guidelines for Supporting the Support Person

- Orient them to the labour room and the unit; explain locations of the cafeteria, washroom, and waiting room, visiting hours, and names and functions of personnel present.
- Inform them of sights and smells they can expect to encounter; encourage them to sit down or leave the room, if necessary.
- Respect the labouring person and support person's decision about the degree of their involvement. Offer them freedom to make decisions.
- Tell them when their presence has been helpful and continue to reinforce this throughout labour.
- Offer to teach them comfort measures; demonstrate or role model performance of these measures.
- Inform them frequently of the progress of the labour and the patient's needs. Keep them informed about procedures to be performed.
- Prepare them for changes in the labouring person's behaviour and physical appearance.
- Remind them to eat; offer snacks and fluids if possible.
- Relieve them of the job of support person as necessary. Offer blankets if they are to sleep by the bedside.
- Acknowledge the stress experienced by each support person during labour and birth and identify normal responses.
- Attempt to modify or eliminate unsettling stimuli such as extra noise and extra light; create a relaxing and calm environment.

the family during the childbirth process. The doula provides supportive nonmedical care measures, whereas the nurse provides this care and also focuses on monitoring the status of the labouring patient and fetus and implementing clinical care protocols, including pharmacological interventions, and documenting assessment findings, actions, and responses (Simkin, 2012). In an ideal world all labouring persons would be offered a doula, but unfortunately this is not possible because of financial constraints or geographic locations.

Siblings During Labour and Birth. The preparation of siblings for acceptance of the new child helps promote the attachment process and may help the older children accept this change. The older child or children who know that they are important to the family become active participants. Rehearsal for the event before labour is essential.

The age and developmental level of children influence their responses to the addition of a new family member; therefore, preparation for the children to be present during labour is adjusted to meet each child's needs. The child younger than 2 years shows little interest in pregnancy and labour. However, for the older child such preparation may reduce fears and misconceptions. Parents need to be prepared for labour and birth themselves and feel comfortable about the process and the presence of their children. Most parents have a "feel" for their children's level of maturity and their physical and emotional ability to observe and cope with the events of the labour and birth process.

Preparation can include a description of the anticipated sights, events (e.g., ROM, monitors, IV infusions), smells, and sounds; a labour and birth demonstration; a tour of the birthing unit; and an opportunity to be around a real newborn. Storybooks about the birth process can be read to or by children to prepare them for the event. Films are available for preparing preschool and school-age children to participate in the labour and birth experience. Children must learn that their parent will be working hard during labour and birth and may not be able to talk to them during contractions. The labouring parent may groan, scream, grunt, and pant at times and say things that would not otherwise be said (e.g., "I can't take this anymore"; "Take this baby out of me"). They can be told that labour is uncomfortable but that their parent's body is made for birth.

Most agencies require that a specific person be designated to watch over the children who are participating in the childbirth experience, to provide them with support, explanations, diversions, and comfort as needed. Health care providers involved in attending patients during birth must be comfortable with the presence of children and the unpredictability of their questions, comments, and behaviours.

Emergency Interventions

Emergency conditions that require immediate nursing intervention can arise with startling speed. See Chapter 19 for information on the management of atypical or abnormal FHR. Management of other emergency situations, including meconium-stained amniotic fluid, shoulder dystocia, prolapsed umbilical cord, ruptured uterus, and amniotic fluid embolus, are discussed in Chapter 20.

SECOND STAGE OF LABOUR

The **second stage of labour** is the stage in which the infant is born. This stage begins with full cervical dilation (10 cm) and complete effacement (100%) and ends with the baby's birth. The force exerted by uterine contractions, gravity, and bearing-down efforts facilitates achievement of the expected outcome of a spontaneous, uncomplicated vaginal birth.

Researchers have discovered that second-stage labour lasts longer than had been believed in the past (Kopas, 2014). The mean duration of second-stage labour is 60 to 70 minutes in nulliparous patients and 20 to 30 minutes in multiparous patients (SOGC, 2018). The use of epidural anaesthesia during labour often increases the length of the second stage of labour because the epidural blocks or reduces the patient's urge to bear down and limits their ability to attain an upright position to push. Other factors that influence the length of second-stage labour include the patient's age, BMI, emotional state and adequacy of support, and level of fatigue, along with fetal size, position, and sometimes presentation (Kelly et al., 2017; Kilpatrick & Garrison, 2017).

It has been determined that there is no association between the duration of the second stage of labour and perinatal outcomes, such as low Apgar scores at 5 minutes, newborn seizures, or admission to neonatal intensive care units. Therefore, it is difficult to set a time limit for the length of the second stage (Lee et al., 2016).

The following guideline lists time frames for both nulliparous and multiparous patients that suggest second-stage labour may be either progressing too slowly or not at all (Lee et al., 2016).

Nulliparous patients

- 3 or more hours with no regional anaesthesia
- 4 or more hours with regional anaesthesia

Multiparous patients

- 2 hours with no regional anaesthesia
- 3 hours with regional anaesthesia

It is reasonable to consider intervention when there is no further descent of the fetus despite optimum uterine contractions and maternal expulsive efforts (Lee et al., 2016). It is important to understand that as

long as some progress is being made and the patient and fetal status is reassuring, there is no need for rigid time limits or arbitrary rules related to the duration of second stage (Kelly et al., 2017).

The second stage comprises two phases: the passive phase and the active pushing (descent) phase (Lee et al., 2016; SOGC, 2018). The *passive phase*, sometimes referred to as *delayed pushing, labouring down,* or *passive descent,* is the time from complete cervical dilation until the patient begins actively pushing. During this early phase, the fetus continues to descend passively through the birth canal and rotate to an anterior position as a result of ongoing uterine contractions. The patient is quiet and often relaxes with their eyes closed between contractions. The urge to bear down is not strong, and some patients do not experience it at all or only during the acme (peak) of a contraction. Delayed pushing has been shown to result in significant decreases in pushing time and a reduction in the number of operative vaginal births (Lee et al., 2016).

Careful monitoring with assurance of normal fetal status should be used during delayed pushing. If descent is slow and the labouring patient becomes anxious, they should be encouraged to change positions frequently and use gravity and movement to facilitate descent and progress to the active pushing phase, signalled by a perception of the need to bear down.

During the phase of *active pushing phase*, the labouring patient has strong urges to bear down, as the Ferguson reflex is activated when the presenting part presses on the stretch receptors of the pelvic floor. This stimulation causes the release of oxytocin from the posterior pituitary gland, which stimulates stronger, expulsive uterine contractions. Physiological management of this phase involves spontaneous, rather than directed, pushing. Instead of giving instructions, caregivers encourage the patient to push when they feel the urge to do so and should also encourage shorter bearing-down efforts using open-glottis pushes (Lee et al., 2016). Table 17.4 lists common behaviours seen in the patient during the second stage of labour.

The nurse should encourage the patient to "listen" to and trust their body as they progress through the phases of the second stage of labour. The nurse can validate the patient's experience of pressure, stretching, and straining as normal and as a signal that the descent of the fetus is progressing and the body is capable of withstanding birth. The nurse can honestly explain what is happening and describe the progress being made.

Nursing Care During the Second Stage of Labour

The only certain objective sign that the second stage of labour has begun is the inability to feel the cervix during vaginal examination, indicating that it is fully dilated and effaced. The precise moment that this occurs is not easily determined because it depends on when a vaginal examination is performed to validate full dilation and effacement. This makes timing of the actual duration of the second stage difficult. Box 17.13 describes the nursing care and lists signs that indicate the onset of the second stage. These signs commonly appear at the time the cervix reaches full dilation. However, they can appear earlier in labour. Patients with an epidural block may not exhibit such signs.

Patients may begin to experience an irresistible urge to bear down before full dilation. This is most often related to the station of the presenting part below the level of the ischial spines of the pelvis. This occurrence creates a conflict between the labouring patient, whose body

TABLE 17.4 Expected Progress and Response During the Second Stage of Labour

Criterion	Passive Phase (Average Duration 10–30 Minutes)	Active Pushing (Descent) Phase (Average Duration Varies)*
Contractions		
Intensity	Period of physiological lull for all criteria; period of peace and rest; "labouring down"	Significant increase becoming overwhelmingly strong and expulsive
Frequency		4 to 5 contractions every 10 minutes
Duration		90 seconds
Descent, station	0 to +2	+2 to +4; Rate of descent increases and Ferguson reflex† is activated; fetal head becomes visible at introitus and birth occurs
Spontaneous bearing-down efforts	Slight to absent, except at peak of strongest contractions	Increased urge to bear down; becomes stronger as fetus descends to vaginal introitus and reaches perineum
Vocalization	Quiet; concern over progress	Grunting sounds or expiratory vocalizations; announces contractions; may scream
Behaviour	Experiences sense of relief that transition to second stage is finished Feels fatigued and sleepy Feels a sense of accomplishment and optimism because the "worst is over" Feels in control	Senses increased urge to push and describes increasing pain; describes *ring of fire* (burning sensation of acute pain as vagina and perineum stretch and fetal head crowns) Expresses feeling of powerlessness Shows decreased ability to listen to or concentrate on anything but giving birth Alters respiratory pattern: has short 4- to 5-second breath holds with regular breaths in between, 5 to 7 times per contraction Frequent repositioning Often shows excitement immediately after birth of head

*Duration of descent phase can vary, depending on maternal parity, effectiveness of bearing-down effort, and presence of spinal anaesthesia or epidural analgesia.

†Pressure of presenting part on stretch receptors of pelvic floor stimulates release of oxytocin from posterior pituitary, resulting in more intense uterine contractions.

BOX 17.13 Nursing Care in Second-Stage Labour

Assessment

Signs That Suggest Onset of the Second Stage

- Urge to push or feeling need to have a bowel movement
- Sudden appearance of sweat on upper lip
- An episode of vomiting
- Increased bloody show
- Shaking of extremities
- Increased restlessness; verbalization (e.g., "I can't go on.")
- Involuntary bearing-down efforts

Physical Assessment

- Perform every 5 to 30 minutes: maternal blood pressure, pulse, and respirations.
- Assess every 5 minutes: fetal heart rate and pattern.
- Assess every 10 to 15 minutes: vaginal show; signs of fetal descent; and changes in maternal appearance, mood, affect, energy level, and condition of support person. Assess every contraction and bearing-down effort.

Interventions

Passive Phase

- Help patient to rest in a position of comfort; encourage relaxation to conserve energy.
- Promote progress of fetal descent and onset of urge to bear down by encouraging position changes, pelvic rock, ambulation, and showering.

Active Pushing (Descent) Phase

- Help patient to change position and encourage spontaneous bearing-down efforts.
- Help patient to relax and conserve energy between contractions.
- Provide comfort and pain-relief measures as needed.
- Cleanse perineum promptly if fecal material is expelled.
- Coach patient to pant during contractions and to gently push between contractions when the head is emerging.
- Provide emotional support, encouragement, and positive reinforcement of efforts.
- Keep patient informed regarding progress.
- Create a calm and quiet environment.
- Offer mirror to watch birth or encourage patient to feel top of fetal head as they are pushing.

is telling them to push, and the health care providers, who believe that pushing the fetal presenting part against an incompletely dilated cervix will result in cervical edema and lacerations and slow the progress of labour. The timing of when a patient pushes in relation to dilation of the cervix should be based, however, on research evidence rather than on tradition or routine practice. If the patient's cervix is not yet completely dilated, encouraging them to breathe through contractions using shallow, frequent panting or puffing breaths (as though blowing out a candle) and to assume a side-lying or hands-and-knees position may be beneficial in assisting them to avoid pushing (Kelly et al., 2017). Pushing with the urge to bear down at the acme of a contraction may be safe and effective for a patient if the cervix is soft, retracting, and 8 cm or more dilated and if the fetus is at +1 station and rotating to an anterior position.

Professional standards and agency policy determine the specific type and timing of assessments and the way in which findings are documented. Signs and symptoms of impending birth may appear unexpectedly, requiring immediate action by the nurse (Box 17.14).

In the hospital, birth may occur in a delivery room, a labour, birth, and recovery (LBR) room, or labour, birth, recovery, and postpartum (LBRP) room. If the patient is to be transferred to another room for birth, the nurse needs to make the transfer early enough to avoid rushing the patient.

Position During Second Stage. No single ideal position for childbirth exists. Labour is a dynamic, interactive process involving the uterus, pelvis, and voluntary muscles. In addition, angles between the labouring patient's pelvis and the fetus constantly change as the fetus turns and flexes through the birth canal. The patient may want to assume various positions for childbirth and should be encouraged to change positions frequently and to labour in any position that feels comfortable and natural (King & Pinger, 2014; PHAC, 2018) (see Figures 17.11, *B* and 17.13). If progress with pushing is not occurring, patients should be encouraged to change positions every 20 to 30 minutes. The supine and lithotomy positions, however, should be avoided (Kopas, 2014; PHAC, 2018; Simpson & O'Brien-Abel, 2014).

Birth attendants play a major role in influencing a patient's choice of position for birth, with midwives tending to advocate the non lithotomy positions (e.g., upright, lateral) for the second stage of labour. Evidence suggests that any upright or lateral position used in second-stage labour (e.g., walking, standing, sitting, kneeling, squatting, hands-and-knees, or side-lying) results in less pain, less fatigue, less perineal trauma, fewer episiotomies, fewer forceps- or vacuum-assisted births, and fewer FHR abnormalities (Gupta et al., 2017; King & Pinger, 2014). In an upright position, gravity can promote descent of the fetus, and uterine contractions are generally stronger and more efficient in effacing and dilating the cervix, resulting in shorter labour and less need for oxytocin (Blackburn, 2018; Lawrence et al., 2013). An upright position also is beneficial to the labouring patient's cardiac output, thereby increasing perfusion of the uterus. The use of upright and lateral positions is also associated with less pain and perineal damage, fewer episiotomies and abnormal FHR patterns, and fewer operative vaginal births (Simpson et al., 2019; Walker et al., 2018).

Squatting is extremely effective in facilitating the descent and birth of the fetus. Pushing efforts are maximized and gravity assists the patient's efforts (Kelly et al., 2017; Simpson et al., 2019). Patients should assume a modified, supported squat until the fetal head is engaged, at which time a deep squat can be used. A firm surface is required for this position. In a birthing bed, a squatting bar is available that the patient can use to help support themselves (see Figure 17.11, *B*). A birth ball can help a patient maintain the squatting position. The fetus will be aligned with the birth canal, and pelvic and perineal relaxation are facilitated as they sit on the ball or hold the squatting bar in front of them for support.

When a patient uses the supported standing position for bearing down, their weight is borne on both femoral heads, allowing the pressure in the acetabulum to increase the transverse diameter of the pelvic outlet by up to 1 cm. This can be helpful if descent of the head is

BOX 17.14 Guidelines for Assistance at Emergency Birth of a Fetus in the Vertex Presentation

1. Call for assistance!
2. The patient usually assumes the position most comfortable for themselves. A lateral position is often recommended to facilitate a controlled birth of the head, thereby minimizing the risk for perineal trauma.
3. Reassure the patient that birth is usually uncomplicated in these situations. Use eye-to-eye contact and a calm, relaxed manner. If someone else is available, such as the partner, that person could help support the patient in the position, assist with coaching, and provide positive reinforcement and praise of their efforts.
4. Wash your hands and put on gloves.
5. Place under patient's buttocks whatever clean material is available.
6. Avoid touching the vaginal area to decrease the possibility of infection.
7. As the head begins to crown, perform the following tasks:
   - Tear the amniotic membranes if they are still intact.
   - Instruct the patient to pant or pant-blow, thus minimizing the urge to push.
   - Place the flat side of your hand on the exposed fetal head and apply gentle pressure toward the vagina to prevent the head from "popping out." The patient may participate by placing their hand under yours on the emerging head. Note: Rapid birth of the fetal head must be prevented because a rapid change of pressure within the moulded fetal skull follows, which may result in dural or subdural tears and cause vaginal or perineal lacerations.
8. After the birth of the head, check for the umbilical cord. If the cord is around the baby's neck, try to slip it over the baby's head or pull it gently to get some slack so that you can slip it over the shoulders.
9. Support the fetal head as external rotation occurs. With one hand on each side of the baby's head, exert *gentle* pressure downward so the anterior shoulder emerges under the symphysis pubis and acts as a fulcrum; as *gentle* pressure is exerted in the opposite direction, the posterior shoulder, which has passed over the sacrum and coccyx, emerges.
10. Be alert! Hold the baby securely because the rest of the body may emerge quickly. The baby will be slippery! Cradle the baby's head and back in one hand and the buttocks in the other and place the baby skin-to-skin on the mother's abdomen.
11. Dry the baby quickly to prevent rapid heat loss, keep the baby skin-to-skin with the parent, and cover with warm blankets (remember to keep the head warm as well). Unless immediate resuscitation is required, there is no urgency to cut the cord. There is sufficient evidence that delayed cord clamping is beneficial for the baby, especially in the preterm population.
12. When ready, double-clamp and cut the cord. Collect arterial and venous cord gases as well as cord blood if the parent is Rh negative. Compliment the patient on a job well done and on the baby, if appropriate.
13. Wait for the placenta to separate. *Do not* tug on the cord. Note: Inappropriate traction may tear the cord, separate the placenta, or invert the uterus. Signs of placental separation include a slight gush of dark blood from the introitus, lengthening of the cord, and change in the uterine contour from a discoid to globular shape.
14. Instruct patient to push to deliver the separated placenta. Gently ease out the placental membranes using an up-and-down motion until the membranes are removed. Check placenta for completeness and keep the placenta until it can be inspected by the primary health care provider. If birth occurs outside a hospital setting, to minimize complications, do not cut the cord without proper clamps and a sterile cutting tool. Inspect the placenta for intactness. Check firmness of the uterus. Gently massage the fundus and demonstrate to the patient how they can massage their own fundus properly.
15. If supplies are available, clean the patient's perineal area and apply a perineal pad.
16. In addition to gentle massage of the fundus, the following measures can be taken to prevent or minimize hemorrhage:
   - Put the baby to the parent's breast as soon as possible. Sucking or nuzzling and licking the nipple stimulates the release of oxytocin from the posterior pituitary. Note: If the baby does not or cannot breastfeed, manually stimulate the patient's nipples.
   - Do not allow the patient's bladder to become distended. Assess the bladder for fullness and encourage them to void if fullness is found.
   - Expel any clots from the patient's uterus after ensuring that the fundus is firm.
17. Comfort or reassure the patient and family or friends. Keep the baby skin-to-skin with parent and provide additional warmth to the patient. Provide fluids to patient if available and tolerated.
18. If this is a multifetal birth, identify the infants in order of birth (using letters A, B, etc.).
19. Make notations regarding the following aspects of the birth:
   - Fetal presentation and position
   - Presence of cord around neck (nuchal cord) or other parts and number of times cord encircled part
   - Colour, character, and amount of amniotic fluid if rupture of membranes occurs immediately before birth
   - Time of birth
   - Estimated time of determination of Apgar score (e.g., 1 and 5 minutes after birth), resuscitation efforts implemented, and ultimate condition of baby
   - Sex of baby
   - Time of placental expulsion and appearance and completeness of the placenta
   - Maternal condition: affect, behaviour, and demeanour, amount of bleeding, and status of uterine tonicity
   - Any unusual occurrences during the birth (e.g., parental response, comments, or gestures in response to birth of baby)

delayed, because the occiput has not rotated from the lateral (transverse diameter of pelvis) to the anterior position. Birthing chairs or rocking chairs may be used to provide labouring patients with a good physiological position to enhance bearing-down efforts during childbirth, although some patients feel restricted by a chair. The upright position provides a potential psychological advantage in that it allows the labouring person to see the birth as it occurs and maintain eye contact with the attendant.

Oversized beanbag chairs and large floor pillows may be used for both labour and birth. They can mould around and support the patient in whatever position they select. These chairs are of particular value for patients who wish to be actively involved in the birth process. Birthing stools can be used to support the patient in an upright position similar to squatting. Some patients may feel more comfortable sitting on the toilet to push because they are concerned about passing stool during this stage. Sitting on the toilet is similar to squatting and is an ideal position for the primiparous patient to start the pushing stage. Patients must be closely monitored and removed from the toilet before birth is imminent. Because sitting on chairs, stools, toilets, or commodes can increase perineal edema and blood loss, it is important to assist the patient to change positions frequently.

The side-lying (lateral) position, with the upper part of the labouring person's leg held by the nurse or partner or placed on a pillow, is also an effective position for the second stage of labour (Figure 17.15, *A*). Patients

Fig. 17.15 **A:** Pushing, side-lying position. Perineal bulging can be seen. **B:** Pushing, semisitting position. Midwife helps mother feel top of fetal head. (*A,* Courtesy Michael S. Clement, MD. *B,* Courtesy Roni Wernik.)

using the lateral position have more control over their bearing-down efforts. In addition, a slower, more controlled descent of the fetus results in a reduced risk of perineal trauma. Some patients prefer a semisitting, or semirecumbent position. If the semirecumbent position is used, the patient's legs should not be forced against the abdomen during bearing down. This position increases perineal stretching and the risk for perineal trauma and spinal and lower-extremity neurological injuries; it is physiologically inappropriate and should be abandoned (Simpson et al., 2019).

The hands-and-knees position, along with pelvic rocking, is an effective position for birth because it enhances placental perfusion, helps rotate the fetus from a posterior to an anterior position, and may facilitate the birth of the shoulders, especially if the fetus is large (see Figure 17.13, *B*). Perineal trauma may also be reduced.

The birthing bed is commonly used today and can be set for different positions according to the patient's needs (Figure 17.16). The patient can squat, kneel, sit, recline, or lie on one side, choosing the position most comfortable for them. At the same time there is exposure for examination and birth. Squatting bars, over-the-bed tables, birth balls, and pillows can be used for support. The bed can be positioned for the administration of anaesthesia and is ideal for helping patients receiving an epidural to assume different positions to facilitate birth.

Bearing-Down Efforts. As the fetal head reaches the pelvic floor, most patients experience the urge to bear down. Reflexively, the patient will begin to exert downward pressure by contracting the abdominal muscles while relaxing the pelvic floor. This bearing down is an involuntary response to the Ferguson reflex. A strong expiratory grunt or groan (vocalization) often accompanies pushing when the patient exhales while pushing. Nurses should not discourage this natural vocalization made by patients during open-glottis bearing-down efforts.

When coaching a patient to push, the nurse should encourage them to push as they feel the urge to do so (instinctive, spontaneous pushing) rather than giving a prolonged push on command (directed, closed-glottis pushing). Prolonged breath-holding or sustained, directed bearing down is still a common practice, often beginning at 10-cm dilation and before the urge to bear down is perceived. The patient is coached to hold their breath, closing the glottis, and to push while the nurse or partner counts to 10. This method of bearing down may trigger the **Valsalva manoeuvre**, which occurs when the patient closes the glottis (closed-glottis pushing), increasing intrathoracic and cardiovascular pressure. This reduces cardiac output and decreases perfusion of the uterus and the placenta. Adverse effects associated with prolonged breath-holding and forceful pushing efforts include fetal hypoxia and subsequent acidosis, increased risk for pelvic floor damage (structural and neurogenic), and perineal trauma (Blackburn, 2018; Simpson et al., 2019). The benefits of spontaneous pushing efforts rather than sustained Valsalva pushes include less fatigue and enhanced comfort. In addition, these more effective bearing-down efforts result in less time spent actively pushing (Lee et al., 2016). Based on this evidence it is essential that perinatal nurses advocate for the practice of delayed and spontaneous bearing-down efforts with the patient in an upright or lateral position (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Delayed Pushing in Second-Stage Labour

A nurse is caring for Emily, a 25-year-old G1 T0 P0 A0 L0 at 39 weeks of gestation. A vaginal examination was done and it was determined that Emily's cervix is completely dilated. She has an epidural, which is working well. Currently, Emily is feeling neither pressure nor pain. On learning that Emily's cervix is completely dilated, her health care provider exclaims, "Good! Get in there and help her push so we can have this baby! I've had a long day!"

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about effective management of second-stage labour?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Delayed pushing
   b. Positioning for pushing
   c. Spontaneous versus directed pushing efforts
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Emily's care.

Fig. 17.16 The versatility of today's birthing bed makes it practical in many settings. **A:** Semirecumbent (modified throne position). **B:** High Fowler's (similar to sitting or squatting position). **C:** Lithotomy with foot rests. **D:** Lithotomy with stirrups. (Courtesy Julie Perry Nelson.)

Spontaneous open-glottis pushing for 5 to 7 seconds at a time is encouraged. The patient usually pushes two to three times per contraction, although they may not push at all during some contractions. The nurse or support person reminds the patient to take a cleansing breath after each contraction. Open glottis pushing helps to maintain adequate oxygen levels for the labouring patient and fetus, thus enhancing fetal well-being. Pushing efforts become more frequent with a longer duration as second-stage labour progresses (Simpson et al., 2019). The patient may spontaneously bear down as the fetus crowns, even if a contraction is not occurring (Kelly et al., 2017; King & Pinger, 2014; Simpson & O'Brien-Abel, 2014).

A patient can become confused and anxious when being told to do something in conflict with what their body is telling them. Using phrases such as "You are doing so well; do it again," "You are moving the baby down," and "Follow what your body is telling you," rather than "Push, push, push," encourages a patient to feel confident in their body and what they are feeling. Encouraging the labouring patient to use a mirror to see the baby's head or to use their hand and feel the head may increase the effectiveness and strength of the pushing.

A patient may reach the second stage of labour and then experience a lack of readiness to complete the process and give birth to a child. They may have doubts about their readiness to be a parent or want to wait for a support person or primary health care provider to arrive. Fear, anxiety, or embarrassment regarding the unfamiliar or painful sensations and behaviours during pushing (e.g., sounds made, passage of stool) may be other inhibiting factors. Fear that the baby will be in danger once it emerges from the protective intrauterine environment also may be present. By recognizing that a patient may experience a need to hold back the birth of the baby, the nurse can address these concerns and effectively coach the patient through this stage of labour.

To ensure slow birth of the fetal head, the nurse should encourage the patient to control the urge to bear down by coaching them to take panting breaths or exhale slowly through pursed lips as the baby's head crowns. At this point, the patient often needs simple, clear directions from one person. Amnesia between contractions is often pronounced in the second stage, and the patient may have to be roused to participate in the bearing-down process.

Fetal Heart Rate and Pattern. The nurse must assess the FHR every 5 to 15 minutes depending on the method of fetal health surveillance, during the second stage of labour. If atypical or abnormal patterns develop, prompt assessment or intervention must be initiated. The patient can be turned on their side to reduce the pressure of the uterus against the inferior vena cava and descending aorta (see Figure 17.4). Often this is all that is required to restore a normal FHR pattern. Oxygen may be administered at 8 to 10 L/min via a tight-fitting face mask if there is evidence of maternal hypoxia or hypovolemia. If the FHR pattern does not become normal immediately, the primary health care provider should be notified quickly because medical intervention to hasten birth may be indicated. See Chapter 19 for more interventions related to abnormal FHR patterns.

LEGAL TIP: Documentation
All observations (e.g., labouring patient's vital signs, fetal heart rate and pattern, progress of labour) and nursing interventions, including the patient's response, should be documented concurrently with care. The course of labour, the patient's status, and the fetal response may change without warning. All documentation must be accurate, complete, timely, and according to agency policy and professional standards.

Support of the Partner. During the second stage of labour, the labouring patient needs continuous support and coaching (see Table 17.4). Because this process can be physically and emotionally tiring for support people, the nurse should offer them nourishment and fluids and encourage them to take short breaks. If birth occurs in an LBR or LBRP room, the support person usually wears street clothes. The support person who attends the birth in a delivery room or operating room may be instructed to put on a cover gown or scrub clothes, mask, hat, and shoe covers as required by agency policy. The nurse should also encourage support measures that can be used for the labouring person and point out areas of the room in which the partner can move freely. Refer to Box 17.12 for more detailed information about how to support the support person.

The nurse can encourage partners to be present at the birth of their infants if doing so is in keeping with their cultural and personal expectations and beliefs. The presence of partners maintains the psychological closeness of the family unit, and the partner can continue to provide the supportive care given during labour. The labouring patient and their partner need to have an equal opportunity to initiate the attachment process with the baby.

Supplies, Instruments, and Equipment. To prepare for birth in any setting, the birthing table is usually set up during the later part of the active phase of labour. Instruments are arranged according to agency protocol on the instrument table or cart (Figure 17.17). Principles of sterile technique are followed for gloving, identifying and opening sterile packages, adding sterile supplies to the table, unwrapping sterile instruments, and handing them to the primary health care provider. The crib or radiant warmer and equipment are readied for the support and stabilization of the infant, if required (Figure 17.18). The items used for birth may vary among different facilities; therefore, the procedure manual of each facility should be consulted to determine the protocols specific to that facility.

The nurse estimates the time until the birth will occur and notifies the primary health care provider if they are not in the room. Even the most experienced nurse can miscalculate the time left before birth occurs; therefore, every nurse who attends a patient in labour must be prepared to assist with an emergency birth if the primary health care provider is not present (see Box 17.14).

Birth in a Delivery Room. Currently, patients most often give birth vaginally in a birthing room, in the same bed where they have laboured, rather than in a delivery room. The patient will need assistance if they need to move from the labour bed to the delivery table (Figure 17.19). The patient's position for birth varies from a lithotomy position with the legs in stirrups or with the legs held and supported by the nurse or support person, to one in which the feet rest on footrests while holding on to a squat bar, to a side-lying position with the upper leg supported by the support person, nurse, or squat bar.

Although not recommended as the ideal position for birth, the lithotomy position makes it more convenient for the primary health care provider to deal with complications that may arise. To place the patient in this position, the buttocks are brought to the edge of the table and the legs are placed in stirrups. Care must be taken to pad the stirrups, raise and place both legs simultaneously, and adjust the shanks of the stirrups so that the calves of the legs are supported. There should be no pressure on the popliteal space. If the stirrups are not the same height, ligaments in the patient's back can be strained during bearing down, leading to considerable discomfort in the postpartum period.

Once the patient is positioned, the foot of the bed may be removed so the primary health care provider attending the birth can gain better perineal access for assisting with the birth of a large baby or using forceps or vacuum extractor. Alternatively, the foot of the bed can be left in place and lowered slightly to form a ledge that allows access for birth (see Figure 17.16, *A*).

The nurse needs to continue to coach and encourage the patient. The nurse should keep the primary health care provider informed of the FHR pattern. An oxytocic medication such as oxytocin can be prepared so that it is ready to administer after delivery of the anterior shoulder.

Fig. 17.19 Delivery room. (iStock.com/Trout55)

The primary health care provider may put on a mask that has a shield or protective eyewear and may put on a cap and shoe covers. The provider will scrub their hands and put on a waterproof sterile gown and gloves. Nurses attending the birth may also wear caps, protective eyewear, masks, gowns, and gloves. The labouring patient may then be draped with sterile drapes. Birth in an LBR or LBRP room usually does not require this type of protective covering but wherever the birth occurs, routine precautions need to be observed (see Box 17.6).

Mechanism of Birth: Vertex Presentation

The three phases of spontaneous birth of a fetus in a vertex presentation are (1) birth of the head, (2) birth of the shoulders, and (3) birth of the body and extremities (see Chapter 16).

With voluntary bearing-down efforts, the head appears at the introitus (Figure 17.20). **Crowning** occurs when the widest part of the head (the biparietal diameter) distends the vulva just before birth. The patient may state that they feel a burning sensation at this time as the perineum is stretched. A warm, wet compress to the perineum may alleviate this discomfort and assist the tissue to stretch and yield to the crowning head. Immediately before birth, the perineal musculature becomes greatly distended. If an **episiotomy** (incision into the perineum to enlarge the vaginal outlet) is necessary, it is done at this time. Local anaesthetic should be administered before the episiotomy. Box 17.15 shows the process of normal vaginal childbirth in a series of photographs.

The obstetrical health care provider may use a hands-on approach to control the birth of the head, believing that guarding the perineum results in a gradual birth that will prevent fetal intracranial injury, protect the patient's tissues, and reduce postpartum perineal pain. This approach involves (1) applying pressure against the perineum to aid in flexing the head as the back of the neck catches under the symphysis pubis; (2) applying upward pressure from the coccygeal region (modified Ritgen manoeuvre) (Figure 17.21) to extend the head during the actual birth, thereby protecting the musculature of the perineum; and (3) assisting the mother with voluntary control of the bearing-down efforts by coaching them to pant while letting uterine forces expel the fetus.

Some health care providers use a hands-poised (hands-off) approach when attending a birth. In this approach hands are prepared to place light pressure on the fetal head to prevent rapid expulsion. They are not placed on the perineum or used to assist with the birth of the shoulders and body. Hands-off techniques may reduce the number of episiotomies, but it is not clear that these techniques have a beneficial effect on other perineal trauma (Aasheim et al., 2017).

The umbilical cord may encircle the neck (**nuchal cord**) but it is rarely so tight as to cause hypoxia. After the head is born, gentle palpation is used to feel for the cord. If present, the cord should be slipped gently over the head, if possible. If the loop is tight or if there is a second loop, the cord is clamped twice, cut between the clamps, and unwound from around the neck before the birth is allowed to continue. Alternatively, the obstetrical health care provider may perform a somersault manoeuvre to avoid clamping and cutting the cord before the birth. Mucus, blood, or meconium in the nasal or oral passages may prevent the newborn from adequately ventilating their lungs with their initial breaths. To address this concern, moist gauze sponges may be used to wipe the nose and mouth to promote newborn transition. Suction is not recommended unless meconium is present.

Perineal Trauma Related to Childbirth

Most acute injuries and lacerations of the perineum, vagina, uterus, and their support tissues occur during the birth. There is evidence to suggest that alternative measures for perineal management, such as application of warm compresses and gentle antenatal perineal massage and stretching, may lessen the degree of perineal lacerations and trauma (Aasheim, et al., 2017; Beckmann & Stock, 2013) (see Evidence-Informed Practice box: When an OASIS Is Not a Scenic Travel Destination: Minimizing Anal Sphincter Injury in Childbirth). Aggressive perineal massage during labour should be avoided because it results in trauma to the perineal tissue and has not been shown to decrease the future risk for pain, pain with sexual intercourse, or urinary or fecal incontinence.

Some degree of damage occurs to the soft tissues of the birth canal and adjacent structures during every birth. The tendency to sustain lacerations varies with each patient as the soft tissue in some patients may be less distensible. Damage usually is more pronounced in nulliparous patients because the tissues are firmer and more resistant than those in multiparous patients. Other risk factors associated with perineal trauma include heredity, the patient's nutritional status, birth position, pelvic anatomy (e.g., narrow subpubic arch with a constricted outlet), fetal malpresentation and position (e.g., breech presentation, occiput-posterior position), large (macrosomic) infants, use of forceps or vacuum to facilitate birth, prolonged second stage of labour, and rapid labour in which there is insufficient time for the perineum to stretch.

Some injuries to the supporting tissues, whether they are acute or nonacute or were repaired or not, may lead to genitourinary and sexual issues later in life (e.g., pelvic relaxation, uterine prolapse, cystocele, rectocele, dyspareunia, urinary and bowel dysfunction). Use of Kegel exercises in the prenatal and postpartum periods improves and restores the tone and strength of the perineal muscles (see Chapter 5, Patient Teaching box, Kegel Exercises). Health practices, including good nutrition and appropriate hygienic measures, help maintain the integrity and suppleness of the perineal tissues, enhance healing, and prevent infection.

EVIDENCE-INFORMED PRACTICE

When an OASIS Is Not a Scenic Travel Destination: Minimizing Anal Sphincter Injury in Childbirth

Ask the Question

For patients in labour, what perinatal interventions to minimize perineal trauma are safe and effective?

Search for the Evidence

Search Strategies: English research-based publications on perineal trauma, birth, postpartum, anal sphincter, lacerations

Databases Used: Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, and the professional website for ACOG

Critical Appraisal of the Evidence

Perineal lacerations that reach the anal sphincter (third degree) and the rectal wall (fourth degree) are called *obstetrical anal sphincter injuries (OASIS).* Risk factors include large baby (>4 kg), nulliparity, induction or augmentation of labour, operative/instrumental birth, prolonged second-stage labour, epidural anaesthesia, and shoulder dystocia.

- OASIS is associated with long-term postpartum anal incontinence and urgency, pelvic pain, and dyspareunia (LaCross et al., 2015).
- OASIS may be a complication of an episiotomy, which compromises the integrity of the perineum and may allow further tearing. Of all the risk factors for anal injury and incontinence, episiotomy is the most modifiable (LaCross et al., 2015).
- Although obesity is on many lists as a risk factor, it may be significantly protective against third- and fourth-degree lacerations (Garretto et al., 2016). This may be due to stretchier tissue, disbursement of contraction force, and/or less frequent use of squatting in second-stage labour. Decreased ability by the provider to visualize the perineum due to maternal obesity may also mask the true extent of perineal damage (Garretto et al., 2016).
- Perineal support during crowning involves the provider using one hand to press the tissue under the crown, between the vagina and rectum, in order to support some weight of the fetal head as it lays heaviest on the opening. Some practices include using the other hand to apply gentle counterpressure against the fetal skull, to slow down birth of the head. Evidence regarding the practice of provider support of the perineum during crowning is mixed. A systematic review and meta-analysis found no difference between perineal support and hands-off support during birth in three randomized controlled trials (RCTs), but a protective effect of perineal support against OASIS in three nonrandomized studies (NRSs). The RCTs were the higher-quality evidence, but the NRSs were much larger (6 647 vs. 74 000 women). The authors did not find the evidence sufficient to make a recommendation (Bulchandani et al., 2015).

Apply the Evidence: Nursing Implications

- The American College of Obstetricians and Gynecologists (ACOG) (2016) recommends the use of warm compresses and perineal massage during first- and second-stage birth; this significantly decreases third- and fourth-degree tears. In addition, perineal massage during the final 6 weeks of pregnancy may decrease perineal trauma.
- The Society of Obstetricians and Gynaecologists of Canada (SOGC) states that the use of episiotomy should be avoided in spontaneous vaginal births (Lee et al., 2016). When necessary, the mediolateral cut is less associated with OASIS; however, the mediolateral episiotomy is more likely to result in dyspareunia and pelvic pain.
- Women with OASIS should be given antibiotics, stool softeners, and laxatives, as well as counselling on avoiding constipation.

EVIDENCE-INFORMED PRACTICE—CONT'D

- Women who have had prior OASIS have a low risk for recurrence but may reasonably be offered a Caesarean birth, if they request it (ACOG, 2016).

Fig. 17.21 Birth of head with modified Ritgen manoeuvre. Note control to prevent too-rapid birth of head.

Perineal Lacerations. Perineal lacerations usually occur when the fetal head is being born. The extent of the laceration is defined in terms of its depth:

First degree—Laceration extends through the skin and structures superficial to muscles.
Second degree—Laceration extends through muscles of perineal body.
Third degree—Laceration continues through anal sphincter muscle.
Fourth degree—Laceration that extends completely through the anal sphincter and the rectal mucosa.

Perineal injury is often accompanied by small lacerations on the medial surfaces of the labia minora below the pubic rami and may involve the tissue to the sides of the urethra ("periurethral") and clitoris. Lacerations in this highly vascular area often result in profuse bleeding.

Third- and fourth-degree lacerations must be repaired carefully so the patient retains fecal continence. Measures should be taken to promote soft stools (e.g., dietary fibre, fluid, activity, and stool softeners) in order to increase the patient's comfort and foster healing. Antimicrobial therapy may be used in some cases. Enemas and suppositories are contraindicated for these patients. Simple perineal injuries usually heal without any significant concerns, regardless of whether they were repaired. However, it is easier to repair a new perineal injury to prevent sequelae than it is to correct long-term damage.

Episiotomy. An episiotomy is an incision made in the perineum to enlarge the vaginal outlet. It is recommended that the use of episiotomy be abandoned unless medically indicated or the childbearing person requests one (Lee et al., 2016; PHAC, 2018). The pain and discomfort resulting from episiotomies can interfere with parent–infant interaction, breastfeeding, re-establishment of the sexual relationship with a partner, and even emotional recovery after birth. The side-lying position for birth causes less tension on the perineum, making possible a gradual stretching of the perineum with fewer indications for episiotomies.

Different types of episiotomies are performed, depending on the site and direction of the incision (Figure 17.22). Mediolateral episiotomy is used in operative births when the need for posterior extension is likely. Although a fourth-degree laceration may be prevented, a third-degree laceration may occur. The blood loss is greater and the repair more difficult and painful than with midline episiotomies. Though it may be more painful in the postpartum period, the mediolateral episiotomy is preferred to the midline (median) episiotomy because of its

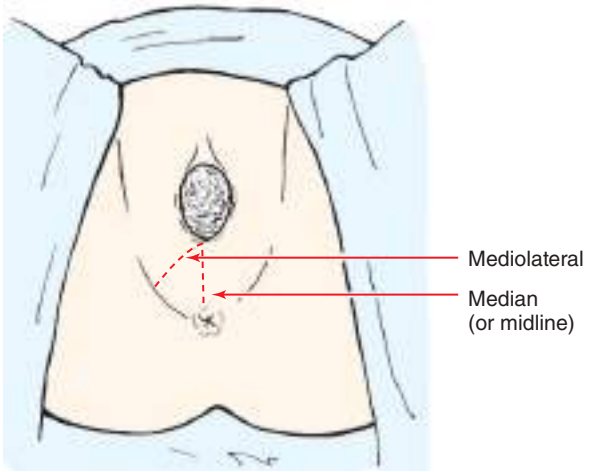

Fig. 17.22 Types of episiotomies.

association with a higher incidence of third- and fourth-degree lacerations (Cargill & MacKinnon, 2018).

Vaginal Lacerations. Vaginal lacerations often occur in conjunction with perineal lacerations. Vaginal lacerations tend to extend up the lateral walls (sulci) and, if deep enough, involve the levator ani. Additional injury may occur high in the vaginal vault near the level of the ischial spines. Vaginal vault lacerations may be circular and may result from the use of forceps to rotate the fetal head or from rapid fetal descent or precipitous birth.

Cervical Injuries. Cervical injuries may occur when the cervix retracts over the advancing fetal head. These lacerations occur at the lateral angles of the external os. Most lacerations are shallow and bleeding is minimal. Larger lacerations may extend to the vaginal vault or beyond it into the lower uterine segment; serious bleeding may occur. Extensive lacerations may follow hasty attempts to dilate the cervix artificially or to deliver the fetus before full cervical dilation is achieved. Injuries to the cervix can have adverse effects on future pregnancies and childbirths.

Female Genital Cutting (FGC). An increasing number of patients are moving to Canada from countries where FGC is a common practice. FGC comprises all procedures that involve partial or total removal of the external female genitalia or other injury to the female genital organs for nonmedical reasons (see Chapter 5, Female Genital Cutting). This practice has been criminalized in Canada. FGC that seals or narrows the vaginal opening (infibulation) may lead to complications in childbirth, including prolonged or obstructed labour. Patients may need the scar tissue surgically opened during childbirth to facilitate safe passage of the fetus. Caesarean birth is more common in patients who have undergone FGC, although in some cases this could be due to lack of caregiver knowledge and bias about FGC (PHAC, 2018). It should not be considered an indication for Caesarean birth.

While it is not illegal to reinfibulate following childbirth according to the Canadian Criminal Code, requests for reinfibulation should be declined on medical grounds because repetitive cutting and suturing of the vulva is likely to increase scar tissue, thus causing or perpetuating dyspareunia or voiding difficulties. If incisions are made or tearing occurs during childbirth, it is reasonable to repair defects in a way that will promote good hemostasis, vaginal support, and normal appearance (Perron et al., 2013). As always, patients need to be cared for with respect, dignity, and privacy. Patients need information about the implications of FGC on their labour and birth. Accepting and respectful attitudes are particularly important. Care needs to be patient centred—respecting the patient's wishes and views as well as explaining why some requests may not be possible for legal reasons (PHAC, 2018). After the birth the patient may need extra care for pain management and proper wound healing.

Water Birth

There is evidence that immersion in water during first-stage labour can reduce pain and anxiety and length of labour. During the second stage of labour, immersion may increase the patient's satisfaction with the birth experience. There is no evidence of increased adverse effects to the fetus or labouring patient from labouring in water or water birth, although further research is needed (Cluett et al., 2018).

If a patient wishes to have a water birth (Figure 17.23), it usually occurs as part of a planned home birth with registered midwives, although it may occur in hospital. The newborn can be placed in the parent's arms until the cord is cut.

Fig. 17.23 Water birth. (Eddie Lawrence/Science Source)

Immediate Assessments and Care of the Newborn

The time of birth is the precise time when the entire body is out of the birth canal; this time is recorded. In the case of multiple births, each birth would be noted in the same way. In most situations, immediate skin-to-skin contact and delayed cord clamping are likely to be implemented.

Skin-to-skin contact is recommended for the healthy term newborn immediately after vaginal birth and as soon as possible following Caesarean birth. The baby is placed prone on the parent's bare abdomen or chest and dried. Next, a cap may be placed on their head. The wet blankets are removed, and baby and parent are covered with fresh warm blankets. Immediate skin-to-skin contact has been shown to positively affect parent–infant bonding, breastfeeding duration, cardiorespiratory stability, and body temperature. Blood glucose levels during the first 2 hours of life are higher in these babies than in newborns who did not receive immediate skin-to-skin contact (Kilpatrick & Garrison, 2017). Immediate skin-to-skin contact should be the standard of care because this practice conveys many benefits and has no adverse effects. Routine assessments and procedures can be completed with the newborn on the parent's chest (PHAC, 2018).

It is now recommended that the umbilical cord not be clamped until 1 to 3 minutes after birth, or until after the cord stops pulsating, to allow physiological transfer of blood to the newborn. Delayed cord clamping allows for a placental transfusion of up to 30% of the total fetal-placental blood volume. The transfusion includes many types of stem cells, red blood cells, and whole blood. It is recommended that delayed cord clamping be considered standard of care because it improves both the short- and long-term hematological status of the newborn and has no clinically significant adverse effects, although there may be a small additional risk of jaundice in newborns that requires phototherapy (Lee et al., 2016; McDonald et al., 2013; PHAC, 2018). At the appropriate time, the obstetrical health care provider may ask if the partner would like to cut the cord. If so, the partner is given a sterile pair of scissors and instructed to cut the cord approximately 2.5 cm above the clamp.

Immediate care after the birth focuses on assessing and stabilizing the newborn. The nurse is usually the primary person responsible for care of the newborn at this time because the primary health care provider is involved with the delivery of the placenta and care of the childbearing person. The nurse must watch the newborn for any signs of distress and initiate appropriate interventions should any appear. For care of the newborn with meconium-stained amniotic fluid, see Chapter 20.

THIRD STAGE OF LABOUR

The **third stage of labour** lasts from the birth of the baby until the placenta is expelled.

Nursing Care During the Third Stage of Labour

The goals in the management of the third stage of labour are the prompt separation and expulsion of the placenta achieved in the easiest, safest manner. Before separation of the placenta, blood is collected from the umbilical cord. Cord blood is collected for arterial and sometimes venous cord gases, as well as for blood type if the mother is Rh negative. The placenta is almost always expelled within 15 minutes after the birth of the baby. If the third stage has not been completed within 30 minutes, the placenta is considered to be retained, and interventions to hasten its separation and expulsion are usually instituted (Sheibani & Wing, 2017). See Box 17.16 for nursing care during the third stage of labour.

Under normal circumstances the placenta is attached to the decidual layer of the thin endometrium of the basal plate by numerous fibrous anchor villi. After the birth of the fetus, strong uterine contractions and the sudden decrease in uterine size cause the placental site to shrink. This causes the anchor villi to break and the placenta to separate from its attachments. Normally, the first few strong contractions that occur after the baby's birth cause the placenta to shear away from the basal plate. A placenta cannot detach itself from a flaccid (relaxed) uterus because the placental site is not reduced in size.

Placental Separation and Expulsion. Depending on the preferences of the primary health care provider, a passive (expectant) or active approach may be used to manage the third stage of labour. Passive management involves patiently watching for signs that the placenta has separated from the uterine wall spontaneously and monitoring for spontaneous expulsion. It may involve the use of gravity or nipple stimulation to facilitate separation and expulsion, but no oxytocic (uterotonic) medications are given. A quiet, relaxed environment that supports close skin-to-skin contact between parent and newborn also promotes the release of endogenous oxytocin.

In active management, placental separation and expulsion are facilitated by administration of an oxytocic medication (e.g., oxytocin) after the birth of the anterior shoulder of the fetus, clamping and cutting of the umbilical cord within 3 minutes after birth, and gently controlling cord traction following uterine contraction and separation of the placenta. Research findings and the World Health Organization recommend active management of the third stage of labour because this decreases the rate of postpartum hemorrhage caused by uterine atony (Leduc et al., 2018).

To assist in the delivery of the placenta, the patient is instructed to push when signs of separation have occurred (Figure 17.24). If possible, the placenta should be expelled by the patient's effort during a uterine contraction. Alternate compression and elevation of the fundus plus minimal, controlled traction on the umbilical cord may be used to facilitate delivery of the placenta and amniotic membranes. Oxytocics may be administered after the placenta is removed because they stimulate the uterus to contract, thereby helping to prevent hemorrhage (see the Evidence-Informed Practice box: Active Third-Stage Labour Management for Preventing Postpartum Hemorrhage).

After the placenta and the amniotic membranes emerge, the primary health care provider will examine them for intactness to ensure that no portion remains in the uterine cavity (i.e., no fragments of the placenta or membranes are retained) (Figure 17.25).

When the third stage of labour has been completed, the primary health care provider examines the patient for any perineal, vaginal, or cervical lacerations requiring repair. If an episiotomy was performed, it is sutured. Immediate repair promotes healing, limits residual damage, and decreases the possibility of infection. The patient usually feels some discomfort while the primary health care provider carries out the postbirth vaginal examination. The nurse can help the patient use breathing and relaxation or distraction techniques for dealing with the discomfort. During this time, the nurse performs a quick assessment of the newborn's physical condition and places matching identification bands on the baby and parent(s), usually while the newborn is skin-to-skin.

After any necessary repairs have been completed, the nurse cleanses the vulvar area gently and applies a perineal pad or an ice pack to the perineum. The nurse should reposition the birthing bed or table and lower the patient's legs simultaneously from the stirrups if birth occurred in a lithotomy position. The postpartum patient should be given a clean gown and blanket, which can be warmed if needed.

Some families have culturally based beliefs regarding the care of the placenta and the manner of its disposal after birth, such as viewing the care and disposal of the placenta as a way of protecting the newborn from bad luck and illness. Requests by the family to take the placenta

BOX 17.16 Nursing Care in Third-Stage Labour

Assessment

Signs That Suggest Onset of the Third Stage

- A firmly contracting fundus
- A change in the uterus from a discoid to a globular ovoid shape as the placenta moves into the lower uterine segment
- A sudden gush of dark blood from the introitus
- Apparent lengthening of the umbilical cord as the placenta descends to the introitus
- The finding of vaginal fullness (the placenta) on vaginal examination or of fetal membranes at the introitus

Physical Assessment

- Perform every 15 minutes: maternal blood pressure, pulse, and respirations.
- Assess for signs of placental separation and amount of bleeding.
- Assess parental response to completion of childbirth process and their reaction to the newborn.

Interventions

- Assist labouring patient to bear down, to facilitate expulsion of the separated placenta.
- Administer an oxytocic medication as ordered to ensure adequate contraction of the uterus, thereby preventing hemorrhage.
- Provide nonpharmacological and pharmacological comfort and pain-relief measures.
- Perform hygienic cleansing measures.
- Keep patient informed of progress of placental separation and expulsion and perineal repair, if appropriate.
- Explain the purpose of medications administered.
- Introduce parents to their baby and facilitate the attachment process by delaying eye prophylaxis and other tasks like weighing and measuring the baby; cover parent and baby together for skin-to-skin contact.
- Provide private time for parents to bond with their new baby.
- Encourage breastfeeding when newborn shows signs of interest.

EVIDENCE-INFORMED PRACTICE

Active Third-Stage Labour Management for Preventing Postpartum Hemorrhage

Ask the Question

For third-stage labour, what management techniques are most effective for prevention of postpartum hemorrhage (PPH)?

Search for the Evidence

Search Strategies: English research-based publications on uterotonics, postpartum hemorrhage, labour bleeding, cord clamping, active management, uterotonic were included.

Databases Used: Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, and the professional websites for ACOG, SOGC, and AWHONN

Critical Appraisal of the Evidence

PPH is the major cause of postpartum death worldwide, especially in low- and middle-income countries. In 2003, the International Confederation of Midwives, the International Federation of Gynecologists and Obstetricians, and the World Health Organization Safe Motherhood Initiative adopted a program recommending the use of active management of third-stage labour. To prevent PPH, health care providers actively manage third-stage labour by clamping the cord before pulsations have stopped, administering uterotonics (such as oxytocin or prostaglandins) to increase uterine contractions, and providing steady traction on the cord and counterpressure on the fundus, causing earlier expulsion of the placenta.

Cochrane Database of Systematic Reviews reported the following:

- Maternal effects (7 studies, 8 000 women): When compared to expectant management, the active management protocol results in less maternal blood loss and less maternal anemia, less transfusion, and less use of additional uterotonics in the first 24 hours. Adverse effects of active management include higher maternal diastolic pressure, afterpains, use of analgesia, and postpartum vomiting. Active management is more likely to result in readmission for bleeding, for unknown reasons (Begley et al., 2015). The authors call for more research on the individual components of the protocol and more research in high-risk countries.
- Effects on the newborn: Birthweight is less when the cord was clamped prior to the cessation of pulsing, because there is less transfer of blood volume to the newborn (Begley et al., 2015). The effects of this are unknown.
- Controlled cord traction (CCT) requires a skilled birth attendant to apply adequate power without causing uterine inversion. A Cochrane Review of three high-quality trials involving 28 000 women found that CCT was associated with reduced risk of having to manually extract the placenta and reduced blood loss (Hofmeyr et al., 2015). The authors recommended that CCT could be offered routinely when the birth attendant has the necessary training but cautioned that considerable investment in training would be necessary for low-resource areas. CCT can be omitted when uterotonic agents are given.
- A randomized controlled trial of 934 women found that the active management group had a significantly higher postpartum hemoglobin than the expectant (non-active) management group (Yildirim et al., 2016).

Apply the Evidence: Nursing Implications

- In developed countries, active management of third-stage labour is beneficial and recommended. However, it may be possible to individualize the protocol for patients at low risk for PPH, in order to accommodate family preferences. Patients should be educated before labour on their options for third-stage management.
- Some patients may request that the cord clamping be delayed until pulsations have ceased. This may benefit the newborn without significantly increasing the patient's risk for PPH.
- Nurses carefully assess the fundus and bleeding while recovering the immediate postpartum patient and are frequently the first to notice PPH.
- A protocol for PPH should be made clear to all staff. All staff should be able to identify excessive bleeding and implement the immediate interventions of emptying the bladder, massaging the uterus, and notifying the health care provider.
- Easily accessed kits of necessary medications should be available, along with training in their use.
- In low-resource countries, CCT should only be used by birth attendants trained in proper technique. Funding for training and further research would be a targeted investment in the prevention of the biggest risk factor for childbearing patients worldwide.
- Understanding the risks and benefits of active management are important for collaborative decision making.

Pat Mahaffee Gingrich

home and dispose of it according to their customs may be at odds with health care agency policies, especially those related to infection control and disposal of biological wastes. Many cultures follow specific rules regarding disposal of the placenta in terms of method (burning, drying, burying, or eating); site for disposal (in or near the home); and timing of disposal (immediately after birth, time of day, or by astrological signs). Disposal rituals may vary according to the sex of the child and the length of time before another child is desired. Health care providers can provide culturally safe health care by encouraging families to express their wishes regarding the care and disposal of the placenta and by establishing a policy to fulfill these requests.

Some cultures believe that eating the placenta is a means of restoring a postpartum patient's well-being after birth or of ensuring high-quality breast milk. Recently, there has been interest among postpartum persons in consuming their placentas to achieve claimed health benefits, including improved mood, energy, and lactation. Because of a lack of good scientific evidence to substantiate claims of the benefits of placentophagy and documented risks related to this practice, the SOGC does not recommend

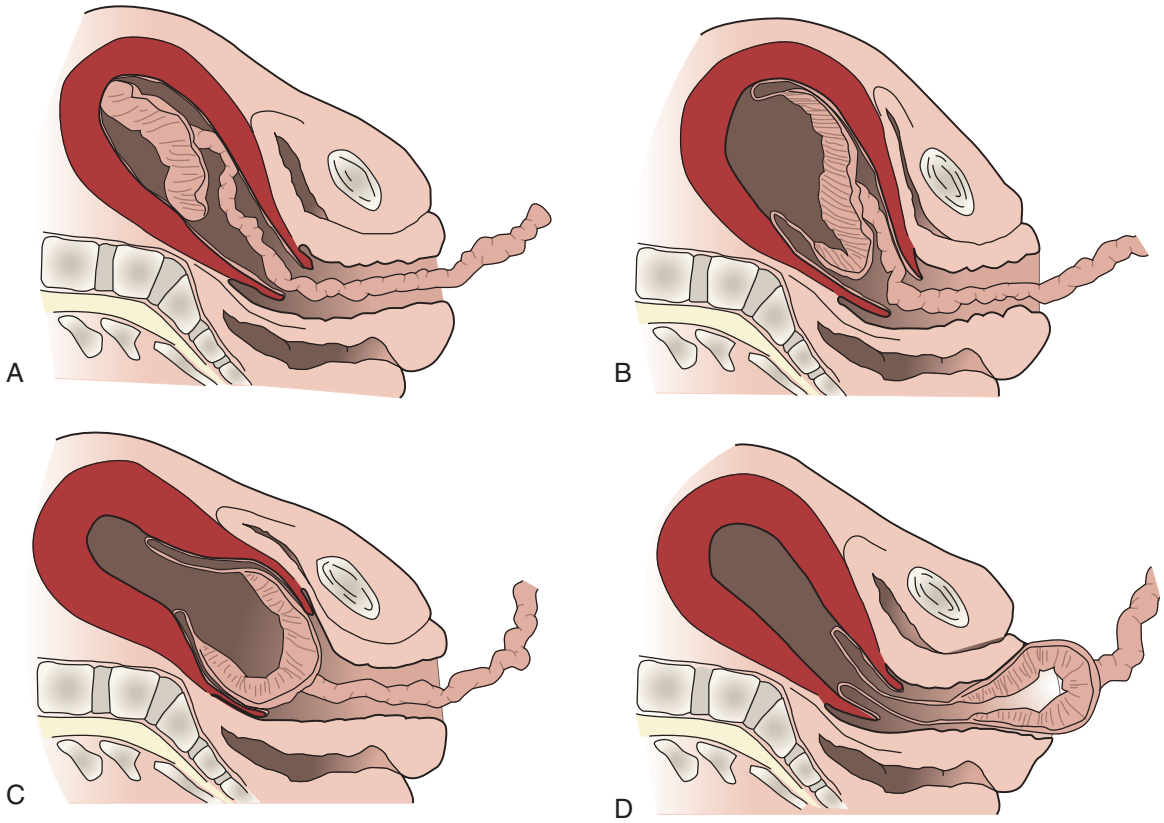

Fig. 17.24 Third stage of labour. **A:** Placenta begins the separation process in central portion, accompanied by retroplacental bleeding. Uterus changes from discoid to globular shape. **B:** Placenta completes separation and enters lower uterine segment. Uterus is globular in shape. **C:** Placenta enters vagina, cord is seen to lengthen, and there may be increased bleeding. **D:** Expulsion (birth) of placenta and completion of third stage.

placentophagy (Elwood et al., 2019). Possible related risks include infection, thromboembolism from estrogens in placental tissue, and accumulation of environmental toxins. Patients need to be given evidence-based information in order to make informed choices (Hayes, 2016).

Umbilical Cord Blood Banking

Increasing numbers of families are requesting that the blood from the umbilical cord be collected and subsequently banked. Blood from the umbilical cord contains hematopoietic stem cells, which offer several advantages over bone marrow or stem cells obtained from other locations when transplanted. Current recommendations for cord blood transplant are limited to certain genetic, hematological, and malignant disorders, however, and it is very unlikely that the child or another family member will develop a condition that could be treated with a transfusion of autologous umbilical cord blood. In Canada, expectant parents may choose public or private cord blood banking. The Canadian Blood Services has set up the National Public Cord Blood Bank in several hospitals across the country. Currently, the patient needs to have their baby at that hospital in order to donate the cord blood. There are a few other options for public donation of cord blood in certain cities (e.g., Toronto area and Montreal/Quebec City). Private cord banking is available in many centres throughout the country; arrangements are made prior to birth of the newborn for collection. The cost of private banking can include an initial fee of $1 000 to $2 000 along with an additional yearly fee. The decision to bank cord blood is a personal one made by parents. Pregnant patients and families should be provided with unbiased information about umbilical cord blood banking options, including the benefits and limitations of public and private banks (Armson et al., 2015).

Fig. 17.25 Examination of the placenta. (iStock.com/AzmanL)

Cord blood collection is done after the birth and before delivery of the placenta. Health care providers need to be aware of the proper method of collection to ensure that the maximum amount of blood is collected and that it is collected in a sterile manner. Delayed cord clamping may decrease the amount of blood collected; parents need to be aware of this so they can make informed choices about the care they want.

FOURTH STAGE OF LABOUR

The **fourth stage of labour** begins with the expulsion of the placenta and lasts until the patient is stable in the immediate postpartum period, usually within the first 2 hours after birth. This is a crucial time for the patient and newborn. Both are not only recovering from the physical process of birth but also becoming acquainted with each other and additional family members. During this time, the postpartum patient's organs undergo their initial readjustment to the nonpregnant state, and the functions of body systems begin to stabilize. Meanwhile, the newborn continues the transition from intrauterine to extrauterine existence. It is important that the newborn is placed skin-to-skin as soon as possible after birth and that breastfeeding is initiated when the newborn shows interest (see further discussion in Chapter 26).

Nursing Care During the Fourth Stage of Labour

In most hospitals the patient remains in the labour and birth area during this recovery time, and the labour and birth nurse cares for both the postpartum parent and newborn. When fourth-stage recovery is complete, the patient will remain in the same room if they are in an LBRP unit or will be transferred to a room on the postpartum unit if they gave birth in an LBR or delivery room. Patients who are in LBRP rooms will stay in one room from admission until discharge. Often the same nurse will care for the family through all parts of the childbirth experience.

If the recovery nurse has not previously cared for the postpartum patient, their assessment begins with a handover report from the nurse who attended the patient during labour and birth and a review of the antenatal, labour, and birth records. Of primary importance are conditions that could predispose the patient to hemorrhage, such as precipitous labour, large baby, grand multiparity (having given birth to six or more infants), induced labour, or a magnesium sulphate infusion during labour. For healthy patients, hemorrhage is probably the most dangerous potential complication.

During the first hour, physical assessments of the postpartum patient are frequent. All factors except temperature are assessed every 15 minutes for 1 hour. Temperature is assessed at the beginning and end of the recovery period. After the fourth 15-minute assessment, if all parameters have stabilized within the normal range, the process is usually repeated once in the second hour. Box 17.17 describes the physical assessment of the patient during the fourth stage of labour.

During the fourth stage of labour, patients may experience intense tremors that resemble shivering from a chill. These are commonly seen and are not related to infection. It is helpful to offer the patient warm blankets and reassurance that the chills or tremors are common and self-limiting and last only a short while.

The nutritional status of the patient needs to be assessed. Restriction of food and fluid intake and the loss of fluids (blood, perspiration, or emesis) during labour cause many patients to express a strong desire to eat or drink soon after birth. In the absence of complications, a patient who has given birth vaginally, has recovered from the effects of the anaesthetic, and has stable vital signs, a firm uterus, and small-to-moderate lochial flow may have fluids and a regular diet, as desired. In the immediate postpartum period patients who have undergone a Caesarean birth may be restricted to clear liquids and ice chips until there is evidence of gastric motility (e.g., hunger, bowel sounds, passing gas), although this practice is not based on good research.

BOX 17.17 Assessment During the Fourth Stage of Labour

Blood Pressure
- Measure blood pressure per assessment schedule (every 15 minutes for first hour).

Pulse
- Assess rate and regularity (every 15 minutes for the first hour).

Temperature
- Determine temperature at the beginning of the recovery period and after the first hour of recovery.

Fundus
- Position patient with knees flexed and head flat.
- Just below the umbilicus, cup hand and press firmly into the abdomen. At the same time, stabilize the uterus at symphysis with the opposite hand (see Figure 22.3).
- If the fundus is firm (and bladder is empty), with uterus in midline, measure its position relative to the patient's umbilicus. Lay fingers flat on the abdomen under the umbilicus; measure how many centimetres fit between the umbilicus and top of the fundus. If the fundus is above the umbilicus, this is recorded as plus (+) cm; if below, as minus (–) cm. One fingerbreadth (fb) equals 1 cm. For example, if fundus is 1 fb or 1 cm above umbilicus, fundal height may be recorded as either +1, u+1, or 1/u. If fundus is 1 fb or 1 cm below umbilicus, fundal height may be recorded as either −1, u−1, or u/1.
- If the fundus is not firm, massage it gently to contract and expel any clots before measuring distance from the umbilicus.
- Place hands appropriately; massage gently only until firm.
- Expel clots while keeping hands placed as in Figure 22.3. With the upper hand, firmly apply pressure downward toward the vagina; observe perineum for amount and size of expelled clots.
- Fundal massage and expressing clots may be uncomfortable for the postpartum patient. Advise taking deep breaths throughout.

Bladder
- Assess distension by noting location and firmness of uterine fundus and observing and palpating the bladder. A distended bladder is seen as a suprapubic rounded bulge that is dull to percussion and fluctuates like a water-filled balloon. When the bladder is distended, the uterus is usually boggy in consistency, well above the umbilicus, and deviated to the patient's right side.
- Assist patient to void spontaneously. Measure amount of urine voided.
- Catheterize as necessary.
- Reassess after voiding or catheterization to make sure that the bladder is not palpable and the fundus is firm and in the midline.

Lochia
- Observe lochia on perineal pads and on linen under the patient's buttocks. Determine amount and colour; note size and number of clots; note odour.
- Observe perineum for source of bleeding (e.g., lacerations, episiotomy).

Perineum
- Ask or assist patient to turn on their side and flex their upper leg on their hip.
- Gently lift upper buttock.
- Observe perineum in good lighting.
- Assess laceration repair or episiotomy site repair for **r**edness (erythema), **e**dema, **e**cchymosis (bruising), **d**rainage, and **a**pproximation (REEDA).
- Assess for presence of hemorrhoids.

Once the postpartum patient has had a chance to bond with the baby, breastfeed, and eat, most new parents are ready for a nap or at least a quiet period of rest. Following this rest period the patient may want to shower and change clothes. Most new parents are capable of self-care or are helped in these activities by family members or support persons.

Postanaesthesia Recovery. The person who has given birth by Caesarean or who has received regional anaesthesia for a vaginal birth requires special attention during the recovery period. Obstetrical recovery areas are held to the same standard of care that would be expected of any other postanaesthesia recovery room. When caring for a patient recovering from anaesthesia, the nurse needs to have available cardiopulmonary support and emergency supplies. Patients who are recovering from anaesthesia require further assessments every 15 minutes, including activity, respirations, oxygen saturation, level of consciousness, and colour.

If the patient received general anaesthesia, they should be awake and alert and oriented to time, place, and person. Their respiratory rate should be within normal limits, and the oxygen saturation levels should be at least 95%. If the patient received epidural or spinal anaesthesia, they should be able to raise their legs, extended at the knees, off the bed; or flex their knees, place their feet flat on the bed, and raise their buttocks well off the bed. The numb or tingling, prickly sensation should be entirely gone from their legs. The length of time required to recover from regional anaesthesia varies greatly. Often it takes several hours for these anaesthetic effects to disappear completely.

Care of the Newborn. A brief assessment of the newborn is performed immediately, even while the postpartum patient is holding the newborn. This assessment includes assigning Apgar scores at 1 and 5 minutes after birth (see Table 26.1). Major priorities for immediate newborn care include maintaining a patent airway, supporting respiratory effort, and preventing cold stress by drying and, preferably, covering the newborn with a warmed blanket while on their parent's abdomen or chest or, less optimally, placing them under a radiant warmer.

The fourth stage of labour is when breastfeeding should be initiated because the newborn is in an alert state and ready to nurse. When the baby is at the breast, the nurse has an opportunity to give the newborn a vitamin K injection. There is strong evidence to support the role of breastfeeding in reducing pain in the newborn during a painful procedure (see Chapter 26). After the baby has gone to the breast, the baby can be weighed and measured, eye prophylaxis administered, and an identification bracelet applied that corresponds to the parent's identification bracelet. Once these activities are done, the baby should be given back to the parent and placed skin-to-skin to support transition of the newborn. In some agencies, the partner (or another person designated by the childbearing patient) is also given a corresponding identification bracelet.

Care of the Family. Most parents enjoy being able to handle, hold, explore, and examine the baby immediately after birth. Parents can assist with the thorough drying of the newborn. Skin-to-skin contact should be encouraged based on cultural expectations (see Cultural Awareness box). Holding the newborn next to the skin of either parent helps to maintain the baby's temperature.

Many parents wish to begin breastfeeding their newborns at this time, to take advantage of the newborn's alert state (first period of reactivity) and stimulate the production of oxytocin that promotes contraction of the uterus and prevents hemorrhage. Breastfeeding should be initiated within the first hour after birth.

CULTURAL AWARENESS

Birth Story: The "Slimy, Wriggling" Infant

Leona moved to Canada from El Salvador several years ago, while pregnant with her second child. She spoke little English and had no family present for her labour and birth—her husband was at home with their older child. Leona explained that when her baby was born, the physician laid him on her abdomen. She took one look at the "slimy, wriggling" baby and promptly "passed out." She remembers waking up in her room some time later.

In El Salvador, she reported, a newborn is washed and wrapped in a blanket before being presented to the mother. She said the "Canadian" approach made the birthing experience much more traumatic than she had expected. Several years later, Leona was able to laugh at the memory, but she did not laugh at the time of her son's birth.

Family–Newborn Relationships

The postpartum patient's reaction to the sight of their newborn may range from excited outbursts of laughing, talking, and even crying to apparent apathy. A polite smile and nod may be the only acknowledgement of the comments of nurses and the primary health care provider. Occasionally, the reaction is one of anger or indifference; the patient turns away from the baby, concentrates on their own pain, and may make hostile comments. These varied reactions can arise from pleasure, exhaustion, or deep disappointment. When evaluating parent–newborn interactions after birth, the nurse should also consider the cultural characteristics of the patient and family and the expected behaviours of that culture. In some cultures, the birth of a male child is preferred, and postpartum patients may grieve when a female child is born (Callister, 2014).

Whatever the reaction and its cause may be, the postpartum patient needs continued acceptance and support from all staff. Notation of the parents' reaction to the newborn should be made in the chart. Nurses can assess this reaction by asking themselves the following questions: How do the parents look? What do they say? What do they do? Further assessment of the parent–newborn relationship can be conducted as care is given during the period of recovery. This assessment is especially important if warning signs (e.g., passive or hostile reactions to newborn, disappointment with sex or appearance of newborn, absence of eye contact, or limited interaction of parents with each other) were noted immediately after birth. The nurse may find it helpful to discuss with the patient's primary health care provider any warning signs that may have been noted.

Siblings often experience interest and excitement when the newborn appears. They can then be encouraged to touch or hold the baby (Figure 17.26).

Parents usually respond to praise of their newborn. Many need to be reassured that the dusky appearance of the baby's extremities (acrocyanosis) immediately after birth is normal until circulation is well established. If appropriate, the nurse should explain the reason for the misshaped nature of the newborn's head due to moulding or caput. Information about hospital routine can be communicated. However, it is important for nurses to recognize that the cultural background of the parents may influence expectations of care and handling of their newborn immediately after birth.

Determining a patient's satisfaction with and impressions of the childbirth experience is a critical component in the provision of high-quality perinatal health care that meets the needs of patients

Fig. 17.26 Big brother being introduced to baby sister. (iStock.com/StudioStella)

and families. Reviewing one's childbirth experience with someone who will listen, support, and explain has been found to reduce the degree of postpartum mood disorders experienced by many patients during the first week or so after birth.

KEY POINTS

- The onset of labour may be difficult to determine for both nulliparous and multiparous patients.
- During the first stage of labour the cervix dilates from 0 to 10 cm dilated. The first stage of labour has two phases: latent (or early) and active.
- The familiar environment of the pregnant person's home is most often the ideal place for a patient during the latent phase of the first stage of labour.
- The nurse assumes much of the responsibility for assessing the progress of labour and keeping the primary health care provider informed about progress in labour and deviations from expected findings.
- The fetal heart rate pattern reveals the fetal response to the stress of the labour process.
- Regardless of the actual labour and birth experience, the patient's or couple's perception of the birth experience is most likely to be positive when events and performances are consistent with expectations, especially regarding the patient maintaining control during labour and birth.
- The labouring person's level of anxiety may rise when they do not understand what is being said to them about their labour because of the medical terminology being used or because of a language barrier.
- Coaching, emotional support, and comfort measures help the labouring patient to use their energy constructively in relaxing and working with the contractions.
- The progress of labour is enhanced when a patient changes their position frequently during the first stage of labour.
- Doulas provide a continuous supportive presence during labour that can have a positive effect on the process of childbirth and its outcome.
- The cultural beliefs and practices of a patient and support people, including the partner, can have a profound influence on their approach to labour and birth.
- The quality of the nurse–patient relationship is a factor in the patient's ability to cope with the stressors of the labour process.
- Siblings present for labour and birth need preparation and support for the event.
- Persons with a history of sexual abuse often experience profound stress and anxiety during childbirth, and care must be taken that they are not retraumatized during labour and birth.
- Assessment of the labouring patient's urinary output and bladder is critical to ensure their progress and prevent injury to the bladder.
- Inability to palpate the cervix during vaginal examination indicates that complete effacement and full dilation have occurred and is the only certain, objective sign that the second stage has begun.
- When allowed to respond to the rhythmic nature of the second stage of labour, the patient normally changes body position, bears down spontaneously, and vocalizes (open-glottis pushing) when they perceive the urge to push (Ferguson reflex).
- Nurses can advocate to prevent routine use of episiotomy and reduce the incidence of lacerations by empowering patients to take an active role in their childbirth and educating health care providers about approaches to managing childbirth that reduce the incidence of perineal trauma.
- Objective signs indicate that the placenta has separated and is ready to be expelled; excessive traction (pulling) on the umbilical cord, before the placenta has separated, can result in patient injury.
- During the fourth stage of labour the patient's fundal tone, lochial flow, and vital signs should be assessed frequently to ensure recovery after giving birth.
- Most parents and families enjoy being able to handle, hold, explore, and examine the baby immediately after birth. Skin-to-skin contact between the parents and baby should be encouraged.
- Patients should be encouraged to initiate breastfeeding within 60 minutes of birth.
- Stimulation of the patient's nipple manually or by the infant's suckling stimulates the release of oxytocin from the posterior pituitary gland. Oxytocin stimulates the uterus to contract and thereby prevents hemorrhage.
- Nurses should observe progress in the development of parent–child relationships and be alert for warning signs that may appear during the immediate postpartum period.

Maximizing Comfort During Labour and Birth

Laura Payant
Originating US Chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Discuss sources of intrapartum discomfort and pain.
2. Discuss physiological and psychological factors that affect a patient's perception and response to pain during labour and birth.
3. Describe nonpharmacological methods to maximize comfort during labour and birth.
4. Describe breathing and relaxation techniques used for each stage of labour.
5. Discuss types of analgesia and anaesthesia used during labour and birth.
6. Describe methods of assessing a patient's coping during labour.
7. Describe nursing care and support for patients receiving pharmacological and nonpharmacological pain management during labour and birth.

Although labour and birth are considered to be natural processes, labouring patients may experience discomfort and pain, as well as a variety of other challenging sensations. Labour pain is situation specific and of limited duration and, contrary to many other sources of pain, is not indicative of underlying pathology but part of a normal physiological process. Labour pain is also a complex, multidimensional experience that is unique to each person and includes sensory, cognitive, and affective components.

Pregnant patients commonly worry about the pain they will experience during labour and birth and how they will respond to and cope with that pain. A variety of nonpharmacological and pharmacological methods can help manage the pain of labour. The methods selected depend on the situation, their availability, the health care providers' knowledge of labour pain management, and the preferences of the labouring patient.

This chapter discusses sources of intrapartum discomfort and pain and factors that affect a patient's perception and response to pain in labour and birth. It will also describe pain management options and nursing care for nonpharmacological and pharmacological methods commonly used for pain relief during labour and birth.

PAIN DURING LABOUR AND BIRTH

Neurological Origins

The pain and discomfort experienced during labour originates from different sites as labour progresses. The pain has three origins: visceral, somatic, and referred. During the first stage of labour, pain originates from the uterus and cervix. Uterine contractions cause cervical effacement and dilation. Uterine *ischemia* (decreased blood flow and therefore local oxygen deficit) results from compression of the arteries supplying the myometrium during uterine contractions. Pain impulses during the first stage of labour are transmitted via the T10 to T12 and L1 spinal nerve segments and accessory lower thoracic and upper lumbar sympathetic nerves. These nerves originate in the uterine body and the cervix (Blackburn, 2018).

Visceral pain is generated from distension of the lower uterine segment, stretching of cervical tissues as it effaces and dilates, pressure and traction on adjacent structures (e.g., fallopian tubes, ovaries, ligaments) and nerves, and uterine ischemia that predominates during the first stage of labour. Visceral pain is felt over the lower portion of the abdomen. *Referred* pain occurs when the pain that originates in the uterus radiates to the abdominal wall, lumbosacral area of the back, iliac crests, gluteal area, thighs, and lower back (Blackburn, 2018).

During most of the first stage of labour, the patient usually experiences discomfort only during contractions and is free of pain between contractions. Some labouring patients, especially those whose fetus is in a posterior position, experience continuous contraction-related low back pain, even in the interval between contractions. As labour progresses and the pain becomes more intense and persistent, patients may become fatigued and discouraged, often experiencing difficulty coping with contractions (Blackburn, 2018; Burke, 2014).

During the second stage of labour, the patient experiences *somatic* pain, which is often described as intense, sharp, burning, and well localized. This pain results from the following:

- Distension of and traction on the peritoneum and uterocervical supports during contractions
- Pressure against the bladder and rectum
- Stretching and distention of perineal tissues and the pelvic floor to allow passage of the fetus
- Lacerations of soft tissue (e.g., cervix, vagina, perineum)

As labouring patients concentrate on the work of bearing down to give birth to their baby, they may report a decrease in pain intensity. Pain impulses during the second stage of labour are carried from perineal tissues via the S2–S4 spinal nerve segments and the parasympathetic system (Blackburn, 2018). During the second stage of labour, patients also experience rectal pressure and an urge to push.

Pain experienced during the third stage of labour and the afterpains of the early postpartum period are uterine, similar to that experienced early in the first stage of labour. Areas of discomfort during labour are illustrated in Figure 18.1.

Perception of Pain

The physiological causes of pain during labour are the same for all patients. However, pain is a subjective experience and is defined completely by the person who is experiencing it. Therefore, patients vary in how they perceive and cope with labour pain. Factors that influence the way a person deals with pain include culture, age, previous personal experience with pain, parity, and the physical, psychological, and emotional support available to them (Collins, 2017). The unique circumstances of every labour (e.g., previous surgical or diagnostic procedures that affect the responsiveness of the cervix to uterine contractions, medical and nursing procedures performed during labour, and length of labour) also influence the patient's experience of pain (Burke, 2014).

Pain tolerance refers to the level of pain, in this case a labouring patient, is able to endure. When this level is exceeded, the patient will seek measures to relieve the pain. Factors that influence a patient's pain tolerance level and whether they request pharmacological pain relief measures include their desire for a medication-free birth, their childbirth preparation, the nature of their support during labour, the health care environment, and the willingness and ability of the patient to participate in nonpharmacological measures for comfort (Burke, 2014).

Expression of Pain

Pain is expressed by both physiological and sensory or emotional (affective) reactions. During labour and birth, the pain or discomfort experienced gives rise to identifiable physiological effects. Sympathetic nervous system activity is stimulated in response to anxiety, stress, and intensifying pain, resulting in increased catecholamine levels. Blood pressure and heart rate increase. The patient's respiratory patterns change in response to an increase in oxygen consumption. Hyperventilation, sometimes accompanied by respiratory alkalosis, can occur as pain intensifies. Placental perfusion may decrease, and uterine activity may diminish, potentially prolonging labour and affecting fetal well-being (Burke, 2014).

Certain emotional (affective) expressions of pain often are seen. Such changes include increasing anxiety with lessened perceptual field, writhing, crying, groaning, gesturing (hand clenching and wringing), and excessive muscular excitability throughout the body.

Factors Influencing Pain Response

Pain during childbirth is unique to each labouring patient. How they perceive or interpret that pain is influenced by a variety of physiological, psychological, emotional, social, cultural, and environmental factors. Labouring patients' perception of their personal control during labour has been found to enhance their satisfaction with pain management during childbirth (Callister, 2014). Labouring patients who approach pain as a challenge for which they have sufficient resources to cope effectively are unlikely to equate pain with suffering. In contrast, patients who do not feel confident about their ability to cope with pain or do not have coping strategies may feel threatened and view their pain experience as suffering.

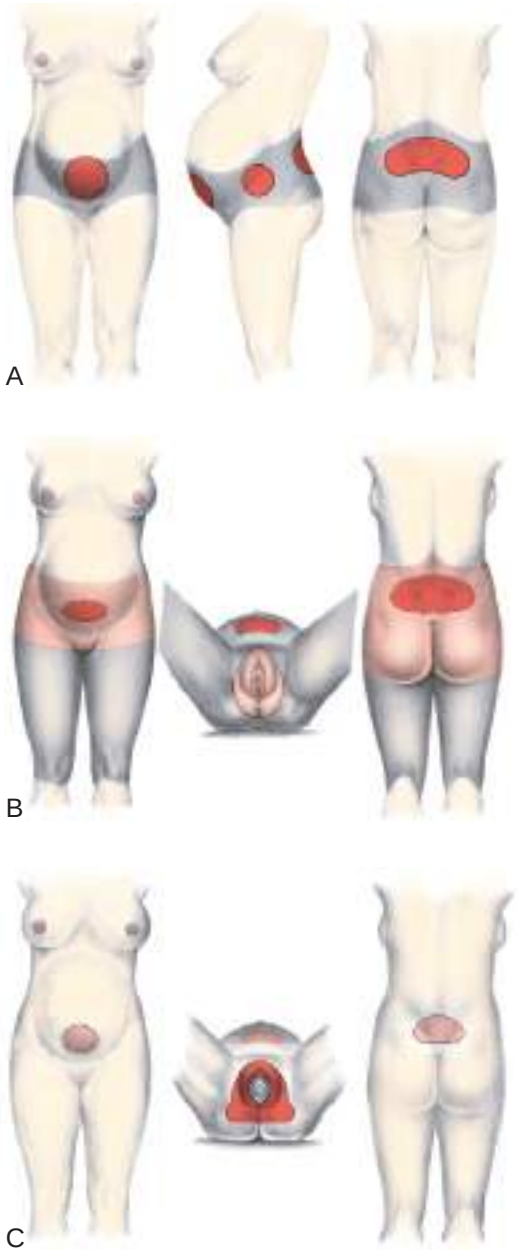

Fig. 18.1 Discomfort during labour. **A:** Distribution of labour pain during first stage. **B:** Distribution of labour pain during later phase of first stage and early phase of second stage. **C:** Distribution of labour pain during later phase of second stage and during birth. (Grey shading indicates areas of mild discomfort; light-coloured shading indicates areas of moderate discomfort; dark-coloured shading indicates areas of intense discomfort.)

Pain is normally something most people try to avoid, but pain in labour needs to be presented as normal and having an important role in promoting labour. Patients who learn to work with the pain may facilitate movement of the fetus through the birth canal. Actively responding to the pain by changing positions, rocking, or moaning may speed up the process of labour. Those people supporting the labouring patient also need to understand the role of pain in normal labour and to feel comfortable watching the patient work with the pain.

Physiological Factors. A variety of physiological factors can affect the intensity of pain experienced by patients during childbirth. Physical factors that affect pain intensity include a scarred cervix, fatigue, the interval and duration of contractions, fetal size and position, rapidity of fetal descent, and maternal position (Burke, 2014). When upright positions are assumed during labour, they seem to result in decreased pain and an overall increase in comfort compared with that in the supine position. Labouring patients also report that being able to move freely to find a position of comfort is an important factor in reducing pain and muscle tension and in maintaining control during labour (Simkin & Ancheta, 2005). The relation of fetal size to the dimensions of the pelvis of the labouring patient may also influence pain intensity.

Beta-endorphins are endogenous opioids secreted by the pituitary gland that act on the central and peripheral nervous systems to reduce pain. The level of beta-endorphins increases during pregnancy and birth in humans. Beta-endorphins are associated with feelings of euphoria and analgesia. The pain threshold may rise as beta-endorphin levels increase, enabling patients in labour to tolerate acute pain (Blackburn, 2018).

Culture. As nurses care for patients and families from a variety of cultural backgrounds, they must have knowledge and understanding of how culture mediates the response to pain. Although all patients expect to experience at least some pain and discomfort during childbirth, it is often their culture and religious belief system that determines how they will perceive, interpret, respond to, and manage the pain. Cultural influences may impose certain behavioural expectations regarding acceptable and unacceptable behaviour when one experiences pain.

An understanding of the beliefs, values, expectations, and practices of various cultures will provide the nurse with some information about how the patient might respond to pain, but in order to provide culturally competent nursing care, the nurse must assess each patient individually, as each patient may have a different experience and response to the pain. This will, in turn, enable the nurse to provide appropriate pain-relief measures that preserve the patient's sense of control and self-confidence. It is important for the nurse to recognize that, although a patient's behaviour in response to pain may vary according to their cultural background, it may not accurately reflect the intensity of the pain being experienced. The nurse must assess the patient for the physiological effects of pain and listen to the words the patient uses to describe the sensory and affective qualities of the pain (Callister, 2014) (see Cultural Awareness box Culture and Pain).

CULTURAL AWARENESS

Culture and Pain

Talk to a patient and their partner from a culture different from your own who have experienced childbirth. Ask the patient to describe their reactions to pain, how they sought relief of pain, the atmosphere of the childbirth setting, and the attitudes of the health care providers. Ask the partner if they were present for the birth and to describe their role in the birth. How did the partner's culture influence their role and reaction to childbirth? How did the patient's culture influence their response to labour and the associated pain? What expressions of pain are "acceptable" in their culture? If the partner was present, how did they help the labouring person cope with the pain? What is the role of support persons in the labour process? Are the responses of the couple different from your responses to those same questions?

Anxiety and Fear. Anxiety and fear are commonly associated with increased pain during labour. Mild anxiety is considered normal for a patient during labour and birth. However, excessive anxiety and fear cause catecholamine secretion, which increases the stimuli to the brain from the pelvis because of decreased blood flow and increased muscle tension. As anxiety heightens, muscle tension increases, the effectiveness of the uterine contractions decreases, and the experience of discomfort increases, and a cycle of increased fear and anxiety begins (Figure 18.2) (Blackburn, 2018). Ultimately, this cycle will slow the progress of labour, as the catecholamine secretion can decrease the secretion of oxytocin from the hypothalamus. The patient's confidence in their ability to cope with pain will be diminished, potentially resulting in reduced effectiveness of pain-relief measures being used.

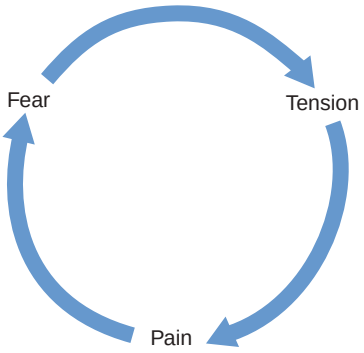

Fig. 18.2 Fear–tension–pain cycle.

Previous Experience. Previous experience with pain and childbirth may affect a patient's description of pain and their ability to cope with it. Childbirth for a healthy young adult may be a first experience with significant pain; thus, the patient may not have developed effective pain coping strategies. The intensity of even early labour pain may be described as "the worst pain imaginable." The nature of previous childbirth experiences also may affect a patient's responses to pain. For patients who have had a difficult and painful previous birth experience, anxiety and fear from the past experience may lead to an increased perception of pain (see Clinical Reasoning Case Study: Anxiety in a Multipara in Active Labour). Conversely, a patient who has experienced a labour and birth in which the degree of pain matched their expectations and in which their coping skills were successful may have less anxiety and feel a sense of pride in their accomplishment. However, anxiety is likely to increase if previously successful coping skills were ineffective during a more difficult labour.

CLINICAL REASONING CASE STUDY

Anxiety in a Multipara in Active Labour

Jody was admitted in labour to a labour, birthing, and recovery (LBR) room 2 hours ago. She is 39 weeks' gestation in her second pregnancy. She is noticeably anxious and tells you that her first pregnancy ended at term but that the labour was "terrible. It was 22 hours long. I had an epidural but had to push and push to get the baby out."

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about what interventions may be appropriate?
2. Assumptions— What assumptions can be made about the following factors?
   a. Effects of anxiety on progress in labour
   b. Effect of parity on labour
   c. Effect of epidural analgesia on ability to push
   d. Education needed by Jody
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusions?

Sensory pain for **nulliparous** patients is often greater than that for **multiparous** patients during early latent labour (dilation less than 4 cm) because their reproductive tract structures are less supple. However, during the active phase of the first stage of labour and during the second stage of labour, multiparous patients may experience greater sensory pain than nulliparous patients because their more supple tissue increases the speed of fetal descent and thereby intensifies discomfort. The firmer tissue of nulliparous patients results in a slower, more gradual descent (Archie & Roman, 2013). Parity may also influence the perception of labour pain because nulliparous patients often have longer labours and therefore tend to experience greater fatigue. Fatigue magnifies pain, thus causing many patients to have an increased perception of the intensity of pain during labour.

Gate-Control Theory of Pain. Intense pain stimuli can at times be ignored. This is possible because certain nerve cell groupings within the spinal cord, brainstem, and cerebral cortex have the ability to modulate the pain impulse through a blocking mechanism. The gate-control theory of pain helps explain the way that some pain-relief techniques taught in childbirth preparation classes work to relieve the pain of labour. According to this theory, pain sensations travel along sensory nerve pathways to the brain, but only a limited number of sensations, or messages, can travel through these nerve pathways at one time. Using distraction techniques, such as massage or stroking, music, focal points, and imagery, reduces or completely blocks the capacity of nerve pathways to transmit pain. These distractions are thought to work by closing down a hypothetical gate in the spinal cord, thus preventing pain signals from reaching the brain and decreasing the perception of pain (Dean et al., 2013).

In addition, when the patient in labour engages in neuromuscular and motor activity, such as changing positions and walking, activity within the spinal cord itself further modifies the transmission of pain. Cognitive work involving concentration on breathing and relaxation requires selective and directed cortical activity that activates and closes the gating mechanism as well. As labour intensifies, more complex cognitive techniques are required to maintain effectiveness. The main impetus behind the gate-control theory as it relates to pain is to introduce the brain to a positive stimulus by using all of the five senses. The brain then begins to accept the more positive stimulus, while paying less attention to negative stimuli such as discomfort or pain. Stimulating the senses will not create a pain-free environment, but it can help decrease the discomforts of labour.

Supportive Care. Although the predominant medical approach to labour is that it is painful and the pain must be removed, an alternative view is that labour is a natural process; patients can experience comfort and transcend the discomfort or pain of birth. Having needs and desires met engenders a feeling of comfort. Comfort may be viewed as strengthening. The most helpful interventions in enhancing comfort are using a caring nursing approach and providing a continuous supportive presence. The World Health Organization (2018) recommends that care during labour should respect the patient's dignity, privacy, confidentiality, and culture while also ensuring that the patient is free of harm, is permitted informed choices, and is provided with continuous support during labour and birth (see Figure 17.1). The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends that health care providers support patients in their choice of pain-management options, which may include both pharmacological and nonpharmacological options (Lee et al., 2016).

Evidence indicates that a patient's satisfaction with a childbirth experience is determined by how well their personal expectations of childbirth were met and the quality of support and interaction they received from caregivers (Box 18.1). In addition, satisfaction is influenced by the degree to which the patient was able to stay in control of their labour and to participate in decision making regarding the labour, including the pain-relief measures used (Collins, 2017).

The value of the continuous supportive presence of a person (e.g., doulas, family members, friends, nurses, or partner) who provides physical comfort, facilitates communication, and offers information and guidance to the patient in labour has long been known. Emotional support is demonstrated by giving praise and reassurance and conveying a positive, calm, and confident demeanor when caring for the patient in labour (Borders et al., 2013). Patients who have continuous support beginning early in labour are less likely to use pain medications or epidural analgesia or anaesthesia and are more likely to experience a spontaneous vaginal birth and express satisfaction with their childbirth experience. Interestingly, research findings have concluded that a more positive effect was achieved when continuous support was provided by people other than hospital staff members (Bohren et al., 2017). The SOGC recommends that all patients in labour receive continuous close support from an appropriately trained person (Lee et al., 2016; Dore & Ehman, 2020).

Environment. The quality of the environment can influence pain perception and the labouring patient's ability to cope with their pain. Environment includes the individuals present (e.g., how they communicate, their philosophy of care, practice policies, and quality of support) and the physical space in which the labour occurs. Patients who are in a supportive environment feel more in control and thus are more likely to have a better labour and birth experience. Studies have shown a correlation between perceived control in childbirth and increased satisfaction with the entire childbirth experience (Meyer, 2013).

Labouring patients often prefer to be cared for by familiar caregivers in a comfortable, homelike setting. The environment should be safe and private, allowing a patient to feel free to be themselves as they try out different comfort measures. Stimuli such as light, noise, and temperature should be adjusted according to the patient's preferences. The environment should have space for movement, and equipment should be readily available for a variety of nonpharmacological pain-relief measures, such as birthing balls, comfortable chairs, tubs, and showers. The familiarity of the environment can be enhanced by bringing items from home, such as pillows, objects for a focal point, and music.

BOX 18.1 Suggested Measures for Supporting a Patient in Labour

- Provide companionship and reassurance.
- Offer positive reinforcement and praise.
- Encourage participation in distracting activities and nonpharmacological measures for comfort.
- Encourage fluid intake.
- Provide nourishment if possible.
- Assist with personal hygiene.
- Offer information and advice.
- Ensure the patient is the primary decision maker regarding their care.
- Interpret the patient's wishes to other health care providers and to their support group.
- Create a relaxing environment.
- Use a calm and confident approach.
- Support and encourage the patient's family members by role modelling labour support measures and providing time for breaks.

Childbirth Preparation Methods. The childbirth education movement began in the 1950s. Historically, popular childbirth methods taught in Canada and the United States were the Dick-Read method, the Lamaze method, and the Bradley method (husband-coached childbirth). Although these three organizations continue to exist, they are now less focused on a "method" approach. Rather, pregnant patients are assisted to develop their birth philosophy and inner knowledge and then choose from a variety of skills to use to cope with the labour process. Few childbirth educators adhere strictly to one particular method. Instead, they incorporate a variety of strategies aimed at increasing the labouring patient's ability to cope with labour and minimize the need for medication.

Gaining popularity are methods developed and promoted by Birthing From Within, Childbirth and Postpartum Professional Association (CAPPA), HypnoBirthing, and the Bonapace Method, to name a few (see Additional Resources at end of the chapter). These organizations offer classes and other services that focus on a patient's confidence in their innate ability to give birth. The pregnant person or couple are helped to recognize the uniqueness of their pregnancy and childbirth experience.

Most proponents of prepared childbirth agree that the major causes of pain in labour are fear and tension (see Figure 18.2). The aim of all childbirth methods is to reduce these factors and eliminate pain by increasing the pregnant patient's knowledge of the labour and birth process, enhancing their self-confidence and sense of control, preparing a support person, and training the pregnant person in physical conditioning and relaxation breathing.

In the role as advocate, the childbirth educator can let families know which care routines are ineffective or harmful and provide expectant parents ways to ask their care providers about their own routine practices. These discussions might affect their choice of care provision.

Attendance at childbirth education classes in Ontario is reported to be approximately one in four pregnant persons, with the majority of attendees being first-time parents, and virtually all people who took prenatal classes found them to be useful (Best Start Resource Centre, 2014). Increasing numbers of pregnant persons are utilizing online childbirth education rather than attending traditional classes because it may be less expensive and more convenient for many working patients and their partners.

Nonpharmacological Pain Management

Relieving or reducing pain during labour is important. Nonpharmacological measures are often simple and safe, have few if any major adverse effects, are relatively inexpensive, and can be used throughout labour. In addition, they provide the patient with a sense of control over their childbirth as they make choices about the measures that are best for them. During the prenatal period, the patient should explore a variety of nonpharmacological measures. Techniques that they find helpful in relieving stress and enhancing relaxation (e.g., music, meditation, massage, warm baths) may be very effective as components of a plan for managing labour pain. The patient should be encouraged to communicate to the health care provider their preferences for relaxation and pain-relief measures and to actively participate in their implementation.

Many of the nonpharmacological methods for relief of discomfort are taught in different types of prenatal preparation classes, and the patient or couple may have searched the Internet or read various books on the subject in advance (see Community Focus box). Many of these methods require practice for best results (e.g., hypnosis, patterned breathing, controlled relaxation techniques, and biofeedback), although the nurse may use some of them successfully without the labouring patient or couple having prior knowledge of them (e.g., slow-paced breathing, massage and touch, effleurage, counterpressure). Labouring patients should be encouraged to try a variety of methods and to seek alternatives if the measure being used is no longer effective.

Nonpharmacological methods may be used in combination with pharmacological methods, particularly as labour progresses.

COMMUNITY FOCUS

Resources for Alternative and Complementary Methods of Pain Relief

Survey your community for services that provide pregnant patients with instruction in complementary or alternative nonpharmacological methods (e.g., biofeedback, aromatherapy, yoga, transcutaneous electrical nerve stimulation, massage, hypnosis) to relieve and cope with discomforts in pregnancy and pain during labour. Create a booklet that describes each of the methods. Include the following information in the booklet:

- A description of the methods and how they work
- Evidence available to validate effectiveness of the methods
- Internet URLs of resources for the methods
- Agencies providing instruction in the methods; include contact information (address, telephone number), cost of the classes or service, and credentials of persons providing instruction
- At what point in pregnancy instruction should begin and the level of preparation and practice necessary for effective use

With the increasing use of epidural analgesia, nurses may be less likely to encourage patients to use nonpharmacological measures, in part because these methods may be viewed as more complex and time-consuming than monitoring a patient receiving an epidural. In addition, new nurses may not have had the opportunity to develop skill in the implementation of these methods. It is imperative that perinatal nurses develop a commitment to and expertise in using a variety of nonpharmacological pain-relief strategies in order to provide these as options for labouring patients. Although research data to support the effectiveness of many of these nonpharmacological measures are limited, there are sufficient reports of their benefits from patients and health care providers to recommend that nurses encourage their use (Burke, 2014). The analgesic effect of many nonpharmacological measures is comparable or even superior to that of opioids that are administered parenterally (Box 18.2).

Relaxation. Relaxation or reduction of body tension is a technique suggested by virtually all childbirth education organizations. Learning relaxation in childbirth education classes can help couples with the stresses of pregnancy, childbirth, and adjustment to parenting and can be a form of stress management throughout life (Figure 18.3). Evidence suggests that relaxation lowers the intensity of labour pain during the latent phase (Smith et al., 2018a). Relaxation is ideally combined with activity such as walking, slow dancing, rocking, and position changes that help the baby rotate through the pelvis. Rhythmic motion stimulates mechanoreceptors in the brain, which decreases pain perception.

The nurse can assist the patient by providing a quiet and relaxed environment, offering cues as needed, and recognizing signs of tension (e.g., frowning, change in tone of voice, clenching of fists). A relaxed environment for labour is created by controlling sensory stimuli (e.g., light, noise, temperature) and reducing interruptions. Nurses should remain calm and unhurried in their approach and sit rather than stand at the bedside whenever possible (Burke, 2014).

BOX 18.2 Nonpharmacological Strategies to Encourage Relaxation and Relieve Pain

Cutaneous Stimulation Strategies
Counterpressure
Effleurage (light massage)
Therapeutic touch and massage
Walking
Rocking
Changing positions
Application of heat or cold
Transcutaneous electrical nerve stimulation (TENS)
Acupressure/acupuncture
Hydrotherapy (showers, bath)
Intradermal water block

Sensory Stimulation Strategies
Aromatherapy
Breathing techniques
Music
Imagery
Use of focal points

Cognitive Strategies
Childbirth education
Relaxation
Hypnosis
Biofeedback

Fig. 18.3 Expectant parents learning relaxation techniques. (From Marblehead Parenting. http://www.marbleheadparenting.com/prenatal1.html).

Imagery and Visualization. Imagery and visualization are useful techniques to purposely direct thoughts to relieve stress and provide a sense of relief (Burke, 2014). Imagery and visualization can be used to produce a sense of well-being during pregnancy, assist with cervical dilation, and decrease the experience of pain and tension during labour. With imagery the patient focuses their attention on a pleasant scene, a place where they feel relaxed, or an activity they enjoy. The person might imagine walking through a restful garden or breathing in light, energy, and a healing colour, and breathing out worries and tension. Visualization of the baby coming down the birth canal during the second stage of labour can also be used effectively to enhance pushing efforts. Choosing the subject for the imagery and practising the technique during pregnancy can enhance effectiveness during labour. All of these can be taught as lifetime skills useful to the couple and can be used to teach their children to cope with the stresses of life.

Music. Music can provide a distraction, enhance relaxation, and lift spirits during labour, thereby reducing the patient's level of stress and anxiety and the perception of pain. It can be used to promote relaxation in early labour and to stimulate movement as labour progresses. Music can help create a more relaxed atmosphere in the birth room, leading to a more relaxed approach by health care providers. Patients should be encouraged to prepare their musical preferences in advance and to bring an electronic musical device with them in labour. They should choose familiar music that is associated with pleasant memories, which can also facilitate the process of guided imagery and cause the release of endorphins, which can alter the perception of pain (Burke, 2014; Collins, 2017). Use of a headset or earphones may increase the effectiveness of the music because other sounds will be shut out. Live music provided at the bedside by a support person may be helpful in transmitting energy that decreases tension and elevates mood. Changing the tempo of the music to coincide with the rate and rhythm of each breathing technique may facilitate proper pacing. Music may have a role with reducing pain and increasing satisfaction with pain relief, although the quality of evidence varies from very low to low (Smith et al., 2018a).

Touch and Massage. Touch and massage have been an integral part of the traditional care for labouring patients. A variety of massage techniques have been shown to be safe and effective during labour (Smith et al., 2018b).

Touch can be as simple as holding the patient's hand, stroking their body, or embracing them. When using touch to communicate caring, reassurance, and concern, it is important that the patient's preference for touch (e.g., who can touch them, where they can touch them, and how they can touch them) and responses to touch be determined. Patients with a history of sexual abuse or from varying cultural backgrounds may be uncomfortable with touch. Touch may potentially cause flashbacks when there is a history of abuse. Thus it is important to ask permission before touching any patient.

Therapeutic touch (TT) is based on the concept of energy fields within the body that are called *prana*. Prana are thought to be deficient in some people who are in pain. TT conducted by a specially trained person works to redirect disrupted energy fields associated with pain. Research has demonstrated the effectiveness of TT to enhance relaxation, reduce anxiety, and relieve pain (Aghabati et al., 2010); however, little is known about the use or effectiveness of TT for relieving pain in labour.

Head, hand, back, shoulder, and foot massage may be effective in reducing tension and enhancing comfort. Some evidence suggests that massage may improve management of labour pain (Jones et al., 2012; Smith et al., 2018b). Hand and foot massage may be especially relaxing in advanced labour when hyperesthesia limits a patient's tolerance for touch on other parts of their body. Combining massage with aromatherapy oil or lotion enhances relaxation both during and between contractions. The patient and their partner should be encouraged to experiment with different types of massage during pregnancy to determine which might feel best and be most relaxing during labour.

Breathing Techniques. Different approaches to childbirth preparation use varying breathing techniques to provide distraction, thereby reducing the perception of pain and helping the patient to maintain control throughout contractions. Relaxed individuals automatically slow their breathing; conversely, slowing one's breathing serves to increase one's relaxation and hence may decrease the feeling of pain. In the first stage of labour, such breathing techniques can promote relaxation of the abdominal muscles and thereby increase the size of the abdominal cavity. This lessens discomfort generated by friction between the uterus and abdominal wall during contractions. Because the muscles of the genital area also become more relaxed, they do not interfere with fetal descent. In the second stage, breathing is used to increase abdominal pressure and thereby assist in expelling the fetus. Breathing also can be used to relax the pudendal muscles to prevent precipitate expulsion of the fetal head (Figure 18.4).

During labour, nursing support includes guiding labouring patients in applying breathing and relaxation methods, adapting methods to their particular needs, and using pushing techniques for birth that avoid breath holding. Such techniques often involve moaning or making other noises as the patient pushes without holding their breath. There is no one right way to breathe; labouring patients are encouraged to find what works for them.

Various breathing techniques can be used for controlling pain during contractions (Box 18.3). The nurse needs to determine what, if any, techniques the labouring couple knows before giving them instruction. Simple patterns are more easily learned. **Paced breathing** is most associated with prepared childbirth and includes slow-paced, modified-paced, and patterned-paced (pant-blow) breathing techniques. Each labour is different, and nursing support includes assisting couples to adapt breathing techniques to their individual labour experience.

The patient and their support person must be aware of and watch for symptoms of respiratory alkalosis when rapid, shallow breathing results in hyperventilation: light-headedness, dizziness, tingling of fingers, or circumoral numbness. Respiratory alkalosis may be eliminated by having the person breathe into a paper bag held tightly around the mouth and nose. This enables them to rebreathe carbon dioxide and replace the bicarbonate ion. The patient can also breathe into their cupped hands if no bag is available. Maintaining a breathing rate that is not more than twice the normal rate will lessen the chances of the patient hyperventilating. The partner can help the labouring patient maintain their breathing rate with visual, tactile, or auditory cues.

Fig. 18.4 Labouring patient using focusing, breathing, and touch from partner during a contraction.

BOX 18.3 Conscious Breathing Techniques

Cleansing Breath

Relaxed breath in through the nose and out the mouth. Used at the beginning and end of each contraction.

Slow-Paced Breathing (Approximately 8 to 10 Breaths/min)

Performed at approximately half the normal breathing rate using deep breaths into the abdomen.

IN-2-3-4/OUT-2-3-4/IN-2-3-4/OUT-2-3-4

Modified-Paced Breathing (Approximately 32 to 40 Breaths/min)

Performed at about twice the normal breathing rate using shallow breathing into the upper chest. Can use the mouth or nose for breathing in and out.

IN-OUT/IN-OUT/IN-OUT …

For more flexibility and variety, the labouring patient may combine the slow and modified breathing by using the slow breathing for beginnings and ends of contractions and modified breathing for more intense peaks. This technique conserves energy, lessens fatigue, and reduces the risk of hyperventilation.

Patterned-Paced Breathing or Pant-Blow Breathing (Same Rate as Modified)

Enhances concentration

3:1 Patterned breathing IN-OUT/IN-OUT/IN-OUT/IN-BLOW (repeat through contractions)

4:1 Patterned breathing IN-OUT/IN-OUT/IN-OUT/IN-OUT/IN-BLOW (repeat through contractions)

As the fetal head reaches the pelvic floor, the patient may feel the urge to push and may automatically begin to exert downward pressure by contracting their abdominal muscles. During second-stage pushing, the labouring patient should find a breathing pattern that is relaxing and feels good to them and is safe for the baby. Any regular or rhythmic breathing that avoids prolonged breath holding during pushing should maintain a good oxygen flow to the fetus.

The patient can control the urge to push by taking panting breaths or by slowly exhaling through pursed lips (as though blowing out a candle or blowing up a balloon). This type of breathing can be used to overcome the urge to push when the cervix is not fully prepared (e.g., less than 8 cm dilated, not retracting) and to facilitate a slow birth of the fetal head.

Effleurage and Counterpressure. **Effleurage** (light massage) and counterpressure bring relief to many patients during the first stage of labour. The gate-control theory may supply the reason for the effectiveness of these measures. *Effleurage* is a light stroking, usually of the abdomen, often in rhythm with breathing during contractions. It is used to distract the patient from contraction pain. The presence of electronic fetal monitor belts may make it difficult to perform effleurage on the abdomen; thus a thigh or the chest may be used. As labour progresses, *hyperesthesia* (hypersensitivity to touch) may make effleurage uncomfortable and thus less effective.

Counterpressure is steady pressure by a support person to the sacral area with a firm object (e.g., tennis ball) or the fist or heel of the hand. Pressure can also be applied to both hips (double hip squeeze) or to the knees. Application of counterpressure helps the labouring patient cope with the sensations of internal pressure and pain in the lower back. It is especially helpful when back pain is caused by pressure of the occiput against spinal nerves when the fetal head is in an occiput-posterior position. Counterpressure lifts the occiput off these nerves, thereby

providing pain relief. If the support person is providing this pressure, they will need to be relieved occasionally because application of counterpressure is hard work.

Hydrotherapy. Bathing, showering, water immersion, and jet hydrotherapy (whirlpool baths) using warm water (e.g., at body temperature) are nonpharmacological measures that can promote comfort and relaxation during labour (Figure 18.5) and may decrease the use of regional analgesia (Cluett et al., 2018). Water immersion is a specific form of hydrotherapy that involves immersion of the labouring patient in water deep enough to completely cover the abdomen.

The water increases buoyancy and provides a sense of weightlessness and freedom of movement. Patients who labour in water report less anxiety and pain, as well as increased satisfaction with their childbirth experience. Water immersion has not been associated with increases in adverse maternal, fetal, or newborn outcomes (Brickhouse et al., 2015; Jones et al., 2012). Additionally, hydrotherapy results in less use of pharmacological pain-relief measures, decreased use of epidural anaesthesia, fewer forceps- or vacuum-assisted births, fewer episiotomies, and less perineal trauma (Arendt & Tessmer-Tuck, 2013; Burke, 2014).

Showers in early labour may provide relaxation and comfort through the application of heat as the handheld showerhead is directed to areas of discomfort (see Figure 18.5, *A* and *B*). The coach or partner can participate in this comfort measure by holding and directing the showerhead.

To reduce the risk of a prolonged labour, hydrotherapy is usually initiated when the patient is in active labour, more than 5 cm dilation. It is at this time that they may be getting discouraged and will welcome the change that hydrotherapy offers. It is important to preserve the patient's modesty because they may be shy about the exposure of their body when getting into a tub or shower.

In addition to pain relief and relaxation, hydrotherapy offers other benefits. If a patient is having "back labour" as the result of an occiput or transverse position, assuming a hands-and-knees or a side-lying position in the tub enhances spontaneous fetal rotation to the occiput-anterior position as a result of increased buoyancy. Less effort is needed to change positions while in the water.

In some settings, jet hydrotherapy may need to be approved by the labouring patient's primary health care provider. If the amniotic membranes are ruptured, the patient's health care provider should be consulted regarding whether hydrotherapy is appropriate. The patient's vital signs must be within normal limits and fetal well-being must also be assessed regularly. When hydrotherapy is in use, fetal heart rate (FHR) monitoring can be done by means of Doppler, fetoscope, or wireless external monitoring (see Figure 18.5, *C*). Placement of internal electrodes is contraindicated for jet hydrotherapy.

If the labouring patient's temperature or the FHR increases, if the labour progress slows or the patient perceives their labour as becoming too intense, or if relief of pain is reduced, the patient should be encouraged to come out of the tub and return at a later time. There is no limit to the time patients can stay in the bath, and often they are encouraged to stay in it as long as desired. However, most patients use hydrotherapy for 30 to 60 minutes at a time. Repeated baths with occasional breaks may be more effective in relieving pain during long labours than extended amounts of time in the water. The temperature of the water should not exceed 37°C, to reduce the risk of hyperthermia. Monitoring of the labouring patient's temperature every hour and offering fluids will ensure that the labouring person's temperature remains below 37.5°C.

Water birth. Emerging evidence suggests that *water birth* (process of giving birth in a tub of warm water), with careful selection criteria and experienced health care providers, does not negatively affect labouring patients and babies. Outcomes of water birth are comparable to those expected in any healthy childbearing population (Bovbjerg et al., 2016). A growing number of hospitals and birthing centres in Canada are offering this birthing option. Water birth should always occur under the supervision of a qualified health care provider.

Fig. 18.5 Water therapy during labour. **A:** Use of shower during labour. **B:** Woman experiencing back labour relaxes as partner sprays warm water on her back. **C:** Woman relaxing in Jacuzzi. (*A* and *B*, Courtesy Marjorie Pyle, RNC, Lifecircle. *C*, Courtesy Spacelabs Medical.)

SAFETY ALERT

Be aware that warm water can cause dizziness. A shower stool should be used and the labouring patient should be assisted when getting into and out of the tub.

Fig. 18.6 Placement of transcutaneous electrical nerve stimulation (TENS) electrodes on back for relief of labour pain.

Transcutaneous Electrical Nerve Stimulation. Transcutaneous electrical nerve stimulation (TENS) involves the placement of two pairs of flat electrodes on either side of the labouring patient's lumbar and sacral spine (Figure 18.6). These electrodes provide continuous low-voltage electrical impulses or stimuli from a handheld battery-operated device. During a contraction, the patient increases the stimulation from low to high intensity by turning control knobs on the device. High intensity should be maintained for at least 1 minute to facilitate release of endorphins. Patients describe the resulting sensation as a tingling or buzzing. Patients tend to rate the device as helpful, although its use does not decrease pain. It appears that the electrical impulses or stimuli somehow make the pain less disturbing. Because the labouring patient maintains control of the TENS device, this element of autonomy may increase their satisfaction with the method. No serious safety concerns are associated with the use of TENS (Collins, 2017; Hawkins & Bucklin, 2017).

Acupressure and Acupuncture. Acupressure and acupuncture can be used in pregnancy, in labour, and postpartum to relieve pain and other discomforts. Pressure, heat, or cold is applied to acupuncture points, termed *tsubos*. These points have an increased density of neuroreceptors and increased electrical conductivity. Acupressure is said to promote circulation of blood, the harmony of yin and yang, and the secretion of neurotransmitters, thus maintaining normal body functions and enhancing well-being (Gisin et al., 2013). Acupressure is best applied over the skin without using lubricants. Pressure is usually applied with the heel of the hand, fist, or pads of the thumbs and fingers (Figure 18.7). Tennis balls or other devices also may be used. Pressure is applied with contractions initially and then continuously as labour progresses to the later part of the active phase (Gisin et al., 2013). Synchronized breathing by the caregiver and the labouring patient is suggested for greater effectiveness. Acupressure points are found on the neck, the shoulders, the wrists, the lower back including sacral points, the hips, the area below the kneecaps, the ankles, the nails on the small toes, and the soles of the feet. Research indicates that labouring patients may experience good pain relief with the use of acupressure (Collins, 2017).

Fig. 18.7 Ho-Ku acupressure point (back of hand where thumb and index finger come together) used to enhance uterine contractions without increasing pain. (Courtesy Julie Perry Nelson).

Acupuncture is the insertion of fine needles into specific areas of the body to restore the flow of qi (energy) and decrease pain, which is thought to be obstructing the flow of energy. Effectiveness may be attributed to the alteration of chemical neurotransmitter levels in the body or to the release of endorphins as a result of hypothalamic activation. Acupuncture should be done by a trained certified therapist. Current evidence indicates that acupuncture relieves labour pain and reduces the use of both epidural anaesthesia and systemic analgesics; however, further study is needed (Hawkins & Bucklin, 2017).

Application of Heat and Cold. Warmed blankets, warm compresses, heated rice bags, a warm bath or shower, or a moist heating pad may enhance relaxation and reduce pain during labour and may shorten labour with no evidence of harm (Smith et al., 2018b). Heat relieves muscle ischemia and increases blood flow to the area of discomfort. Heat application is effective for back pain caused by a fetus in the occiput-posterior position or for general backache from fatigue. During second-stage labour, the application of warm, moist compresses to the perineum relieves the burning sensation that patients often feel when the fetal head crowns (Collins, 2017).

Cold application such as cool cloths, frozen gel packs, or ice packs applied to the back, the chest, or the face during labour may provide comfort when the patient feels warm. They may also be applied to areas of musculoskeletal pain. Cold is often more effective for back pain caused by the posterior presentation. Cooling relieves pain by lowering the muscle temperature and relieving muscle spasms (Burke, 2014). Of note, a patient's culture may make the use of cold during labour unacceptable.

SAFETY ALERT

Heat and cold may be used alternately for a greater effect. Neither heat nor cold should be applied over ischemic or anaesthetized areas because tissues can be damaged. It is important to place one or two layers of cloth between the skin and a hot or cold pack to prevent damage to the underlying skin.

Hypnosis. Hypnosis is a form of deep relaxation, similar to daydreaming or meditation (see Additional Resources at end of the chapter). While under hypnosis, the person is in a state of focused concentration and the subconscious mind can be more easily accessed. Some childbirth preparation classes offer instruction in performing self-hypnosis. Hypnosis techniques used for labour and birth place an emphasis on enhancing relaxation and diminishing fear, anxiety, and perception of pain. Labouring patients using this technique report a greater sense of control over painful contractions and a higher level of satisfaction with their

childbirth experience. Because it reduces the need for pain medication, hypnosis can be helpful when used with other interventions during labour. A few negative effects of hypnosis have been reported, including mild dizziness, nausea, and headache. These negative effects seem to be associated with failure to dehypnotize the patient properly. A Cochrane systematic review showed that hypnosis may reduce the overall use of analgesia during labour, but not epidural use, and that further research is required in this area (Madden et al., 2016).

Biofeedback. Although there is insufficient evidence to show that biofeedback reduces pain in labour, it may be useful as a relaxation technique (Barragan Loayza et al., 2011). It is based on the theory that, if a person can recognize physical signals, certain internal physiological events can be changed (i.e., whatever signs the labouring patient has that are associated with pain). For biofeedback to be effective, the patient must be educated during the prenatal period to become aware of their body and its responses to pain and how to relax. The patient must learn how to use thinking and mental processes (e.g., focusing) to control body responses and functions. Informal biofeedback helps patients develop awareness of their bodies and use strategies to change their responses to stress. If the patient responds to pain during a contraction with tightening of muscles, frowning, moaning, and breath holding, the partner can use verbal and touch feedback to help them relax. Formal biofeedback, which uses machines to detect skin temperature, blood flow, or muscle tension, can also prepare patients to intensify their relaxation responses. There is insufficient evidence at this time to show that biofeedback is effective for pain management during labour (Jones et al., 2012).

Aromatherapy. In aromatherapy, oils distilled from plants, flowers, herbs, and trees are used to promote health and to treat and balance the mind, body, and spirit. These essential oils are highly concentrated, complex essences and are mixed with lotions or creams before they are applied to the skin (e.g., for a back massage). Jasmine, geranium, rose, clary sage, neroli, ylang ylang, and lavender have been reported to provide good pain relief when used in labour. Because these oils contain medicinal properties, they should be used in the smallest amount that provides relief (Collins, 2017). Oils may also be used by adding a few drops to a warm bath, to warm water used for soaking compresses that can be applied to the body, or to an aromatherapy lamp to vapourize a room. Drops of essential oils can also be put on a pillow or on a patient's brow or palms or used as an ingredient in creating massage oil. They can be used with a diffuser that disperses the oils into the air. Certain odours or scents can evoke pleasant memories or feelings of love and security. Thus patients need to choose the scents that will be used during labour before labour begins. Aromatherapy has not been shown to improve labour outcomes. However, there is likely little harm associated with its use, other than the possibility of an allergic reaction (Arendt & Tessmer-Tuck, 2013). Hospital scent policies should be checked for patients planning an in-hospital birth who wish to use aromatherapy.

SAFETY ALERT

Only a professional trained in the use of essential oils should apply them topically to a labouring patient, because some oils can actually be harmful when applied to the skin.

Intradermal Sterile Water Block. An intradermal water block involves the injection of small amounts of **sterile** water (e.g., 0.05 to 0.1 mL) with a fine needle (e.g., 25-gauge) into four locations on the lower back to relieve low back pain (Figure 18.8). It is a simple procedure to perform, with evidence of effectiveness, which is thought to relate to the gate-control mechanism (Collins, 2017; Hawkins & Bucklin, 2017). Other possible explanations for the effectiveness of intradermal water block are the mechanism of counter-irritation (i.e., reducing localized pain in one area by irritating the skin in an area nearby) and an increase in the level of endogenous opioids (endorphins) produced by the injections. Intense stinging occurs for about 20 to 30 seconds after injection, with subsequent relief of back pain for up to 2 hours. The procedure can be repeated, although the labouring patient may find that the stinging accompanying administration creates too much discomfort (Burke, 2014). Although the effectiveness of this technique is largely unproven, no serious safety concerns are associated with its use (Hawkins & Bucklin, 2017).

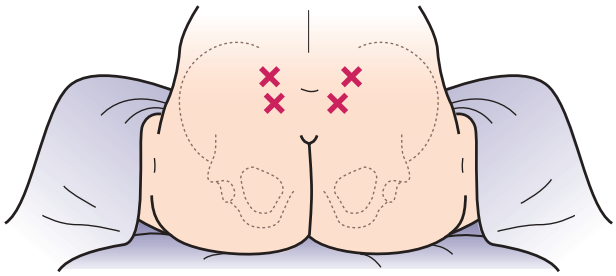

Fig. 18.8 Intradermal injections of 0.1 mL of sterile water in the treatment of patients with back pain during labour. Sterile water is injected into four locations on the lower back, two over each posterior superior iliac spine (PSIS) and two 3 cm below and 1 cm medial to the PSIS. The injections should raise a bleb on the skin. Simultaneous injections administered by two clinicians decrease the pain of injections. (From Leeman, L., Fontaine, P., King, V., et al. [2003]. The nature and management of labor pain: Part I. Nonpharmacologic pain relief. *American Family Physician 68* [6], 1109–1112.)

Maternal Position and Movement. All of the comfort strategies discussed here should be combined with upright and gravity-enhancing positions, such as walking, slow dancing, and rocking. Patients should be informed of the benefits of upright positioning and be encouraged to undertake positions that maintain an upright position (Lee et al., 2016). Rhythmic motion stimulates mechanoreceptors in the brain, which decrease pain perception and may enhance the labour process, as it allows the fetus to move through the birth canal more easily. Labouring patients will often find a position that feels right to them, although they should be encouraged to change their position frequently during labour (Burke, 2014). Changing position in labour alters the relationship between the fetus and pelvis and may result in a more efficient labour (Zwelling, 2010). When encouraging a labouring patient to change positions, the nurse should provide extra support and encouragement and suggest that they remain in the new position throughout several contractions before deciding whether it is comfortable.

Nonpharmacological methods of pain relief may be most effective in latent or early active labour. Labouring patients' needs must be continually re-evaluated, and patients should know what pharmacological choices are available. Nurses should advocate for appropriate pain-relief choices during labour. For more on nonpharmacological pain management, see the Evolve website for the Nursing Care Plan, Nonpharmacological Management of Discomfort.

Pharmacological Pain Management

When nonpharmacological pain-relief measures are no longer effective, the patient and their care provider may consider

pharmacological measures for pain management. When pharmacological and nonpharmacological measures are used together, they increase the level of pain relief. Pharmacological measures for pain management can be implemented as labour becomes more active and discomfort and pain intensify, and when the patients decides that nonpharmacological methods are not working anymore. Less pharmacological intervention often is required when nonpharmacological methods are also used; however, labouring patients are increasingly using pharmacological measures, especially epidural analgesia, to relieve their pain during labour and birth. The rate of epidural analgesia in Canada is 60.4% (Canadian Institute of Health Information [CIHI], 2020).

SAFETY ALERT

Whenever medications are administered, nurses must remain alert for adverse reactions (e.g., difficulty breathing) and be prepared to administer antidotes or summon assistance if necessary. It is important to remember that adverse reactions can occur even if the patient has received the same medication in the past without experiencing such reactions.

Sedatives. Sedatives relieve anxiety and induce sleep. They may be given to a patient experiencing a prolonged latent phase of labour or when there is a need to decrease anxiety or promote sleep. They can also be given to augment analgesics and reduce nausea when an opioid is used.

Benzodiazepines (e.g., diazepam [Valium], lorazepam [Ativan], clonazepam [Rivotril]), when given with an opioid analgesic, seem to enhance pain relief and reduce nausea and vomiting. A major disadvantage of diazepam is that it disrupts thermoregulation in newborns, making them less able to maintain body temperature (Hawkins & Bucklin, 2017).

Analgesia and Anaesthesia. The ideal obstetrical **analgesic** or **anaesthetic** provides adequate pain relief to labouring patients without increasing risk to either the patient or fetus or affecting the progress of labour. Nursing care of the patient requiring obstetrical analgesia and anaesthesia combines the nurse's expertise in maternity care with a knowledge and understanding of human anatomy and physiology and of medications and their therapeutic effects, adverse reactions, and methods of administration.

The term *analgesia* refers to the alleviation of the sensation of pain or the raising of the threshold for pain perception without loss of consciousness.

Anaesthesia encompasses analgesia, amnesia, relaxation, and reflex activity. Anaesthesia abolishes pain perception by interrupting the nerve impulses to the brain. The loss of sensation may be partial or complete, sometimes with loss of consciousness.

The type of analgesic or anaesthetic chosen is determined in part by the labouring patient's decisions, the stage of labour, institutional resources and support, and the method of birth planned (Box 18.4). According to the Canadian Anaesthesiologists' Society, patients should not eat solid foods once they are in established labour because of the delayed gastric emptying of solids. Opioid analgesics may further delay gastric emptying. Clear liquids, on the other hand, are emptied relatively quickly from the stomach and absorbed in the proximal small bowel. There is also evidence that allowing low-risk patients to eat during labour may shorten the length of labour and it does not increase obstetrical risk (Ciardulla, 2017). Provided hospital protocol allows, liquids may be consumed during labour (Dobson et al., 2019).

BOX 18.4 Pharmacological Control of Discomfort by Stage of Labour and Method of Birth

First Stage

Systemic analgesia
- Opioid agonist analgesics
- Opioid agonist–antagonist analgesics

Epidural (block) analgesia
Combined spinal–epidural (CSE) analgesia
Nitrous oxide

Second Stage

Nerve block analgesia/anaesthesia
- Local infiltration anaesthesia
- Pudendal block
- Epidural (block) analgesia and anaesthesia
- Spinal (block) anaesthesia
- CSE analgesia and anaesthesia

Nitrous oxide

Caesarean Birth

Spinal (block) anaesthesia
Epidural (block) anaesthesia
General anaesthesia

Systemic Analgesia. Systemic analgesia (opioids) remains the major method of analgesia for patients in labour when personnel trained in **regional analgesia** (i.e., epidural analgesia) are not available. Opioids can be administered in intermittent intravenous (IV) or intramuscular (IM) doses by health care providers or by the patient themselves using patient-controlled analgesia (PCA). With PCA, the patient self-administers small doses of an opioid analgesic intravenously by using a pump programmed for dose and frequency. Overall, a lower total amount of analgesic is used. Labouring patients appreciate the sense of autonomy provided by this method of pain relief, as well as the elimination of treatment delays while the nurse obtains and administers the medication (Hawkins & Bucklin, 2017).

Opioids provide sedation and euphoria, but their analgesic effect in labour is limited. The pain relief they provide is incomplete, temporary, and more effective in the early part of active labour. All opioids cause adverse effects, the most serious of which is respiratory depression. Other undesirable opioid adverse effects include sedation, nausea and vomiting, dizziness, altered mental status, euphoria, decreased gastric motility, delayed gastric emptying, and urinary retention (Anderson, 2011; Hawkins & Bucklin, 2017; Smith, Burns, et al., 2018; Swart & Kelly, 2017). Prolonged gastric emptying time increases the risk for aspiration if general anaesthesia becomes necessary in a patient who has received opioids (Hawkins & Bucklin, 2017). Bladder and bowel elimination can be inhibited. Because heart rate (e.g., bradycardia), blood pressure (e.g., hypotension), and respiratory effort (e.g., depression) can be adversely affected, opioid analgesics should be used cautiously in patients with respiratory and cardiovascular disorders. Safety precautions should be taken after opioid administration, because several opioid adverse effects increase the risk for injury due to falls.

Opioids readily cross the placenta. Effects on the fetus and the newborn can be profound, including absent or minimal FHR variability during labour and significant newborn respiratory depression requiring

treatment after birth, which may interfere with breastfeeding (Hawkins & Bucklin, 2017; Lee et al., 2016; Swart & Kelly, 2017).

SAFETY ALERT

Opioids decrease the heart rate, respiratory rate, and blood pressure of the labouring patient, all of which affect fetal oxygenation. Therefore, the labouring person's vital signs as well as the FHR pattern must be assessed and documented before and after administration of opioids for pain relief.

Classifications of analgesic drugs used to relieve the pain of childbirth include **opioid (narcotic) agonists** and **opioid (narcotic) agonist-antagonists**. Choice of which medication to use often depends on their availability, institutional resources and support, the primary health care provider's preferences, and the characteristics of the labouring patient. The type of systemic analgesics used therefore often varies among obstetrical units.

Opioid agonist analgesics. Opioid (narcotic) agonist analgesics commonly used in obstetrics include fentanyl, remifentanil, and morphine. As pure opioid agonists, they stimulate the major opioid receptors, mu and kappa. They have no amnesic effect but create a feeling of well-being or euphoria and enhance a patient's ability to rest between contractions. Morphine may be used to provide labour analgesia; however, lack of efficacy at nonsedating doses, and maternal and newborn adverse effects have resulted in decreased usage where better analgesia options, such as epidurals, are available (Grant, 2020). Because opioids can inhibit uterine contractions they should not be administered until labour is well established, unless they are being used to enhance therapeutic rest during a prolonged latent phase of labour (Burke, 2014).

Meperidine hydrochloride (Demerol) used to be the most commonly used opioid agonist analgesic for patients in labour, but it is **no longer recommended** because other medications have fewer adverse effects. Both meperidine and normeperidine, an active metabolite of meperidine, cross the placenta and cause prolonged newborn sedation and neurobehavioural changes. These metabolite-related effects cannot be reversed with naloxone (Anderson, 2011). Both meperidine and normeperidine have long half-lives, thus the newborn effects can persist for the first 2 to 3 days of life (Hawkins & Bucklin, 2017).

Fentanyl citrate (Sublimaze) is a potent, short-acting opioid agonist analgesics (see Medication Guide: Fentanyl [Sublimaze]). Fentanyl rapidly crosses the placenta so is present in fetal blood within 1 minute after IV maternal administration (Anderson, 2011). Fentanyl is used as a labour analgesic because of the rapid onset of action, short half-life, and lack of a metabolite (Hawkins & Bucklin, 2017). A disadvantage of fentanyl is that more frequent dosing is required because of its relatively short duration of action (Hawkins & Bucklin, 2017). As a result, this medication is most commonly administered by PCA pump, intrathecally, via epidural, alone, or in combination with a local anaesthetic agent.

Remifentanil (Ultiva) is an even faster-onset, shorter-acting synthetic opioid agonist with no active metabolites (see Medication Guide: Remifentanil Hydrochloride [Ultiva]). Its onset of action is approximately 1 minute. Remifentanil does cross the placenta but is metabolized rapidly in the fetus, so it does not cause newborn depression. Because remifentanil is metabolized by plasma esterases, it is not affected by impaired renal or hepatic function. Remifentanil should be administered only by PCA pump because of its short (only 3 minute) half-life. Sedation and hypoventilation with oxygen desaturations occur more frequently with remifentanil than with other opioids, so respiratory monitoring is required with its use (Burke, 2014; Hawkins & Bucklin, 2017).

MEDICATION GUIDE

Fentanyl (Sublimaze)

Classification
Opioid agonist analgesic

Action
Potent opioid agonist analgesic that stimulates both mu- and kappa-opioid receptors to decrease the transmission of pain impulses. It has a rapid onset of action (1 to 3 minutes IV) with short duration (0.5 to 1 hour IV; 1 to 2 hours IM).

Indication
Moderate to severe labour pain and postoperative pain after Caesarean birth

Dosage and Route
IV: 50 to 100 mcg every hour
IM: 50 to 100 mcg every hour

Adverse Effects
Sedation, respiratory depression, nausea and vomiting, urinary retention

Nursing Considerations
Assess for respiratory depression; naloxone should be available as an antidote. Implement safety measures as appropriate, including use of side rails and assistance with ambulation; continue use of nonpharmacological pain relief measures. Given its short duration of action, frequent dosing will be necessary when given intravenously. Maximum total dose for fentanyl for labour is usually 500 to 600 mcg.

Source: Anderson, D. (2011). A review of systemic opioids commonly used for labor pain relief. *Journal of Midwifery and Women's Health*, *56* (3), 222–239.

MEDICATION GUIDE

Remifentanil Hydrochloride (Ultiva)

Classification
Opioid agonist analgesic

Action
Fast-onset, short-acting synthetic opioid with no active metabolites. It has a rapid onset of action (approximately 1 minute). Because of its very short half-life (only 3 minutes), remifentanil should be administered only by PCA pump.

Indication
Moderate to severe first-stage labour pain

Dosage and Route
PCA pump (sample setting, as the ideal dosing regimen has not been determined): 0.5 mcg/kg every 2 to 3 minutes with no basal rate

Adverse Effects
Sedation and hypoventilation with oxygen desaturations

Nursing Considerations
Close maternal monitoring (suggested 1:1 nurse/patient ratio) and continuous oxygen saturation monitoring are required. Administer through a dedicated intravenous line. Implement safety measures as appropriate; continue use of nonpharmacological pain relief measures. It can be given to patients with impaired renal or hepatic function.

BOX 18.5 Signs of Potential Complications—Opioid Abstinence Syndrome (Opioid/Narcotic Withdrawal)

- Yawning, rhinorrhea (runny nose), sweating, lacrimation (tearing), mydriasis (dilation of pupils)
- Anorexia
- Irritability, restlessness, generalized anxiety
- Tremors
- Chills and hot flashes
- Piloerection ("goose bumps")
- Violent sneezing
- Weakness, fatigue, and drowsiness
- Nausea and vomiting
- Diarrhea, abdominal cramps
- Bone and muscle pain, muscle spasm, kicking movements

Opioid (narcotic) agonist–antagonist analgesics. An **agonist** is an agent that activates or stimulates a receptor to act; an **antagonist** is an agent that blocks a receptor or a medication designed to activate a receptor. Nalbuphine (Nubain) is a commonly used opioid (narcotic) agonist–antagonist analgesic. **Opioid agonist-antagonist analgesics** are agonists at kappa-opioid receptors and either antagonists or weak agonists at mu-opioid receptors. In the doses used during labour, nalbuphine provides adequate analgesia without causing significant respiratory depression in the labouring patient or the newborn. The major advantage of these drugs is their ceiling effect for respiratory depression, meaning higher doses do not produce additional risk of respiratory depression. They are less likely to cause nausea and vomiting, but sedation may be as great as or greater than that of pure opioid agonists (Anderson, 2011; Hawkins & Bucklin, 2017).

Nalbuphine use also has some disadvantages. Its antagonist activity may limit the amount of analgesia it can produce. Also, it is not suitable for use in patients with an opioid dependence, because the antagonist activity could precipitate withdrawal symptoms in both the parent who gives birth and their newborn (Hawkins & Bucklin, 2017) (see Medication Guide: Nalbuphine Hydrochloride [Nubain] and Box 18.5).

MEDICATION GUIDE

Nalbuphine Hydrochloride (Nubain)

Classification
Opioid agonist–antagonist analgesic

Action
Mixed agonist–antagonist analgesic that stimulates kappa-opioid receptors and blocks or weakly stimulates mu-opioid receptors, resulting in good analgesia but with less respiratory depression and nausea and vomiting than with opioid agonist analgesics. Nalbuphine's analgesic effect is similar to that of morphine, on a milligram-to-milligram basis. It produces a ceiling effect on the patient for pain relief and respiratory depression after 30 mg of the drug has been administered. Duration of action is 2 to 4 hours when given intravenously and 4 to 6 hours when given intramuscularly.

Indication
Moderate to severe labour pain or postoperative pain after Caesarean birth

Dosage and Route
IV, Subcut, or IM: 10 mg every 3 hours as needed

Adverse Effects
Sedation, drowsiness, nausea, vomiting, dizziness, respiratory depression, transient sinusoidal-like FHR pattern

Nursing Considerations
Nalbuphine may precipitate withdrawal symptoms in opioid-dependent patients and their newborns. Assess the patient's vital signs, degree of pain, FHR, and uterine activity before and after administration. Observe for maternal respiratory depression and notify the primary care provider if respirations are ≤12 breaths/min. Encourage voiding every 2 hours and palpate for bladder distension. If birth occurs within 1 to 4 hours of dose administration, observe newborn for respiratory depression. Implement safety measures as appropriate, including use of side rails and assistance with ambulation. Continue use of nonpharmacological pain-relief measures.

Sources: Anderson, D. (2011). A review of systemic opioids commonly used for labor pain relief. *Journal of Midwifery and Women's Health 56*(3), 222–239; Grant, G. J. (2020). Pharmacologic management of pain during labor and delivery. *Up to Date*. https://www.uptodate.com/contents/pharmacologic-management-of-pain-during-labor-and-delivery?sectionName=PAIN%20PATHWAYS&search=labor%20pain&topicRef=101803&anchor=H2&source=see_link#H2.

Opioid antagonists. Opioids such as hydromorphone and fentanyl can cause excessive central nervous system (CNS) depression in the labouring patient, the newborn, or both. However, the current practice of giving lower doses of opioids intravenously has reduced the incidence and severity of opioid-induced CNS depression. *Opioid antagonists* such as naloxone (Narcan) can promptly reverse the CNS depressant effects, especially respiratory depression, in most situations. As stated earlier, however, naloxone cannot reverse the effects of normeperidine, an active metabolite of meperidine. In addition, the antagonist counters the effect of stress-induced levels of endorphins. An opioid antagonist is especially valuable if labour is more rapid than expected and birth occurs when the opioid is at its peak effect. The antagonist may be given intravenously, or it can be administered intramuscularly (see Medication Guide: Naloxone Hydrochloride [Narcan]). The patient should be told that the pain that was relieved with the use of the opioid analgesic will return with the administration of the opioid antagonist.

MEDICATION GUIDE

Naloxone Hydrochloride (Narcan)

Classification
Opioid antagonist

Action
Blocks both mu- and kappa-opioid receptors from the effects of opioid agonists

Indication
Reverses opioid-induced respiratory depression in the labouring patient or newborn; may be used to reverse pruritus from epidural opioids

Dosage and Route
Adult
Opioid overdose: 0.4 to 2 mg IV, may repeat IV at 2- to 3-minute intervals until a maximum of 10 mg has been given; if IV route unavailable, IM or subcutaneous administration may be used

Newborn

Although naloxone has been used in newborns, there is insufficient evidence to evaluate the safety and efficacy of this practice. Animal studies and case reports have raised concerns about complications from naloxone, including pulmonary edema, cardiac arrest, and seizures.

Adverse Effects

Hypotension and hypertension, tachycardia, hyperventilation, nausea and vomiting, sweating and tremulousness

Nursing Considerations

The patient should delay breastfeeding until the medication is out of their system. Do not give to the patient if they are opioid dependent—this may cause abrupt withdrawal in the patient and newborn. If given to the patient for reversal of respiratory depression caused by opioid analgesic, pain will return suddenly. The duration of action of naloxone is shorter than that of most opioids. Therefore, the patient must be monitored closely for the return of opioid-induced respiratory depression when the effects of naloxone are gone. Additional doses of naloxone may be necessary to maintain reversal.

Data on newborn administration from American Academy of Pediatrics & American Heart Association. (2016). *Textbook of neonatal resuscitation,* 7th ed. Author.

MEDICATION ALERT

An opioid antagonist is contraindicated for a newborn of an opioid-dependent patient because it may precipitate neonatal abstinence syndrome (NAS) (withdrawal symptoms). For the same reason, opioid agonist-antagonist analgesics such as nalbuphine (Nubain) should not be given to opioid-dependent patients (see Box 18.5).

Nerve Block Analgesia and Anaesthesia. Several different methods, referred to as *neuraxial analgesic and anaesthetic techniques,* are used in obstetrics to produce sensory blockade and various degrees of motor blockade over a specific region of the body. A variety of local anaesthetic agents are used in obstetrics to produce **regional analgesia** (some pain relief and motor block) and **regional anaesthesia** (complete pain relief and motor block). Most of these agents are related chemically to cocaine and end with the suffix *-caine.* This helps to identify a local anaesthetic.

The principal pharmacological effect of local anaesthetics is the temporary interruption of the conduction of nerve impulses, notably pain. Examples of common agents given are lidocaine (Xylocaine), bupivacaine (Marcaine), chloroprocaine (Nesacaine), and ropivacaine (Naropin).

Rarely, people are sensitive (allergic) to one or more local anaesthetics. Such a reaction may include respiratory depression, hypotension, and other serious adverse effects. Epinephrine, antihistamines, oxygen, and supportive measures should reverse these effects. Sensitivity may be identified by administering tiny amounts of the medication to test for an allergic reaction.

Local infiltration anaesthesia. Local perineal infiltration anaesthesia may be used when an **episiotomy** is to be performed or when lacerations must be sutured after birth in a patient who does not have regional anaesthesia. Rapid anaesthesia is produced by injecting approximately 10 to 20 mL of 1% lidocaine into the skin and then subcutaneously into the region to be anaesthetized. Epinephrine often is added to the solution to localize and intensify the anaesthesia to the region and to prevent excessive bleeding and systemic absorption by constricting local blood vessels. Injections can be repeated to keep the patient comfortable while postbirth repairs are completed.

Pudendal nerve block. Pudendal nerve block, administered late in the second stage of labour, is useful if an episiotomy is to be performed or if forceps or a vacuum extractor is to be used to facilitate birth (in a patient without an epidural). It can also be administered during the third stage of labour if an episiotomy or lacerations need to be repaired. Its use has declined as a result of the increased use of epidural anaesthesia. A pudendal nerve block is considered to be reasonably effective for pain relief, simple to perform, and very safe (Hawkins & Bucklin, 2017). Although a pudendal nerve block does not relieve pain from uterine contractions, it does relieve pain in the lower vagina, vulva, and perineum (Figure 18.9, *A*). A pudendal nerve block must be administered 10 to 20 minutes before perineal anaesthesia is needed. A long needle is used for pudendal blocks (Figure 18.10). The sight of this needle may be frightening; the patient should be reassured that only the tip of the needle will be inserted.

The pudendal nerve traverses the sacrosciatic notch just medial to the tip of the ischial spine on each side. Injection of an anaesthetic solution at or near these points anaesthetizes the pudendal nerves peripherally. The transvaginal approach is generally used because it is less painful for the patient, has a higher rate of success in blocking pain, and tends to cause fewer fetal complications. Pudendal block does not change the patient's hemodynamic or respiratory functions, vital signs, or FHR. However, the bearing-down reflex may be lessened or lost completely.

Spinal anaesthesia. In spinal anaesthesia (block), an anaesthetic solution containing a local anaesthetic alone or in combination with an opioid is injected through the third, fourth, or fifth lumbar interspace into the **subarachnoid space** (Figure 18.11, *A* and *B*), where the anaesthetic solution mixes with cerebrospinal fluid (CSF). Low spinal anaesthesia (block) may be used for vaginal birth, but it is not suitable for labour. If it is used for vaginal birth, the anaesthesia level is from the hips (T10) to the feet (see Figure 18.11, *C*). Spinal anaesthesia (block) used for Caesarean birth provides anaesthesia from the nipple (T6) to the feet.

For spinal anaesthesia (block), the patient sits or lies on their side (e.g., lateral recumbent position) with the back curved to widen the intervertebral space; this position facilitates insertion of a small-gauge spinal needle and injection of the anaesthetic solution in the spinal canal. The nurse supports the patient and encourages the use of breathing and relaxation techniques in order to help the patient remain still

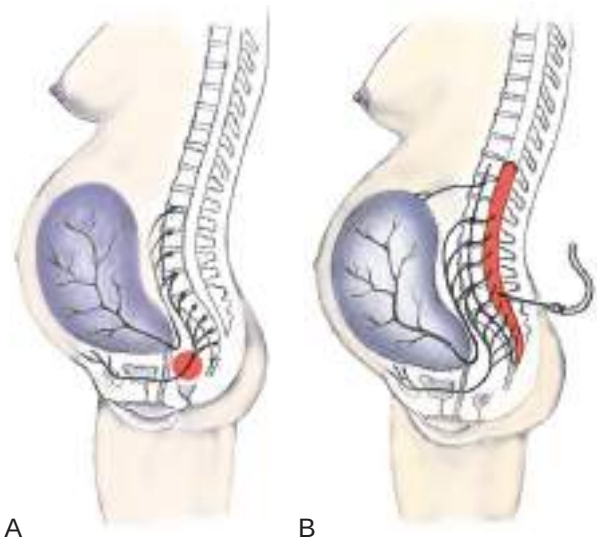

Fig. 18.9 Pain pathways and sites of pharmacological nerve blocks. **A:** Pudendal block; suitable during second and third stages of labour and for repair of episiotomy. **B:** Epidural block; suitable during all stages of labour and for repair of episiotomy.

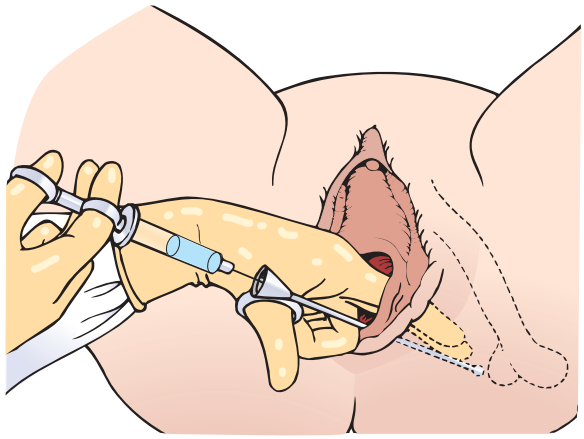

Fig. 18.10 Pudendal block. Use of needle guide ("Iowa trumpet") and Luer-Lok syringe to inject medication.

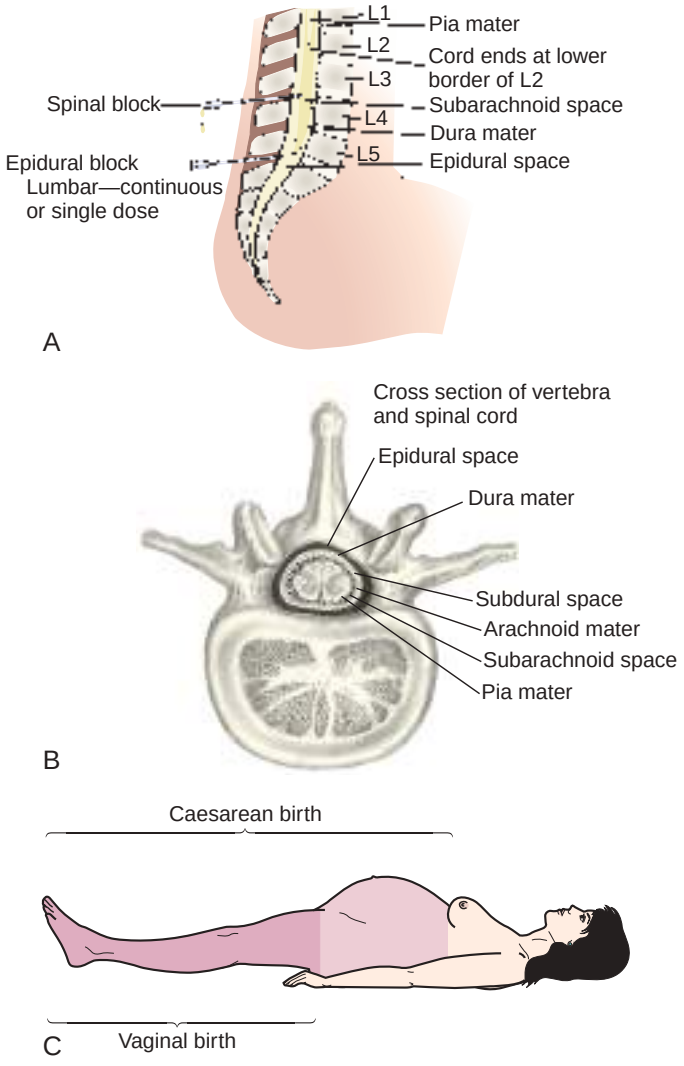

Fig. 18.11 **A:** Membranes and spaces of spinal cord and levels of sacral, lumbar, and thoracic nerves. **B:** Cross section of vertebra and spinal cord. **C:** Levels of anaesthesia necessary for Caesarean and vaginal births.

during placement of the spinal needle. The needle is inserted and the anaesthetic injected between contractions. After the anaesthetic solution has been injected, the needle is removed. The patient may be positioned upright to allow the heavier (hyperbaric) anaesthetic solution to flow downward to obtain the lower level of anaesthesia suitable for a vaginal birth. To obtain the higher level of anaesthesia desired for Caesarean birth, they are positioned supine with head and shoulders slightly elevated. To prevent supine hypotensive syndrome, the uterus is displaced laterally by tilting the operating table or placing a wedge under one of the hips. Usually the level of the block will be complete and fixed within 5 to 10 minutes after the anaesthetic solution is injected, but it can continue to creep upward for 20 minutes or longer (Hawkins & Bucklin, 2017). The anaesthetic effect will last 1 to 3 hours, depending on the type and amount of agent used.

SAFETY ALERT

To reduce the risk for transmission of pathogens, it is recommended that (1) the patient's back is cleansed with an antiseptic before the procedure and (2) during the induction of spinal and epidural anaesthesia/analgesia, the anaesthesia care provider removes jewellery, washes hands, and wears sterile gloves and a face mask.

Marked hypotension, impaired placental perfusion, and an ineffective breathing pattern may occur during any spinal anaesthesia. Before induction of the spinal anaesthetic, the patient's vital signs are assessed and the FHR is evaluated. In addition, the patient's fluid balance should be assessed, and IV fluid is usually administered to decrease the potential for hypotension caused by the *sympathetic blockade* (vasodilation with pooling of blood in the lower extremities decreases cardiac output). If a bolus is given, the fluid should not contain dextrose, which could contribute to newborn hypoglycemia (Hawkins & Bucklin, 2017).

After induction of the anaesthetic, blood pressure, pulse, and respirations and FHR and pattern must be checked and documented every 3 to 10 minutes according to hospital protocol. If signs of serious hypotension (e.g., the systolic blood pressure drops to 100 mm Hg or less or the blood pressure falls 20% or more below the baseline) or abnormal FHR patterns (e.g., bradycardia, minimal or absent variability, late decelerations) develop, emergency care must be given (Burke, 2014) (see Emergency box: Hypotension With Decreased Placental Perfusion).

EMERGENCY

Hypotension With Decreased Placental Perfusion

Signs/Symptoms

Hypotension in patient (20% drop from preblock baseline level or less than 100 mm Hg systolic)
Fetal bradycardia
Absent or minimal fetal heart rate (FHR) variability

Interventions

Turn patient to lateral position or place pillow or wedge under one hip to displace uterus off the ascending vena cava and descending aorta.
Maintain intravenous (IV) infusion at rate specified, or increase administration to provide fluid bolus per hospital protocol.
Administer oxygen by nonrebreather face mask at 8 to 10 L/min if signs of hypoxia or hypovolemia in labouring patient.
Elevate labouring patient's legs.
Notify the primary health care provider and anaesthesiologist.
Administer IV vasopressor (e.g., ephedrine 5 to 10 mg or phenylephrine 50 to 100 mcg) as per primary health care provider's order if previous measures are ineffective.
Remain with the patient; continue to monitor maternal blood pressure and FHR every 5 minutes until condition is stable.

Given the nature of spinal anaesthesia, the patient may be unable to sense their contractions; thus they must be instructed when to bear down during a vaginal birth. Use of a combination of local anaesthetic agent and an opioid reduces the degree of motor function loss, enhancing a patient's ability to push effectively. If the birth occurs in a delivery room (rather than a labour–birth–recovery room), the patient will need assistance in the transfer to a recovery bed.

Advantages of spinal anaesthesia include ease of administration and absence of fetal hypoxia with maintenance of the patient's blood pressure within normal range. The patient's consciousness is maintained, excellent muscular relaxation is achieved, and blood loss is not increased.

Disadvantages of spinal anaesthesia include potential medication reactions (e.g., allergy), hypotension, and the risk of a high spinal leading to an ineffective breathing pattern. In the rare event that a high spinal does occur, causing respiratory depression, cardiopulmonary resuscitation may be required. When a spinal anaesthetic is given, the need for operative birth (e.g., episiotomy, forceps- or vacuum-assisted birth) tends to increase because voluntary expulsive efforts are reduced or eliminated. After birth, the incidence of bladder and uterine atony, as well as postdural puncture headache (PDPH), is higher (see discussion below).

Epidural anaesthesia or analgesia (block). Relief from the pain of uterine contractions and birth (vaginal and Caesarean) can be achieved by injecting a suitable local anaesthetic agent (e.g., bupivacaine, ropivacaine), an opioid analgesic (e.g., fentanyl, sufentanil), or both into the epidural space. Injection is made between the fourth and fifth lumbar vertebrae for a lumbar epidural block (see Figures 18.9, *B*, and 18.11, *A*). Depending on the type, amount, and number of medications used, an anaesthetic or analgesic effect will occur with varying degrees of motor impairment. The combination of an opioid with the local anaesthetic agent reduces the dose of anaesthetic required, thereby preserving a greater degree of motor function.

Epidural anaesthesia and analgesia is the most effective pharmacological pain-relief method for labour that is available. As a result, it is the most commonly used method for relieving pain during labour in Canada. In 2018–2019, epidural rates varied among the provinces. About two thirds of vaginal births in Quebec (73.5%) and Ontario (61.7%) were preceded by an epidural, compared to the rates of Manitoba (38.8%) and British Columbia (44.1%) (CIHI, 2020).

For relieving the discomfort of labour and vaginal birth, a block from T10 to S5 is required. For Caesarean birth, a block from at least T8 to S1 is essential (see Figure 18.11, *C*). The diffusion of epidural anaesthesia depends on the location of the catheter tip, the dose and volume of the anaesthetic agent used, and the patient's position (e.g., horizontal or head-up position). The patient must maintain their position without moving during the insertion of the epidural catheter to prevent misplacement, neurological injury, or hematoma formation. The nurse needs to remain at the patient's side and provide support during the procedure.

! NURSING ALERT

Epidural anaesthesia effectively relieves the pain caused by uterine contractions for most labouring patients. However, it does not completely remove the pressure sensations that occur as the fetus descends in the pelvis.

For induction of the epidural block, the patient is positioned the same as they would be for a spinal block. They may sit with the back curved or assume a lateral recumbent position with the shoulders parallel, legs slightly flexed, and back arched (Figure 18.12). It is important to avoid severe spinal flexion because it could compress the epidural space, increasing the risk for dural puncture.

A large-bore (16-, 17-, or 18-gauge) needle is inserted into the epidural space. A catheter is then threaded through the needle until the tip rests in the epidural space. The needle is then removed, and the catheter is taped in place. After the epidural catheter is inserted and secured, a small amount of medication, called a *test dose,* is injected to ensure that the catheter has not been accidently placed in the subarachnoid (spinal) space or in a blood vessel (Hawkins & Bucklin, 2017).

Initiating neuraxial anaesthesia may be difficult when the patient is obese. It may be more difficult for the patient to assume the position necessary for catheter placement. In addition, excess adipose tissue can obscure the anatomical landmarks used to identify the location of the appropriate insertion site. Although epidural catheter placement can present technical challenges, use of regional anaesthesia can provide adequate pain management for the patient with obesity during labour and birth. Placing the catheter in early labour when the patient is more comfortable may be a recommended solution (Baird et al., 2017). Early placement of a functioning epidural may reduce the risk of requiring a general anaesthetic and the potential complications associated with intubation during an emergent birth. Note that epidural anaesthesia presents less risk for the patient who is obese than does general anaesthesia (see further discussion in Chapter 15).

After the epidural has been initiated, the patient is positioned preferably on their side; this is done so that the uterus does not compress the ascending vena cava and descending aorta, which can impair venous return, reduce cardiac output and blood pressure, and decrease placental perfusion. The patient's position should be alternated from side to side at a minimum every hour. Upright position and ambulation may be possible, depending on the degree of motor impairment. Oxygen should be available if hypotension occurs despite maintenance of hydration with IV fluid and displacement of the uterus to the side. Blood pressure should be monitored every 3 to 10 minutes for the first 30 minutes after insertion according to hospital protocol. Ephedrine or phenylephrine (vasopressors used to increase maternal blood pressure) and increased IV fluid infusion may be needed (see Emergency box: Hypotension With Decreased Placental Perfusion).

The FHR, contraction pattern, and progress in labour must be monitored carefully because the patient may not be aware of changes in strength of uterine contractions or the descent of the presenting part. There is no evidence to support the use of continuous electronic fetal monitoring for patients who have received epidural anaesthesia; intermittent auscultation is appropriate in many situations; and the decision on how to monitor a patient in labour who has an epidural must take into account the entire clinical picture (Dore & Ehman, 2020).

Several methods can be used for an epidural block. An intermittent block is achieved by using repeated injections of anaesthetic solution; it is the least common method because of the inconsistent nature of the pain relief provided from this method. The most common method is the continuous epidural infusion, achieved by using a pump to infuse the anaesthetic solution through the in-dwelling plastic catheter. Patient-controlled epidural analgesia (PCEA), where available, involves an in-dwelling catheter and a programmed pump that allows the labouring patient to control the dosing. PCEA has been found to provide optimal analgesia with higher patient satisfaction and enhanced sense of control during labour while decreasing the total amount of medication, including local anaesthetic, used.

The advantages of an epidural block include the following:

- The patient remains alert and is more comfortable and remains able to participate in the birth.
- Good relaxation is achieved.
- Airway reflexes remain intact.

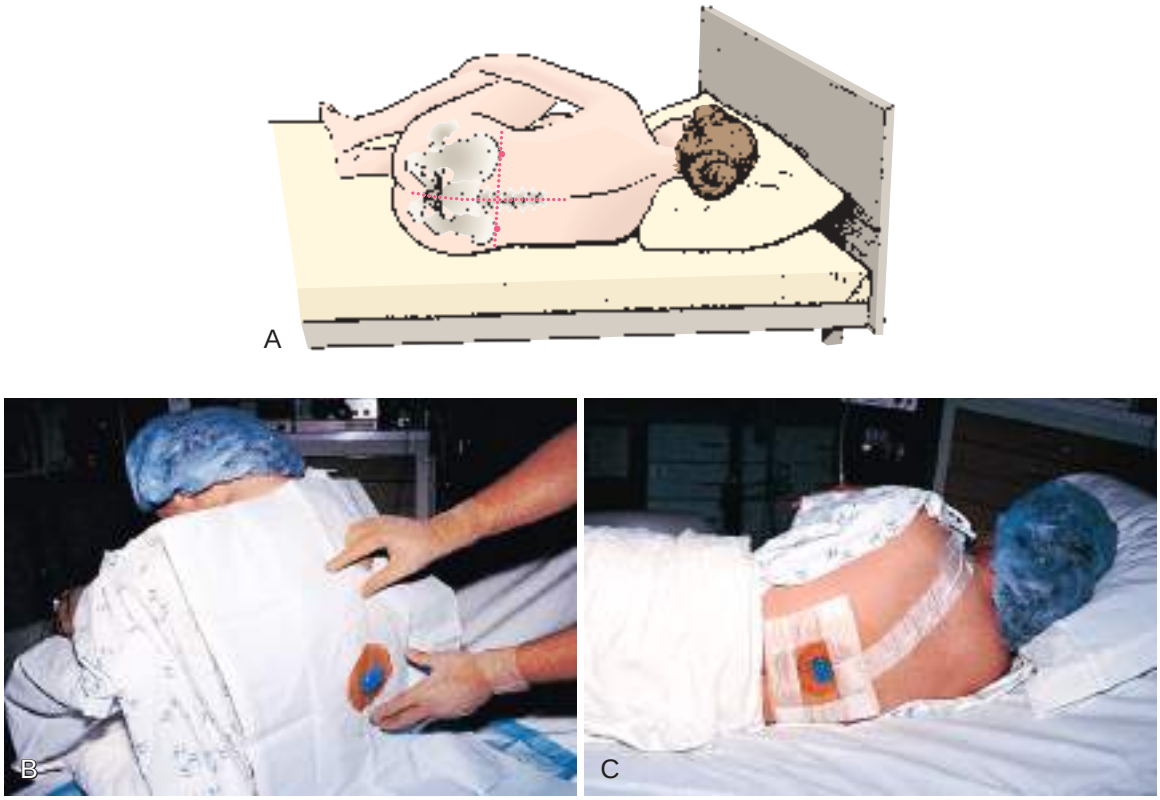

Fig. 18.12 Position for spinal and epidural blocks. **A:** Lateral position. **B:** Upright position. **C:** Catheter is taped to patient's back with port segment located near the shoulder. (*B* and *C*, Courtesy Michael S. Clement, MD.)

- Motor paralysis is mild.
- Gastric emptying is not delayed.

Fetal complications are rare but may occur in the event of rapid absorption of the medication or marked hypotension in the labouring patient. The dose, volume, type, and number of medications used can be modified (1) to allow the patient to push, to assume upright positions, and even to walk; (2) to produce perineal anaesthesia; and (3) to permit forceps-assisted, vacuum-assisted, or Caesarean birth if required.

The disadvantages of an epidural block are also numerous. Length of labour may be longer and there may be an increased requirement for oxytocin (Anim-Somuah et al., 2018; Lee et al., 2016). The patient's ability to move freely and maintain control of their labour is limited, related to the use of numerous medical interventions (e.g., an IV infusion, electronic monitoring, bladder catheterization) and the occurrence of orthostatic hypotension and dizziness, sedation, and weakness of the legs. CNS effects (Box 18.6) can occur if a solution containing a local anaesthetic agent is accidentally injected into a blood vessel or if excessive amounts of local anaesthetic are given. High spinal or "total spinal" anaesthesia, resulting in respiratory arrest, can occur if the relatively high dosage used with an epidural block is accidentally injected into the subarachnoid space. Labouring patients who receive an epidural have a higher rate of fever (i.e., intrapartum temperature of 38°C or higher), especially when labour lasts longer than 12 hours. Temperature elevation is most likely related to thermoregulatory changes, although infection cannot be ruled out. The elevation in temperature can result in fetal tachycardia and subsequent newborn workup for sepsis, regardless of whether or not signs of infection are present.

BOX 18.6 Potential Adverse Effects of Epidural and Spinal Anaesthesia

Hypotension
Local anaesthetic toxicity
Lightheadedness
Dizziness
Tinnitus (ringing in the ears)
Metallic taste
Numbness of the tongue and mouth
Bizarre behaviour
Slurred speech
Convulsions
Loss of consciousness
High or total spinal anaesthesia
Fever
Urinary retention
Pruritus (itching)
Limited movement
Longer second-stage labour
Increased use of oxytocin
Increased likelihood of forceps- or vacuum-assisted birth
Postdural puncture headache

Hypotension as a result of sympathetic blockade can occur in about 14% of patients who receive epidural and 70% of patients who receive spinal anaesthesia during labour (Grant, 2020) (see Emergency box: Hypotension With Decreased Placental Perfusion). Hypotension can

result in a significant decrease in uteroplacental perfusion and oxygen delivery to the fetus. Urinary retention and stress incontinence can occur in the immediate postpartum period. This temporary difficulty in urinary elimination could be related not only to the effects of the epidural block and catheterization done in labour but also to the increased duration of labour and need for forceps- or vacuum-assisted birth associated with the block. **Pruritus** (itching) is an adverse effect that often occurs with epidural or spinal use of an opioid, especially fentanyl and morphine. A relationship between epidural analgesia and longer second-stage labour, increased incidence of fetal malposition, use of oxytocin, and forceps- or vacuum-assisted birth have also been documented. Research findings have not demonstrated a significant increase in Caesarean birth associated with epidural analgesia (Anim-Somuah et al., 2018; Hawkins & Bucklin, 2017). For some labouring patients, the epidural block is not effective and a second form of analgesia is required to establish effective pain relief. When patients progress rapidly in labour, pain relief may not be obtained before birth occurs.

Postdural puncture headache (PDPH). Puncture of the dura mater during spinal insertion and inadvertent puncture during epidural insertion may cause leakage of CSF from the site of puncture of the dura mater (membranous covering of the spinal cord). This is thought to be the major causative factor in *postdural puncture headache* (PDPH), commonly referred to as a *spinal headache*. Spinal headache is most likely to occur when the dura is accidentally punctured during the process of administering an epidural block. The needle used for an epidural block has a much larger gauge than the one used for spinal anaesthesia and thus creates a bigger opening in the dura, resulting in a greater loss of CSF (i.e., "wet tap"). Presumably, postural changes cause the diminished volume of CSF to exert traction on pain-sensitive CNS structures. Characteristically, assuming an upright position triggers or intensifies the headache, whereas assuming a supine position achieves relief. The resulting headache and auditory symptoms (e.g., tinnitus) and visual issues (e.g., blurred vision, photophobia) begin within 2 days of the puncture and may persist for days or weeks (Hawkins & Bucklin, 2017).

The likelihood of headache after dural puncture can be reduced if the anaesthesiologist uses a small-gauge spinal needle and avoids making multiple punctures of the meninges. If a dural puncture is suspected, leaving the epidural catheter through the dural opening at the time of puncture will allow continuous spinal anaesthesia; removal of the catheter 24 hours later may help prevent a spinal headache. Hydration and bed rest in the prone position have been recommended as preventive measures but have been proven to be of little value (Hawkins & Bucklin, 2017).

Conservative management for PDPH usually includes administration of oral analgesics and methylxanthines (e.g., caffeine or theophylline). Methylxanthines cause constriction of cerebral blood vessels and may provide symptomatic relief. Gabapentin and hydrocortisone have also been shown to be effective to decrease pain severity (Basurto Ona et al., 2015).

An autologous epidural blood patch is the most rapid, reliable, and beneficial relief measure for PDPH. The patient's blood (i.e., 10 to 20 mL) is injected slowly into the lumbar epidural space, creating a clot that patches the tear or hole in the dura mater around the spinal cord. Treatment with a blood patch is considered if the headache is severe or debilitating or does not resolve after conservative management. The blood patch is remarkably effective and is nearly complication free (Hawkins & Bucklin, 2017) (Figure 18.13). The patient should be observed for alteration of vital signs, pallor, clammy skin, and leakage of CSF for 1 to 2 hours after the blood patch is performed. If no complications occur, they may resume normal activity. The patient should, however, be instructed to avoid coughing or straining the first day after the blood patch (Hawkins & Bucklin, 2017). They are also taught to avoid using analgesics that affect platelet aggregation (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]) for 2 days, drink plenty of fluids, and observe for signs of infection at the site and for neurological symptoms such as pain, numbness, and tingling in legs and difficulty with walking or elimination.

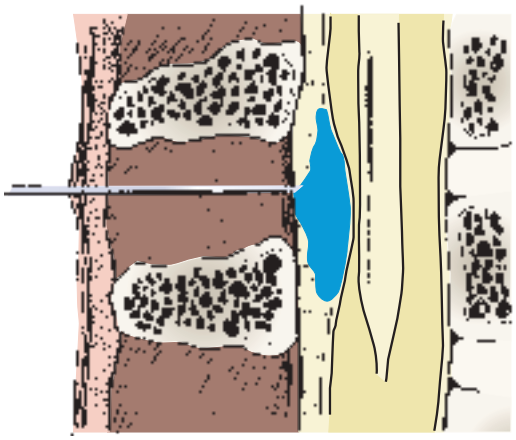

Fig. 18.13 Blood-patch therapy for spinal headache.

Combined spinal–epidural analgesia. In the combined spinal–epidural (CSE) analgesia technique, sometimes referred to as a *walking epidural*, an epidural catheter is inserted into the epidural space in the same manner of a conventional epidural; however, before the epidural catheter is placed, a smaller-gauge spinal needle is inserted through the bore of the epidural needle into the subarachnoid space. A small amount of opioid or combination of opioid and local anaesthetic is then injected intrathecally to rapidly provide analgesia. Afterward, the epidural catheter is inserted as usual. The CSE technique is an increasingly popular approach that can be used to quickly block pain transmission without compromising motor ability. The concentration of opioid receptors is high along the pain pathway in the spinal cord, in the brainstem, and in the thalamus. Because these receptors are highly sensitive to opioids, a small quantity of an opioid agonist analgesic produces marked pain relief lasting several hours. If additional pain relief is needed, medication can be injected through the epidural catheter. The most common adverse effects of CSE are pruritus, urinary retention, immediate or delayed respiratory depression, and nausea. Naloxone can be given intravenously to manage these adverse effects without decreasing the degree of analgesia achieved (Hawkins & Bucklin, 2017). CSE analgesia is also associated with a greater incidence of FHR abnormalities than with epidural analgesia alone, necessitating close assessment of the FHR and pattern (Grant, 2020).

Although patients can walk with CSE, they often choose not to, because of sedation and fatigue, abnormal sensations in and weakness of the legs, and a feeling of insecurity. Often health care providers are reluctant to encourage or assist these patients to ambulate for fear of injury. However, patients can be assisted to change positions and use upright positions during labour and birth.

Epidural and intrathecal (spinal) opioids. Opioids can be used alone, eliminating the effect of a local anaesthetic altogether. The use of epidural or intrathecal (spinal) opioids without the addition of a local anaesthetic agent during labour has several advantages. Opioids administered in this manner do not cause hypotension or affect vital signs in the labouring person. The patient feels contractions but not pain. The ability to bear down during the second stage of labour is preserved because the pushing reflex is not lost and their motor function remains intact.

Fentanyl, sufentanil, or preservative-free morphine may be used. Fentanyl and sufentanil produce short-acting analgesia (i.e., 1.5 to 3.5 hours), and morphine may provide pain relief for 4 to 7 hours. Morphine may be combined with fentanyl or sufentanil. Using

short-acting opioids with multiparous patients and longer-acting opioids with nulliparous patients or patients with a history of long labour is appropriate.

A more common indication for the administration of epidural or intrathecal analgesics is the relief of postoperative pain. For example, a patient who gives birth by Caesarean can receive fentanyl or morphine through a catheter. The catheter can then be removed, and the patient is usually free of pain for 24 hours. Occasionally, the catheter is left in place in the epidural space in case another dose is needed.

Patients who receive epidural morphine can ambulate sooner after a Caesarean birth than patients who do not. The early ambulation and freedom from pain also facilitate bladder functioning, enhance peristalsis, and prevent clot formation (e.g., thrombophlebitis) in the lower extremities. Patients may require additional medication for breakthrough pain during the first 24 hours after surgery. If so, they will usually be given an NSAID such as ibuprofen or naproxen rather than an opioid.

Adverse effects of opioids administered by the epidural and intrathecal routes include nausea, vomiting, diminished peristalsis, pruritus, urinary retention, and delayed respiratory depression. These effects are more common when morphine or fentanyl is administered. Antiemetics, antipruritics, and opioid antagonists are used to relieve these symptoms. For example, naloxone (Narcan), promethazine (Phenergan), diphenhydramine (Benadryl), or metoclopramide (Maxeran) may be administered. Hospital protocols should provide specific instructions for treatment of these adverse effects. Use of epidural opioids is not without risks. Respiratory depression is a serious concern; for this reason, the patient's respiratory rate should be assessed and documented every hour for 24 hours after discontinued or as designated by hospital protocol. Naloxone should be readily available for use if the respiratory rate decreases to less than 10 breaths/min or if the oxygen saturation rate decreases to less than 89%. Administration of oxygen by non-rebreather face mask may also be initiated, and the anaesthesia care provider should be notified.

Contraindications to spinal and epidural anaesthesia. Contraindications to epidural analgesia (Burke, 2014; Hawkins & Bucklin, 2017) include the following:

- Active or anticipated hemorrhage in the labouring patient. Acute hypovolemia leads to increased sympathetic tone to maintain blood pressure. Any anaesthetic technique that blocks the sympathetic fibres can produce significant hypotension that can endanger the labouring patient and fetus.
- Significant hypotension
- Coagulopathy. If a patient is receiving anticoagulant therapy (e.g., last dose of low-molecular-weight heparin within 12 hours) or has a bleeding disorder, injury to a blood vessel may cause formation of a hematoma that may compress the cauda equina or the spinal cord and lead to serious CNS complications.
- Infection at the injection site. Infection can be spread through the peridural or subarachnoid spaces if the needle traverses an infected area.
- Increased intracranial pressure caused by a mass lesion
- Allergy to the anaesthetic drug
- Refusal of the patient or inability to assist with insertion
- Some types of cardiac conditions in the labouring patient

With an increase in the number of patients who have body art and, specifically, low-back tattoos, there has been some concern over whether it is safe to give an epidural through a tattoo. The present recommendation is that an epidural should not be denied to someone with a low-back tattoo, although direct tattoo puncture should be avoided if possible, as there is potential for the epidural to be ineffective (Ziporia et al., 2018).

Epidural block effects on the newborn. Analgesia or anaesthesia during labour and birth has little or no lasting effect on the physiological status of the newborn, although further research needs to be done on the immediate effects of the medications on the newborn, specifically related to breastfeeding. There is no evidence that the administration of analgesic or anaesthetic agents during labour and birth to the labouring patient has a significant effect on the child's later mental and neurological development (Grant, 2020). However, because of the frequent occurrence of fever after epidural analgesia in labouring patients, newborns often undergo septic workup unnecessarily (Jefferies & Canadian Pediatric Society Fetus and Newborn Committee, 2017).

Nitrous Oxide for Analgesia. Nitrous oxide, commonly called *laughing gas*, is an inhaled anaesthetic gas. This form of analgesia is widely used in Canada as well as in the United Kingdom, Australia, and Finland. It can be used during the first and second stages of labour and can be used in combination with other nonpharmacological and pharmacological measures for pain relief. It is administered as a 50:50 oxygen-to–nitrous oxide mixture (Entonox) using a blender device and a mask held by the patient. Patients report that nitrous oxide does not completely relieve pain but reduces their perception of pain. It causes a feeling of euphoria and decreases anxiety.

The main adverse effects of nitrous oxide are nausea and dizziness. Nitrous oxide is safe for both labouring patient and fetus and does not affect uterine activity. Other advantages of nitrous oxide use include rapid onset of action, quick clearance through exhalation without accumulation in the labouring patient or fetal tissues, and the fact that the patient can self-administer the gas while remaining awake, alert, and completely able to function. The maximum therapeutic effect occurs approximately 50 seconds after continuous inhalation is commenced; therefore, beginning the inhalation process 30 seconds before the onset of a contraction (if regular) or as soon as a contraction begins (if irregular) provides the best pain relief (Jackson et al., 2015).

A face mask is used to self-administer the gas. The patient places the mask over their mouth and nose as soon as a contraction begins. The nurse teaches the patient how to correctly position the face mask to create a seal. When the patient inhales, a valve opens and the gas is released. When inhalation stops, the valve closes, which prevents accidental overdosing. The patient is the only person allowed to hold the mask. Special equipment collects the patient's exhalations to protect health care workers from repetitive occupational exposure to nitrous oxide (Collins, 2017; Hawkins & Bucklin, 2017).

Nitrous oxide can also be used during short, painful intrapartum procedures such as perineal repair and manual removal of the placenta. Its ease of use, rapid onset, and rapid termination of action make nitrous oxide a good option for labour analgesia (Klomp et al., 2012).

General Anaesthesia. *General anaesthesia* is rarely used for uncomplicated vaginal birth. General anaesthesia may be necessary if a spinal or epidural block is contraindicated or if circumstances necessitate rapid birth (vaginal or emergent Caesarean) without sufficient time or available personnel to perform a regional block. In addition, being awake and aware during major surgery may be unacceptable for some patients having a Caesarean birth. The major risks associated with general anaesthesia are difficulty with or inability to intubate and aspiration of gastric contents (Hawkins & Bucklin, 2017). Anaesthesiologists are more likely to encounter difficulty with intubating patients with morbid obesity, especially in an emergency situation, than with patients of normal weight.

If general anaesthesia is being considered, the patient should have no solid food for 6 to 8 hours before surgery. They may have clear fluids

up to 2 hours prior to surgery (Dobson et al., 2019). An IV infusion is put in place and, if time allows, the patient will be premedicated with a nonparticulate (clear) oral antacid (e.g., sodium citrate/citric acid) to neutralize the acidic contents of the stomach. Aspiration of highly acidic gastric contents will damage lung tissue. Administration of a histamine (H_2)-receptor blocker such as famotidine (Pepcid) or ranitidine (Zantac) to decrease the production of gastric acid and metoclopramide (Reglan) to accelerate gastric emptying may also be ordered (Hawkins & Bucklin, 2017). Before the anaesthesia is given, a wedge should be placed under one of the patient's hips to displace the uterus. Uterine displacement prevents compression of the aorta and inferior vena cava, which maintains cardiac output and placental perfusion.

Before the induction of anaesthesia, the patient will be preoxygenated with 100% oxygen by non-rebreather face mask for 2 to 3 minutes. This is especially important in pregnant patients, who are more likely than other adults to rapidly become hypoxemic if there is a delay in successful intubation. Next, propofol (Diprivan) or ketamine (Ketalar) is administered intravenously to induce anaesthesia by rendering the patient unconscious. After that, succinylcholine, a muscle relaxant, is administered to facilitate passage of an endotracheal tube (Hawkins & Bucklin, 2017). Sometimes the nurse is asked to assist with applying cricoid pressure—*the Sellick manoeuvre*—before intubation as the patient begins to lose consciousness. This manoeuvre blocks the esophagus and prevents aspiration should the patient vomit or regurgitate (Figure 18.14). Pressure is released once the endotracheal tube is securely in place.

After the patient is intubated, a 50:50 mixture of nitrous oxide and oxygen is administered. A low concentration of a volatile halogenated agent (e.g., isoflurane) may also be administered to increase pain relief and to reduce the patient's awareness and recall (Hawkins & Bucklin, 2017). In low concentrations, these agents do not relax the uterus, so bleeding should not increase because of their use (Hawkins & Bucklin, 2017). In higher concentrations, isoflurane or methoxyflurane relaxes the uterus quickly and facilitates intrauterine manipulation, version, and extraction. However, at higher concentrations, these agents cross the placenta readily and can produce narcosis in the fetus and could reduce uterine tone after birth, increasing the risk for hemorrhage. Given the risk for newborn narcosis, it is critical that the baby be born as soon as possible after the induction of the anaesthetic to decrease the degree of fetal exposure to the anaesthetic agents and the CNS depressants administered to the pregnant patient.

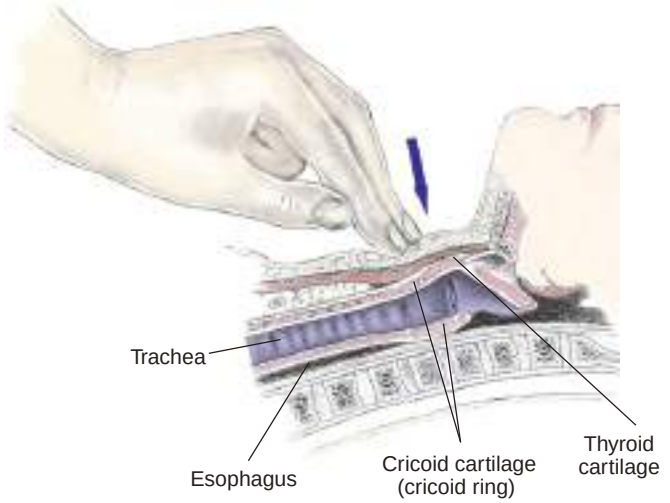

Fig. 18.14 Technique of applying pressure on cricoid cartilage to occlude esophagus to prevent aspiration of gastric contents during induction of general anaesthesia.

Priorities for recovery room care are to maintain an open airway and cardiopulmonary function and to prevent postpartum hemorrhage. Patients who had surgery under general anaesthesia will require pain medication soon after regaining consciousness. Routine postpartum care is organized to facilitate parent–infant attachment as soon as possible and to answer the parent's questions. The nurse needs to assess the new parent's readiness to see their baby, as well as their response to the anaesthesia and to the event that necessitated general anaesthesia (e.g., emergency Caesarean birth when vaginal birth was anticipated).

Nursing Care

The choice of pain relief depends on a combination of factors, including the patient's needs and wishes, an assessment of how the patient is coping with labour, the availability of the desired method or methods, the knowledge and expertise in nonpharmacological and pharmacological methods of the health care providers involved in the patient's care, and the phase and stage of labour (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Labouring Without an Epidural

Jesse is a 17-year-old, single, nulliparous patient who has been admitted with severe pre-eclampsia at 34 weeks of gestation. Jesse's health care provider plans to induce labour and anticipates a vaginal birth. Jesse has not attended any childbirth preparation classes and has been planning to have an epidural for labour and birth. Unfortunately, because her platelet count is very low (28×10^9/L), the anaesthesiologist refuses to place an epidural block. Jesse bursts into tears and says, "I can't make it through labour without an epidural! It's going to hurt too much! Help me!"

Questions

1. Evidence—Is there sufficient evidence about avoiding neuraxial anaesthesia in labouring patients who have low platelet counts?
2. Assumptions—Describe an underlying assumption about each of the following nonpharmacological or pharmacological methods for pain relief during labour:
   a. Breathing and relaxation techniques
   b. Application of heat and cold
   c. Systemic analgesia
   d. Presence of a support person to increase effectiveness of interventions for pain
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Jesse's care.

Assessing Coping During Labour. The nurse will assess the patient to identify the patient's desired level of control in the management of pain and its relief. Commonly, it is not the amount of pain the patient experiences but whether they meet the goals they set for themselves in coping with the pain that influences their perception of the birth experience as "good" or "bad."

The nurse should never assume that, because a patient is in labour, the pain must be uterine in origin. Pain is a subjective phenomenon; as such, the nurse must listen to the patient's description of the pain. A self-assessment tool such as a visual analogue scale allows the patient to indicate on a line how severe or intense they perceive the pain to be. Pain is rated from "no pain" to "pain as bad as it can possibly be." Self-assessment is recommended, to ensure that pain management is based on the subjective nature of the patient's pain rather than on the

nurse's judgement of it. It is not unusual for a nurse to overestimate or underestimate the pain being experienced by a patient. When there are major cultural differences between the health care provider and the patient, inaccurate interpretation of pain intensity may occur.

It is critical that the nurse take note of all pain characteristics, including location, intensity, quality, frequency, duration, and effectiveness of relief measures. While pain scales may be used with the labouring patient, their use may not always be appropriate as all patients cope with pain differently. Some labouring patients may find questions about their level of pain confusing or annoying (Gulliver et al., 2008). Nurses may assume that if a patient rates the pain level as high they require medication, but some patients may be able to manage high levels of pain during labour if they have the appropriate supportive care. Open-ended questions regarding how a patient is coping with labour may be more effective in ensuring that the patient's pain management needs are met. Gulliver et al. (2008) developed a coping with labour algorithm that assists nurses in assessing whether the patient is coping with or not coping with labour, as well as providing appropriate interventions depending on the assessment (Figure 18.15). The nurse observes for the following cues: rhythmic activity, communicating the ability to cope, crying, and the inability to focus. Based on these cues the nurse can determine if the patient is coping or not coping on some level. The algorithm provides nurses with a pathway to provide care that is appropriate to that particular labouring patient (Gulliver et al., 2008; Roberts et al., 2010). These measures may include nonpharmacological pain relief or the use of medication.

Informed Consent. Pregnant patients have the right to be active participants in determining the best pain care approach to use during their labour and birth. The primary health care provider and anaesthesia care provider are responsible for fully informing patients of the alternative methods of pharmacological pain relief available in the hospital and supporting the choices that the patient makes (Lee et al., 2016; WHO, 2018). A description of the various anaesthetic techniques and what they entail is essential to informed consent, even if the patient received information about analgesia and anaesthesia earlier in the pregnancy. The initial discussion of pain management options ideally should take place in the third trimester so that the patient has time to consider all options. Nurses play a part in the informed consent process by clarifying and describing procedures or by acting as the patient's advocate by asking the primary health care provider for further explanations (Box 18.7). All health care providers should consider what the impact of asking a patient whether they want pharmacological pain relief methods has on the patient's decision-making ability. Some patients may feel pressure to use pain medication if they are continuously asked about it.

LEGAL TIP: Informed Consent for Anaesthesia

The patient receives (in an understandable manner) all of the following:

- Explanation of the alternative methods of analgesia and anaesthesia available
- Description of anaesthetic, including its effects and procedure for its administration
- Description of the benefits, discomfort, risks, and consequences for the labouring patient and the fetus
- Explanation of how complications can be treated
- Information that the anaesthetic is not always effective
- Indication that the patient may withdraw consent at any time
- Opportunity to have any questions answered
- Opportunity to have components of the consent explained in the patient's own words

! NURSING ALERT

In some cultures, the husband must consent to procedures performed on the wife. Although in Canada the patient is the person who gives consent and signs the necessary forms, she may not be willing to do so unless her husband also approves.

Timing of Administration. Nonpharmacological measures can be used to relieve pain and stress and enhance progress at any time in labour.

Accurate monitoring of the progress of labour and assessment of the labouring patient's level of coping assist the nurse in helping the patient decide when it is appropriate to start pharmacological control of discomfort. It is often the nurse who notifies the primary health care provider when the patient requests pharmacological measures to relieve the discomfort. Orders are often written for the administration of pain medication as needed by the patient and are based on the nurse's clinical judgement. In the past, pharmacological measures for pain relief were not implemented until labour had advanced to the active phase of the first stage of labour and the cervix had dilated approximately 4 to 5 cm, to avoid suppressing the progress of labour. However, it is now known that epidural anaesthesia in early labour does not increase the rate of Caesarean birth. Whereas it may shorten the duration of the first stage of labour in some patients, epidural anaesthesia lengthens it in others (Hawkins & Bucklin, 2017). It is no longer recommended that patients in labour reach a certain level of cervical dilation or fetal station before receiving epidural anaesthesia as long as a diagnosis of labour has been made (i.e., presence of uterine activity resulting in progressive effacement and dilatation of the cervix) (Lee et al., 2016). It is, however, still recommended that the administration of systemic opioid analgesics be delayed until labour is well established (Burke, 2014).

Preparation for Procedures. The methods of pain relief available to the patient are reviewed and information is clarified as necessary. The procedure and what is expected of the patient (e.g., to maintain flexed position during insertion of epidural needle) must be explained.

The patient can also benefit from knowing the way the medication will be given, the degree of discomfort to expect from administration of the medication, the interval before the medication takes effect, and the expected pain relief from the medication. Skin-preparation measures are described and an explanation is given for the need to empty the bladder before the analgesic or anaesthetic is administered and the reason for keeping the bladder empty. When an in-dwelling catheter is to be threaded into the epidural space, the patient should be told that they may experience a momentary twinge down the leg, hip, or back and that this feeling is not a sign of injury.

Administration of Medication. It is essential for nurses to have current and accurate information about medications used during childbirth. The most effective route of administration is selected for each patient; then the medication is prepared and administered correctly. They must have the knowledge, skill, and judgement needed to perform medication practices safely. Provincial regulatory bodies set practice standards for medication administration.

Any medication can cause a minor or severe allergic reaction. As part of the assessment for such allergic reactions, the nurse should monitor the patient's vital signs, respiratory effort, cardiovascular status, integument status, and platelet and white blood cell count. The patient is observed for adverse effects of medication therapy, especially drowsiness and dyspnea. Minor reactions can consist of rash, rhinitis, fever, shortness of breath, or pruritus. Management of the less acute allergic response is not an emergency.

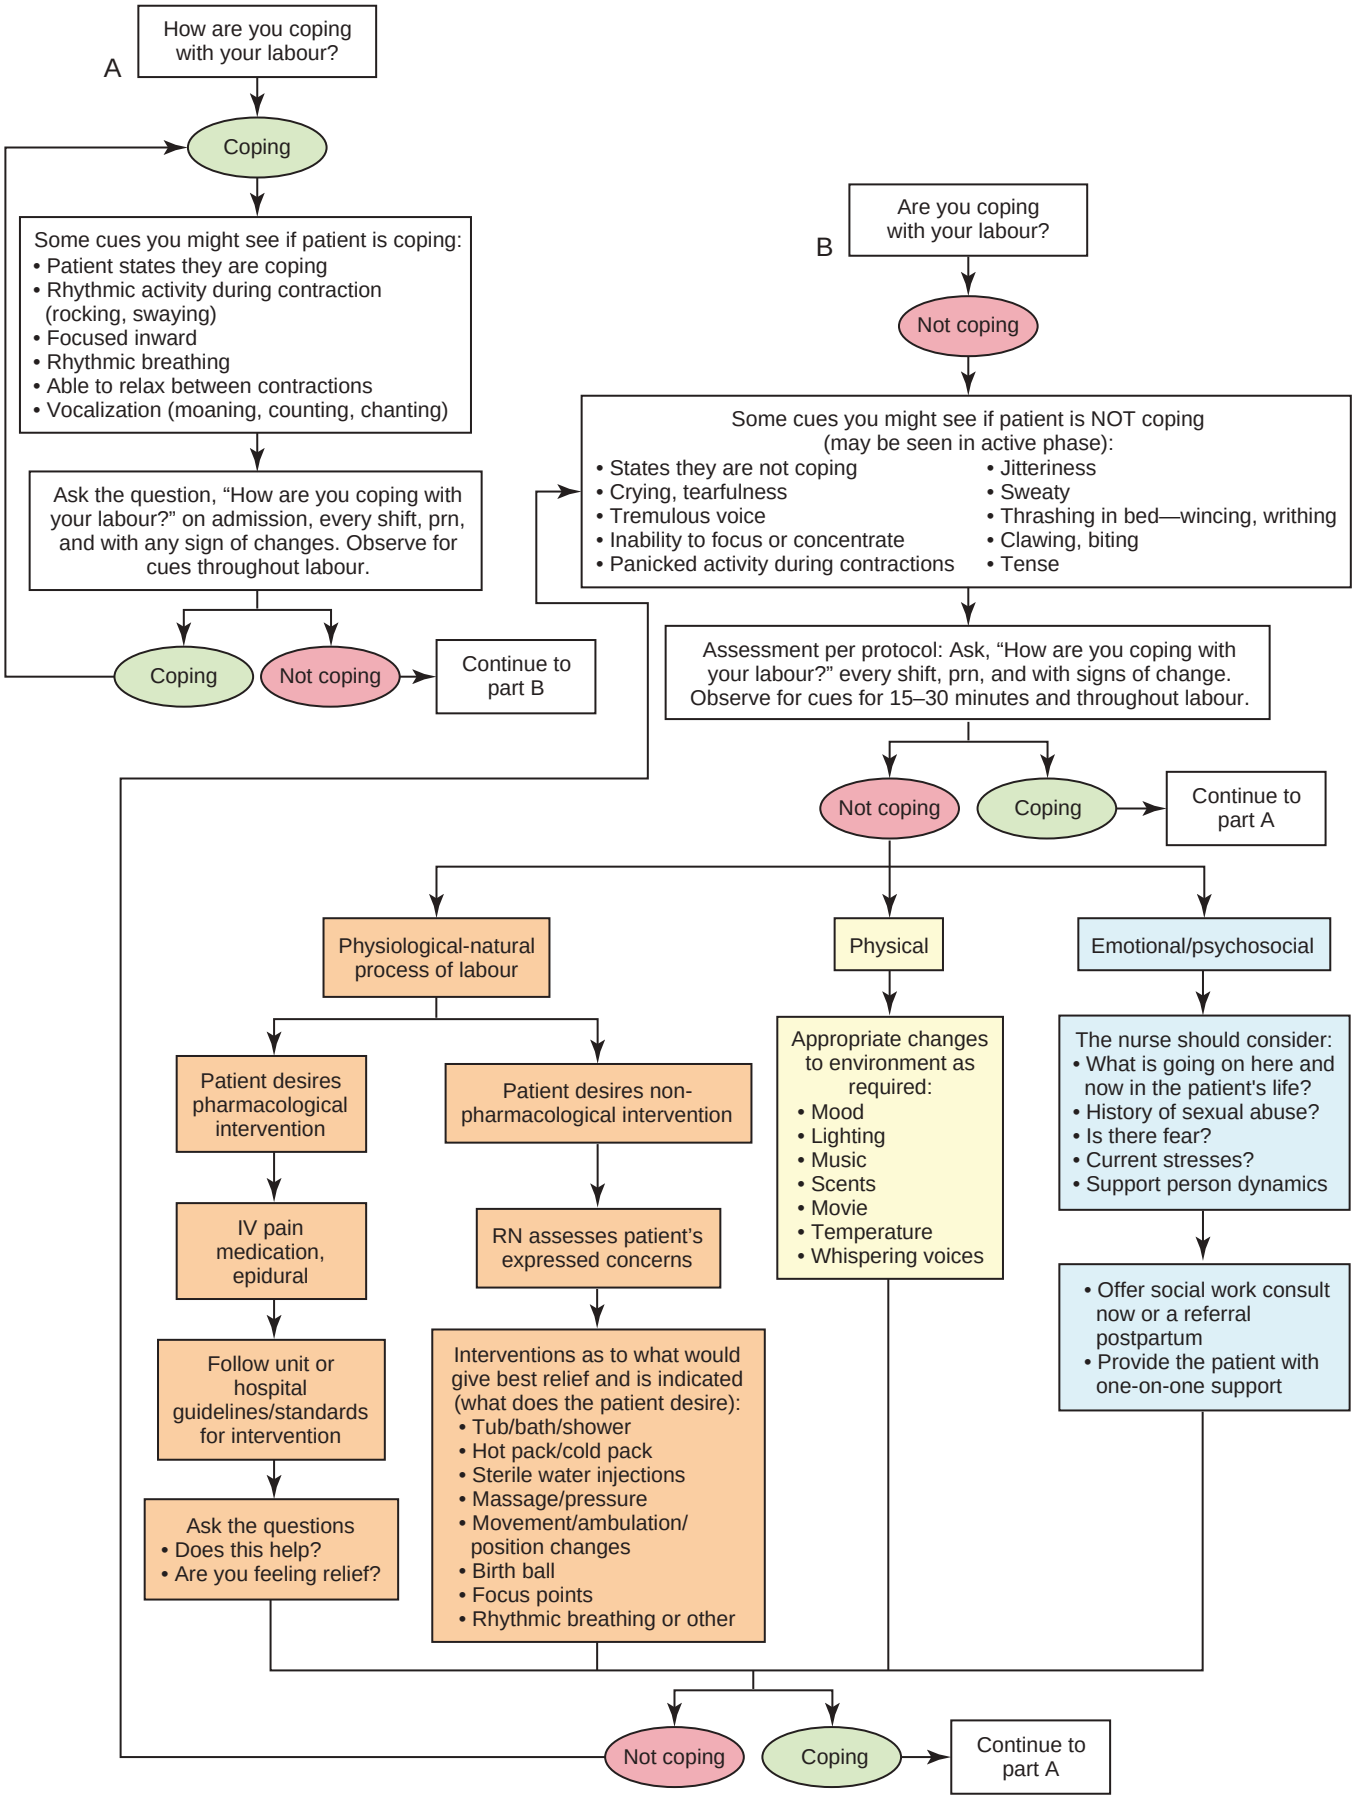

Fig. 18.15 Coping-with-labour algorithm. **A:** How to assess coping in labour. **B:** Strategies to help labouring patients who are not coping. (From Gulliver, B. G, Fisher, J., & Roberts, L. [2008]. A new way to assess pain in labouring women: Replacing the rating scale with a "coping" algorithm. *Nursing for Women's Health, 12*[5], 404–408).

BOX 18.7 Do Patients Have a Choice for Labour Analgesia?

A technological birthing model that uses labour induction, epidural analgesia, continuous electronic fetal monitoring, and Caesarean birth increasingly dominates labour and birth wards in industrialized countries. It is unknown whether the use of epidural analgesia by patients in labour in Canada is a true preference or if it is selected because the only other choice is parenteral opioids. The rate of use of epidural analgesia is high in highly technological teaching hospitals. There is ample evidence of the benefits of the use of doulas and continuous support in labour, yet many patients are not offered these options. Do patients really have choices for pain management if they are not offered alternative pain management strategies or if they are continuously asked if they would like an epidural? Research is needed to discover which pain-relief methods patients would choose if they were offered a wide range of options.

Severe allergic reactions (anaphylaxis) may occur suddenly and lead to shock or death. The most dramatic form of anaphylaxis is sudden, severe bronchospasm, upper airway obstruction, or hypotension. Signs of anaphylaxis are largely caused by contraction of smooth muscles and may begin with irritability, extreme weakness, nausea, and vomiting. This may lead to dyspnea, cyanosis, convulsions, and cardiac arrest. Anaphylaxis must be diagnosed and treated immediately. Initial treatment usually consists of placing the patient in a supine position, injecting epinephrine intramuscularly as per the primary health care provider's order, administering fluid intravenously, securing and supporting the airway with ventilation if necessary, and giving oxygen. If response to these measures is inadequate, IV epinephrine should be given. Cardiopulmonary resuscitation may be necessary (see Chapter 14).

Intravenous route. The preferred route of administration of medications such as fentanyl and nalbuphine is intravenously, administered into the port nearest the insertion of the infusion (proximal port). IV medications may be administered by a physician in some hospitals. The medication is given slowly and in small increments during a contraction. It may be given over a period of three to five consecutive contractions if needed to complete the dose. It is given during contractions to decrease fetal exposure to the medication because uterine blood vessels are constricted during contractions and the medication stays within the labouring patient's vascular system for several seconds before the uterine blood vessels reopen. The IV infusion is then restarted slowly to prevent a bolus of medication from being administered. With this method of injection, the amount of medication crossing the placenta to the fetus is minimized. With decreased placental transfer, the patient's degree of pain relief is maximized. The IV route has the following advantages:

- Onset of pain relief is rapid and more predictable.
- Pain relief is obtained with small doses of the drug.
- Duration of effect is more predictable.

Intramuscular route. Although analgesics are still given intramuscularly, this is not the preferred route of administration for the labouring patient. Advantages of using the IM route are quick administration and no need to start an IV line.

Disadvantages of the IM route include:

- Onset of pain relief is delayed.
- Higher doses of medication are required.
- Medication is released at an unpredictable rate from the muscle tissue and is available for transfer across the placenta to the fetus.

The patient's medication levels (after IM injections) are unequal because of uneven distribution (maternal uptake) and metabolism. IM injections given in the upper portion of the arm (deltoid muscle) seem to result in more rapid absorption and higher blood levels of the medication than when administered in other sites.

Regional (epidural or spinal) anaesthesia. The registered nurse is permitted to do the following:

- Monitor the status of the patient receiving regional anaesthesia, the fetus, and the progress of labour
- Replace empty infusion syringes or bags with the same medication and concentration
- Stop the infusion if there is a safety concern or the patient has given birth
- Remove the catheter if properly educated to do so
- Initiate emergency measures if the need arises
- Communicate clinical assessments and changes in patient status to obstetrical and anaesthesia care providers

In some institutions the registered nurse may also alter the rate of medication infusion and administer bolus doses as ordered. Only qualified care providers (a physician in Canada) are permitted to insert a catheter and initiate epidural anaesthesia, verify catheter placement, and inject medication through the catheter.

SAFETY ALERT

Safe regional anaesthesia administration requires specialized education, experience, and competence. There is potential for significant patient or fetal morbidity and mortality associated with some obstetrical anaesthesia complications. Therefore, a licensed, credentialed anaesthesia care provider should manage regional anaesthesia and analgesia during labour and birth and be readily available to manage obstetrical anaesthesia-related emergencies (Dobson et al., 2019).

Spinal nerve blocks can reduce bladder sensation, resulting in difficulty in voiding, thus the patient should be encouraged to empty their bladder before the induction of the block and should be encouraged to void at least every 2 hours thereafter. The nurse should palpate for bladder distension and measure urinary output to ensure that the bladder is being completely emptied. A distended bladder can inhibit uterine contractions and fetal descent, resulting in a slowing of the progress of labour. If a patient is unable to empty the bladder, a catheter may be necessary. An intermittent catheter is the preferred method, although occasionally an in-dwelling catheter may be inserted and left in place for the remainder of the first stage of labour. The status of the maternal–fetal unit and the progress of labour must be established before the block is performed. The nurse assists the patient to assume and maintain the correct position for induction of epidural and spinal anaesthesia (see Figure 18.12).

Depending on the level of motor block, the patient should be assisted to remain as mobile as possible. When in bed, their position should be alternated side to side at minimum every hour to ensure adequate distribution of the anaesthetic solution and to maintain circulation to the uterus and placenta.

SAFETY ALERT

After receiving an epidural block or opioid intravenously for pain, the patient should not be allowed to ambulate alone. They must either remain in bed or request assistance before attempting to get out of bed. The nurse needs to assess the patient for signs of orthostatic hypotension and return of sensation and motor function of the lower extremities before ambulation.

After a patient receives spinal or epidural anaesthesia, they may no longer require nonpharmacological methods of pain relief and/or assistance with breathing, but they will still need emotional support, reassurance, and information from the nurse. It is important to ensure that the patient receives reassurance and reminders that labour is still progressing. Having the patient feel the contractions with their hand will remind them of what is happening in their body. Some patients may feel disappointed in themselves for requiring pain medication, and they need to be reassured regarding their decision.

Health care providers should be aware that effective epidural anaesthesia may prolong the second stage of labour by 15 to 30 minutes. A delay in the second stage of labour does not negatively affect the labouring patient or fetal outcome, as long as the FHR tracing is normal, the patient's hydration and analgesia are adequate, and there is ongoing progress in the descent of the fetal head. Therefore, operative interventions (e.g., the use of forceps or vacuum) to hasten the birth solely because the second stage is prolonged are unnecessary. Reducing the density of the epidural block during the second stage of labour, delaying pushing until the patient feels the urge to do so, and avoiding arbitrary definitions for the "normal" duration of second-stage labour are suggested as interventions to decrease the risk of operative vaginal birth (Hawkins & Bucklin, 2017). (See Chapter 17 for a full discussion of second-stage labour management.) Box 18.8 summarizes the nursing interventions for patients receiving epidural or spinal anaesthesia.

Safety and General Care. The nurse monitors and records the patient's response to nonpharmacological pain-relief methods and to medications. This includes the degree of pain relief, the level of apprehension, the return of sensations and perception of pain, and allergic or adverse reactions (e.g., hypotension, respiratory depression, fever, pruritus, nausea and vomiting). The nurse continues to monitor maternal vital signs and FHR and pattern at frequent intervals according to the hospital protocol, the strength and frequency of uterine contractions, changes in the cervix and station of the presenting part, the presence and quality of the bearing-down reflex, bladder filling, and state of hydration. Determining the fetal response after the administration of analgesia or anaesthesia is vital. The nurse also assesses the patient's and family's understanding of the need to ensure safety (e.g., keeping side rails up, calling for assistance as needed).

The time that elapses between the administration of an opioid and the baby's birth should be documented and communicated to the team caring for the baby. After birth, the patient who has had spinal, epidural, or general anaesthesia is assessed for return of sensory and motor function in addition to the usual postpartum assessments. Both the nurse and the anaesthesiologist are responsible for documenting assessments and care in relation to regional (epidural or spinal) anaesthesia.

BOX 18.8 Nursing Interventions for the Patient Receiving Epidural or Spinal Anaesthesia

Prior to the Block

- Assess the labouring patient's level of coping, using Figure 18.15.
- Assist primary health care provider or anaesthesia care provider with explaining the procedure and obtaining the patient's informed consent.
- Assess the patient's vital signs, level of hydration, labour progress, and fetal heart rate (FHR) and pattern.
- Insert an intravenous (IV) and infuse a bolus of fluid (Ringer's lactate or normal saline) if ordered (e.g., 500 to 1 000 mL) 15 to 30 minutes before induction of the anaesthesia according to hospital protocol.
- Obtain laboratory results (hematocrit or hemoglobin level, other tests as ordered) and report any abnormalities to the anaesthetist and the patient's primary health care provider.
- Assist the patient to void.

During Initiation of the Block

- Assist the patient with assuming and maintaining proper position.
- Verbally guide the patient through the procedure, explaining sounds and sensations as they are experienced.
- Assist the anaesthesia care provider with documentation of vital signs, time and amount of medications given, etc.
- Monitor vital signs (especially blood pressure) and FHR as ordered.
- Have oxygen and suction readily available.
- Monitor for signs of local anaesthetic toxicity (see Box 18.6) as the test dose of medication is administered.

While the Block Is in Effect

- Continue to monitor the patient's vital signs and FHR as ordered (continuous monitoring of maternal heart rate [electrocardiogram (ECG)] and blood pressure may be ordered to monitor for accidental intravenous injection of medication).
- Continue to assess the patient's level of coping.
- Monitor for bladder distension:
  - Assist with spontaneous voiding on bedpan or toilet.
  - Insert a urinary catheter if necessary.
- Encourage or assist the patient to change positions from side to side every 30 to 60 minutes.
- Promote safety:
  - Keep side rails up on the bed.
  - Place telephone and call light within easy reach.
  - Instruct patient not to get out of bed without help.
- Make sure there is no prolonged pressure on anaesthetized body parts.
- Keep the epidural catheter insertion site clean and dry.
- Continue to monitor for anaesthetic adverse effects (see Box 18.6).

While the Block Is Wearing off After Birth

- Assess regularly for the return of sensory and motor function.
- Continue to monitor the patient's vital signs as ordered.
- Monitor for bladder distension:
  - Assist with spontaneous voiding on bedpan or toilet.
  - Insert urinary catheter if necessary.
- Promote safety:
  - Keep side rails up on the bed.
  - Place telephone and call light within easy reach.
  - Instruct patient not to get out of bed without help.
- Make sure there is no prolonged pressure on anaesthetized body parts.
- Keep the epidural catheter insertion site clean and dry.
- Continue to monitor for anaesthetic adverse effects (see Box 18.6).

KEY POINTS

- Nonpharmacological pain and stress management strategies are valuable for managing labour discomfort on their own or in combination with pharmacological methods.
- The gate-control theory of pain and the stress response form the basis for many of the nonpharmacological methods of pain relief.
- Sedatives may occasionally be used for patients in prolonged early labour when there is a need to decrease anxiety or promote sleep or therapeutic rest.
- The use of opioid agonist–antagonist analgesics in patients with pre-existing opioid dependence may cause symptoms of abstinence syndrome (opioid withdrawal).
- Naloxone (Narcan) is an opioid (narcotic) antagonist that can reverse narcotic effects, especially respiratory depression.
- Pharmacological control of pain during labour requires collaboration among the health care providers and the labouring patient.
- The nurse must understand medications, their expected effects, potential adverse effects, and methods of administration.
- Maintenance of the labouring patient's fluid balance is essential during spinal and epidural nerve blocks.
- Analgesia or anaesthesia can potentially cause respiratory depression in both the patient and the newborn.
- Epidural anaesthesia and analgesia is the most effective pharmacological pain relief method for labour that is available.
- General anaesthesia is rarely used for vaginal birth but may be used for Caesarean birth or whenever rapid anaesthesia is needed in an emergency childbirth situation.
- Patients need to be supported during labour by health care providers who feel comfortable assessing a patient's level of coping during labour and providing the appropriate support based on the patient's needs.
- The type of analgesic or anaesthetic to be used is determined by the patient and health care provider preference, the stage of labour, and the method of birth.

Fetal Health Surveillance During Labour

Lauren B. Rivard

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Explain baseline fetal heart rate (FHR) and identify accelerations and decelerations of the FHR.
2. Identify signs of normal and abnormal intermittent auscultation and normal, atypical, and abnormal electronic fetal monitor fetal health surveillance (FHS) findings.
3. Describe nursing measures that can be used to maintain FHS patterns within normal limits and interventions used to manage atypical and abnormal FHS findings.
4. Identify the appropriate method and differences in the types of FHS monitoring: intermittent auscultation and electronic fetal monitoring.
5. Review the frequency of assessment and documentation of the fetal monitoring process during labour.

FETAL HEALTH SURVEILLANCE

The ability to assess the fetus by auscultation of the fetal heart was initially described more than 300 years ago. With the advent of the fetoscope and stethoscope after the turn of the twentieth century, the listener could hear clearly enough to count the fetal heart rate (FHR). Electronic fetal monitoring (EFM) was introduced in the 1960s and was meant to be used primarily with high-risk patients in labour. The Society of Obstetricians and Gynaecologists of Canada (SOGC) publishes Canadian guidelines for both antepartum and **intrapartum** fetal surveillance that are used in obstetrical practice throughout Canada. This chapter discusses the basis for fetal health surveillance (FHS) during labour, the types of monitoring used, and nursing assessment and management of FHS findings.

EFM involves the use of one or two belts around the labouring patient to monitor contractions and FHR. Intermittent auscultation is done using different types of equipment to auscultate the heart rate at various times during labour. Both of these monitoring techniques are discussed further in this chapter. When EFM was initially introduced, it was thought that it would enable early identification of fetal asphyxia, resulting in an opportunity to prevent fetal death or long-term neurological morbidity, especially from cerebral palsy (CP) (Nelson et al., 2016). The use of EFM rapidly expanded following its introduction to the market because it was thought that monitoring with EFM was more sensitive than auscultation and would provide better insight into potential hypoxic brain injuries in the fetus. However, research has shown that EFM has not reduced the incidence of CP (Nelson et al., 2016). Furthermore, rates of CP are less likely to decline now as more preterm infants survive (Miller et al., 2017). Rising Caesarean birth rates have also been attributed to increased EFM use. The rate of Caesarean births in Canada was 29.4% in 2018–2019 (Canadian Institute for Health Information [CIHI], 2020), an increase from 26.7% in the previous decade. The SOGC recommends **intermittent auscultation** (IA) for healthy patients in spontaneous labour between 37+0 and 41+3 weeks of gestation, in the absence of risk factors for adverse perinatal and newborn outcomes, and reserves the use of EFM for pregnancies at risk of adverse perinatal outcomes (Dore & Ehman, 2020). However, the predominant method of fetal surveillance during labour remains EFM.

BASIS FOR MONITORING

Fetal Response

Labour is a period of physiological stress for the fetus; as such, monitoring of fetal status is an essential part of nursing care throughout labour. Fetal oxygen supply during labour is affected to some degree by uterine activity (UA). However, the individual capacity of the fetus to cope with these periods of decreased oxygen availability determines whether hypoxia will ensue. Maternal, uteroplacental, and fetal factors may reduce the oxygen supply to the fetus and are listed in Box 19.1.

FHR and UA must both be assessed together, and interpretation of the results should be based on the total clinical picture. Standards have

BOX 19.1 Factors That May Affect Fetal Oxygenation in Labour

Maternal Factors

Decreased maternal arterial oxygen tension
- Respiratory disease
- Hypoventilation, seizure, trauma
- Smoking
- Obesity (BMI >35 kg/m^2)

Decreased maternal oxygen-carrying capability
- Significant anemia (e.g., iron deficiency, hemoglobinopathies)
- Carboxyhemoglobin (smokers)

Decreased uterine blood flow
- Hypotension (e.g., blood loss, sepsis)
- Regional anaesthesia
- Maternal positioning

Chronic maternal conditions
- Vasculopathies (e.g., systemic lupus erythematosus, type I diabetes, chronic hypertension)
- Antiphospholipid syndrome
- Cyanotic heart disease
- Chronic obstructive pulmonary disease

Uteroplacental Factors

Excessive uterine activity
- Tachysystole secondary to oxytocin, prostaglandins (PGE_2), or spontaneous labour
- Placental abruption

Uteroplacental dysfunction
- Placental abruption
- Placental infarction—dysfunction marked by IUGR, oligohydramnios, or abnormal Doppler studies
- Chorioamnionitis
- Uterine rupture

Fetal Factors

Malpresentation (e.g., breech)
Polyhydramnios
Oligohydramnios
Cord compression, prolapse or entanglement
- ≥3 nuchal loops

Umbilical cord knots
Single umbilical artery
Decreased fetal oxygen carrying capability
- Significant anemia (e.g., isoimmunization, maternal–fetal bleed, ruptured vasa previa)
- Carboxyhemoglobin (if mother is a smoker)

BMI, Body mass index; *IUGR,* intrauterine growth restriction.
Adapted from Dore, S. & Ehman, W. (2020). SOGC clinical practice guideline: No. 396-Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics & Gynaecology Canada, 42*(3), 316 – 348. https://doi.org/10.1016/j.jogc.2019.05.007.

been established for how frequently the FHR should be assessed, based on the clinical picture and the stage of labour. The SOGC recommends that the FHR be assessed and interpreted hourly in the latent stage of labour (if the patient is admitted to hospital) or when a significant change occurs (e.g., spontaneous rupture of the amniotic membrane or a change in clinical status). In active labour, the FHR should be assessed and interpreted every 15 to 30 minutes; the same is true for the passive phase of the second stage (when the labouring person is not pushing despite being fully dilated). During the active phase of the second stage of labour (when pushing), assessments are required every 5 to 15 minutes, depending on the method of fetal surveillance being used (Dore & Ehman, 2020). In addition, the FHR should be assessed before and after artificial rupture of membranes as well as with the administration of medications and anaesthesia. The FHR should be assessed more frequently when atypical or abnormal FHR patterns are identified (Dore & Ehman, 2020).

The SOGC recommends that each facility have written guidelines regarding the appropriate use of each method of fetal surveillance, including clinically appropriate responses to atypical and abnormal FHS findings (Dore & Ehman, 2020). In clinical practice, FHS patterns (when monitored via EFM) are described as normal, requiring no interventions; as atypical, requiring vigilance and ongoing monitoring; or as abnormal, which requires various interventions, potentially including expediting birth. Interventions for both atypical and abnormal FHS findings are based on the total clinical picture (Dore & Ehman, 2020). The perinatal nurse should document all aspects of FHS, including the method of monitoring used (IA or EFM), the UA pattern, and the associated FHR features that can be documented (based on the method of monitoring) as well as the interpretation of the FHS findings. Documentation should be completed according to institutional policies and guidelines.

Uterine Activity

UA is assessed by palpation; additional assessment methods used include an external tocotransducer or an internal intrauterine pressure catheter (IUPC) (both are used in conjunction with the EFM) (see discussion later in chapter). The following components should be included in a complete assessment of UA: frequency, duration, intensity, and resting tone (Figure 19.1). The type of information obtained depends on the type of monitoring method selected.

- *Frequency* is measured by determining the number of contractions in a 10-minute period averaged out over a 30-minute window (Dore & Ehman, 2020).
- *Duration* is measured in seconds, from the beginning to the end of the contraction. Contraction duration remains fairly stable throughout the first and second stages of labour, ranging from 45 to 80 seconds. *A contraction should last no longer than 90 seconds* (Miller et al., 2017). Duration of contractions is always expressed as a range in seconds, from the shortest to the longest contraction that occurred in the time being documented.
- *Intensity* is determined by palpation or by IUPC. If palpation is the method of assessment, the contractions are described as mild, moderate, or strong. If an IUPC is in place, intensity is measured in mm Hg. To understand how intensity is measured via palpation see Table 19.1.
- *Resting tone* is the degree of muscular tension when the uterus is relaxed. It is assessed between contractions and should last at least 30 seconds. When assessed through palpation, the relaxed uterus is described as soft; if assessed using an IUPC, the average resting tone during labour is less than 25 mm Hg (Dore & Ehman, 2020).

A normal UA pattern in labour is characterized by five or less contractions occurring in a 10-minute window (averaged over a 30-minute time period); these contractions last less than 90 seconds, with a

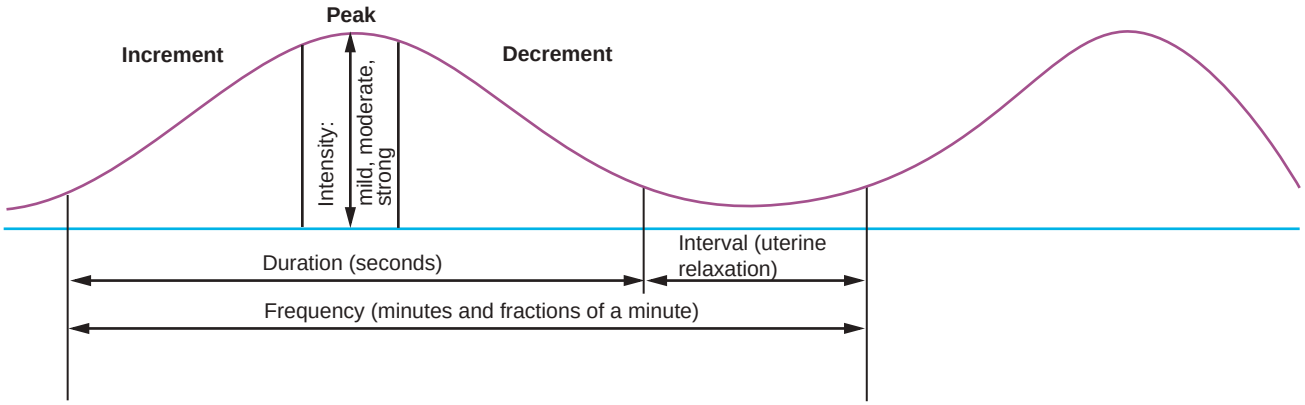

Fig. 19.1 Components of uterine activity during labour. (From Murray, S. S., & McKinney, E. S. [2010]. *Foundations of maternal-newborn nursing* [5th ed.]. Saunders).

TABLE 19.1 Comparison Model for Palpation of Uterine Activity

Palpation of Uterus	Feels Like . . .	Contraction Intensity
Easily indented	Tip of nose	Mild
Can slightly indent	Chin	Moderate
Cannot indent	Forehead	Strong

From Wisner, K., & Holschuh, C. (2018). Fetal heart rate auscultation (3rd ed.). *Nursing for Women's Health, 22*(6), e1–e32. doi:10.1016/j.nwh.2018.10.001.

minimum of 30 seconds of rest period between contractions. Ideally, contractions are moderate to strong in intensity (assessed by palpation) and allow for uterine relaxation to be detected between them.

It is essential to document the UA in conjunction with the FHR assessment. UA can be described as follows:

Normal—less than or equal to five contractions in 10 minutes, averaged over a 30-minute window

Tachysystole—greater than five contractions in 10 minutes, averaged over a 30-minute window

- Tachysystole should always be qualified by presence or absence of associated FHR changes (e.g., tachysystole with normal or atypical or abnormal FHR).
- Tachysystole may occur in both spontaneous and stimulated labour.

When performing IA, the presence of tachysystole denotes an abnormal IA pattern and is an indication to initiate EFM (Dore & Ehman, 2020).

Fetal Assessment

Available methods of FHS serve as screening tests. The goal of intrapartum fetal surveillance is to identify potential fetal decompensation, allowing for timely and effective interventions to prevent perinatal morbidity or mortality (Dore & Ehman, 2020). UA is an essential part of FHS. Components of a normal intrapartum FHS assessment are given in Table 19.2. The types of fetal monitoring (IA and EFM) are discussed later in the chapter.

MONITORING TECHNIQUES

The ideal method of fetal assessment during labour continues to be debated. Research indicates that IA of the FHR and EFM are associated with similar fetal outcomes in low-risk intrapartum patients (Alfirevic et al., 2017; Dore & Ehman, 2020). The use of EFM has been shown to increase the rate of intervention during labour, including Caesarean birth and operative vaginal births, and greater use of analgesia and anaesthesia. Given these findings, only high-risk pregnancies require EFM (Alfirevic et al., 2017; Dore & Ehman, 2020). See Table 19.3 for antenatal and intrapartum conditions that are associated with increased risk for adverse fetal and newborn outcomes and for which the use of EFM is recommended.

Despite the recommendation that EFM be used only for pregnancies with increased risk of adverse outcomes, the use of EFM remains high, perhaps because of the following:

- Lack of nursing staff to provide one-to-one supportive care
- Caregiver skill and comfort with IA
- False belief that EFM will prevent bad outcomes
- False caregiver belief that EFM records will prevent medical legal actions

TABLE 19.2 Normal Intrapartum Fetal Surveillance Findings

	If Using IA	If Using EFM
Baseline FHR	110–160 bpm	110–160 bpm
Rhythm	Regular (e.g., no skipped beats)	Not used with EFM
Variability	Not used with IA	Moderate (range of 6–25 bpm in FHR) Minimal or absent (range of ≤5 bpm in FHR) for <40 min
Deceleration	None heard	None or nonrepetitive uncomplicated variable decelerations or early decelerations
Accelerations	May be heard	Spontaneous accelerations may be present but are not required; accelerations occur with fetal scalp stimulation
Clinical Interpretation	No evidence of fetal compromise	

bpm, Beats per minute; *EFM*, electronic fetal monitoring; *FHR*, fetal heart rate; *IA*, intermittent auscultation.

Adapted from Dore, S., & Ehman, W. (2020). SOGC clinical practice guideline: No. 396—Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics & Gynaecology Canada, 42*(3), 316–348. https://doi.org/10.1016/j.jogc.2019.05.007.

TABLE 19.3 Conditions Associated with Adverse Fetal Outcomes

CONDITIONS ASSOCIATED WITH ADVERSE FETAL OUTCOMES WHERE EFM MAY BE BENEFICIAL*

	EFM is Recommended	EFM Should Be Considered
Antenatal Conditions		
Maternal	Hypertensive disorders of pregnancy	Prepregnancy BMI >35 kg/m^2
	Diabetes: Pre-existing and gestational	Other factors (e.g., smoking, substance use, limited prenatal care)
	Medical diseases (e.g., cardiac; significant anemia, hyperthyroidism, vascular and/or renal disease)	
	Motor vehicle collision/trauma (EFM recommended for a minimum of 4–6 hours)	
	Maternal perception of reduced or absent fetal movements	
	Antepartum hemorrhage	
Fetal	Intrauterine growth restriction	3 or more nuchal loops
	Abnormal umbilical artery Doppler velocimetry	
	Single umbilical artery	
	Oligohydramnios	
	Polyhydramnios	
	Abnormal biophysical profile or nonstress test	
	Significant fetal abnormality (compatible with life)	
	Isoimmunization	
	Multiple pregnancy	
	Velamentous cord insertion	
Intrapartum Conditions		
Maternal	Vaginal bleeding in labour	
	Intrauterine infection/chorioamnionitis	
	Previous Caesarean birth/attempted VBAC	
	Prolonged ROM at term (>24 hours)	
	Combined spinal-epidural analgesia	
	Oxytocin induction or augmentation of labour	
	Post-term pregnancy (>42 weeks' gestation)	
	Labour dystocia	
	Tachysystole	
	Difficulties in reliably determining UA and/or FHR with IA	
Fetal	Abnormal FHR on auscultation	
	Prematurity (<37.0 weeks)	
	Meconium staining of the amniotic fluid	
	Breech presentation	
	FHR arrhythmia	

BMI, Body mass index; *EFM,* electronic fetal monitoring; *FHR,* fetal heart rate; *IA,* intermittent auscultation; *ROM,* rupture of membranes; *UA,* uterine activity; *VBAC,* vaginal birth after Caesarean.

*Note that this list is not exhaustive and should not replace clinical judgement.

Source: Dore, S., & Ehman, W. (2020). SOGC clinical practice guideline: No. 396—Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics & Gynaecology Canada, 42*(3), 316–348. https://doi.org/10.1016/j.jogc.2019.05.007.

Regardless of the method of surveillance used, there should be discussion with the labouring patient about benefits, risks, and limitations of IA and EFM (Dore & Ehman, 2020). Every effort should be made to use the fetal assessment method that the person desires, based on an informed discussion with the health care team. Clinically, auscultation of the FHR in accordance with the frequency recommended is sometimes difficult in today's busy labour and birth units. Despite the method of FHS chosen, all hospitals should strive to ensure one-to-one nurse–patient staffing ratios for labouring patients.

Fig. 19.2 Pinard stethoscope. NOTE: Hands should not touch stethoscope while nurse is listening. (Courtesy Julie Perry Nelson.)

Intermittent Auscultation

IA as a method of FHS involves assessing UA through palpation and listening to and counting the fetal heart sounds at periodic intervals in order to assess overall fetal status. IA of the fetal heart can be performed with a Pinard stethoscope (Figure 19.2), Doppler ultrasound

Fig. 19.3 **A:** Doptone (ultrasound fetoscope). **B:** Ultrasound stethoscope. **C:** DeLee-Hillis fetoscope. (Courtesy Michael S. Clement, MD.)

(doptone), an ultrasound stethoscope, or a DeLee-Hillis fetoscope (Figure 19.3). The doptone, which is used most frequently for IA of the FHR, transmits ultra-high-frequency sound waves reflecting movement of the fetal heart and converts these sounds into an electronic signal that can be counted (see Figure 19.3, *A*). The technique used for auscultation is described in Box 19.2.

! NURSING ALERT

The SOGC recommends against the use of an EFM transducer when conducting IA. EFM transducers are often connected to a hard drive and even when the paper tracing is turned off, there is a high likelihood of an electronic tracing being generated and retained in electronic archives in the medical record (Dore & Ehman, 2020).

IA is easy to use, inexpensive, and less invasive than EFM. It is more comfortable for the labouring patient and provides freedom of movement. Other care measures such as ambulation and the use of baths or showers are more easily carried out when IA is used. IA is recommended for healthy patients at term who are not expected to experience adverse perinatal outcomes (Dore & Ehman, 2020).

When the FHR is auscultated, it should be described as a baseline number and as having a regular or irregular rhythm. When an irregular heart rate is heard (a fetal arrhythmia), the nurse should initiate EFM and communicate with the primary health care provider to initiate further fetal testing. The presence or absence of accelerations (audible increases) and decelerations (audible decreases) from the baseline rate should be noted (Dore & Ehman, 2020; Miller et al., 2017). If the FHS findings are assessed and classified as normal, then IA should continue to be used. If abnormal FHS findings via IA are detected, the nurse should consider the potential causative factors, interpret the information in light of the total clinical picture, institute the appropriate intrauterine resuscitation techniques (such as changing the maternal position), and auscultate the FHR immediately after the next contraction. Initiation of EFM may be considered at this time in response to the current or subsequent IA findings, the clinician's experience, and the total clinical picture (Figure 19.4).

! NURSING ALERT

It is essential to assess the maternal pulse at the same time as listening to the FHR with IA to ensure that the identified FHR is not in fact a maternal heart rate.

Frequency of Intermittent Auscultation. The recommended frequency of IA depends on the stage of labour. In the latent phase of labour, patients are often at home and do not require frequent assessments. If they are hospitalized, IA should be done at the time of admission and approximately every hour or according to the hospitals policies and guidelines. Once the active phase of the first stage of labour is reached, IA assessments should be completed every 15 to 30 minutes. During the active phase of the second stage of labour (when pushing), the frequency of IA assessments increases to every 5 minutes or immediately following each contraction (Dore & Ehman, 2020).

! NURSING ALERT

When the FHR is auscultated and documented, it is **inappropriate** to use the descriptive terms associated with EFM (e.g., *moderate variability, variable deceleration*); these terms are visual descriptions of the patterns produced on the monitor tracing. However, terms that are numerically defined, such as *bradycardia* and *tachycardia*, can be used.

BOX 19.2 Intermittent Auscultation Procedure

Auscultation is performed as follows:

1. Explain the procedure to the patient.
2. Perform Leopold manoeuvres (see Box 17.5) by palpating the patient's abdomen to identify fetal presentation and position.
3. Palpate the uterus for the absence of uterine activity (UA) so that the fetal heart rate (FHR) is assessed between contractions.
4. Place the listening device over the area of maximal intensity, usually the fetal back, to obtain the clearest and loudest sound. Apply ultrasound gel to the Doppler ultrasound device if used.
5. Palpate the labouring patient's radial pulse while simultaneously listening to the FHR to differentiate it from the fetal rate.
6. Listen and count the FHR for 60 seconds between contractions to obtain a baseline FHR. There is no clear evidence about the best way to count to determine the baseline rate. The most accurate rate would be assessed by counting the FHR for 60 consecutive seconds, excluding any periodic changes (audible increases [accelerations] or decreases [decelerations] heard) in the heart rate. Others count for two 30-second counts and add them together to obtain the FHR in beats per minute. And still others may count during four consecutive 15-second intervals, adding the rates obtained together to obtain an approximate baseline and to determine the presence of variations within the rate. The FHR obtained is recorded as a single number or as a range if counted over short time intervals (Dore & Ehman, 2020).
7. After obtaining the baseline FHR, listen and count the FHR for 60 seconds immediately following uterine contractions to determine if the FHR heard following the contraction is within the range of the baseline FHR obtained.
8. After each auscultation, interpret the fetal health surveillance (FSH) findings and document the following:
   - UA (frequency, duration, strength by palpation and resting tone)
   - Baseline FHR
   - Rhythm (regular or irregular)
   - Presence of audible accelerations or decelerations
   - Classification of the FHS as normal or abnormal
9. Make a decision for ongoing care based on the FHS findings and total clinical picture (see Figure 19.4).

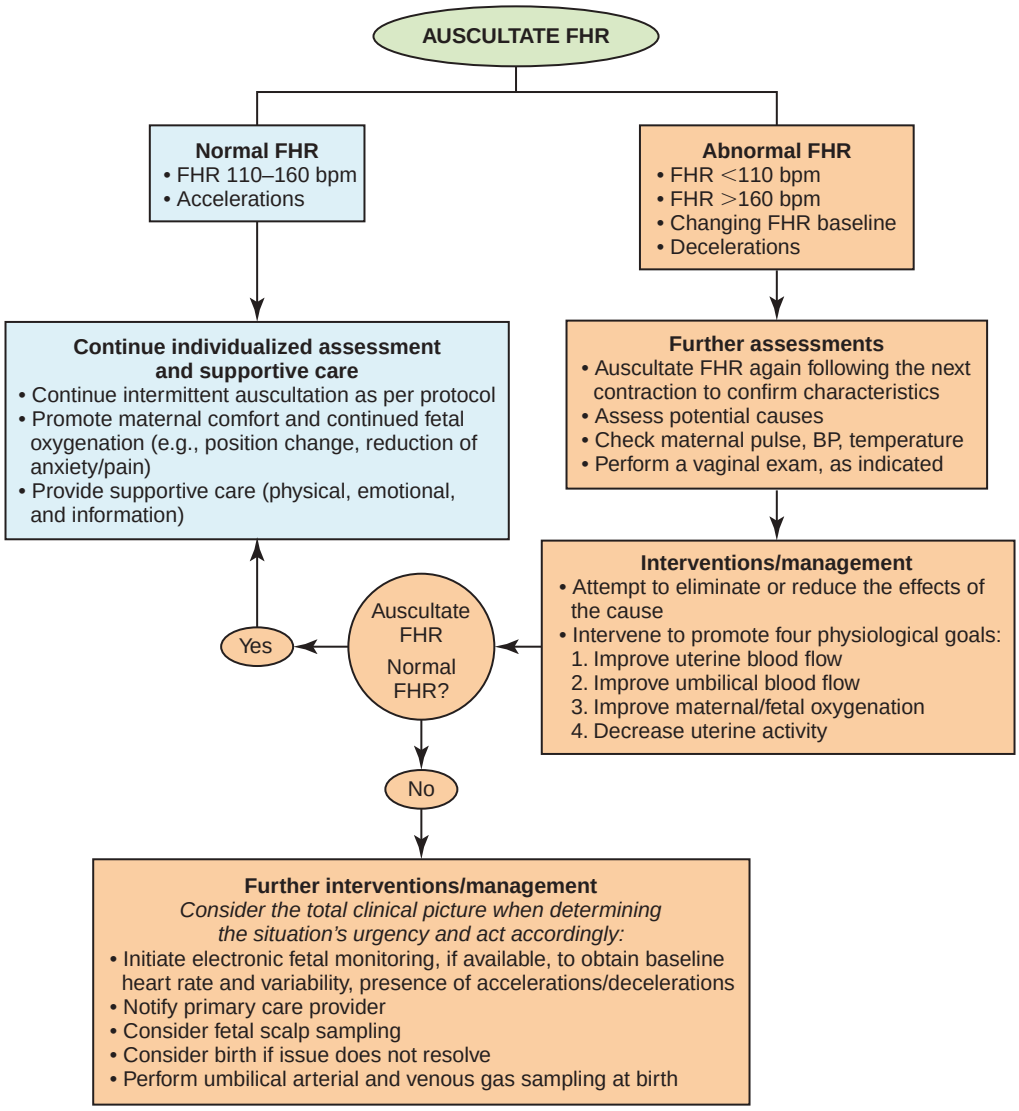

Fig. 19.4 Decision support tool for intermittent auscultation. *BP,* Blood pressure; *bpm,* beats per minute; *FHR,* fetal heart rate. (Reprinted from Liston, R., Sawchuck, D., Young, D., et al. [2018]. SOGC clinical practice guideline: Fetal health surveillance: Antepartum and intrapartum consensus guideline. *Journal of Obstetrics and Gynaecologists of Canada, 40*[4], e251–e271. Copyright 2018, with permission from Elsevier.).

In some situations, IA can be challenging to use, particularly in relation to the labouring patient's body habitus or if the fetus is very active or in a posterior position. The labouring patient can become anxious if the examiner cannot readily hear the FHR. It often takes time for the inexperienced listener to locate the fetal heart and find the area of maximal intensity. To allay concerns, it is helpful to use a Doppler ultrasound device so that the patient can hear the sounds that the nurse hears. If the examiner cannot locate the fetal heartbeat, assistance should be requested. In some cases, ultrasonography can be used to help locate the fetal heartbeat. Seeing the fetal heartbeat on the ultrasound screen can be reassuring to the labouring patient if there was initial difficulty in locating the best area for auscultation.

When using IA, UA is assessed by palpation (see Uterine Activity above). It is essential to document the UA in conjunction with the FHR assessment, to classify the findings as normal or abnormal, to interpret the findings in light of the total clinical picture, and to respond on the basis of assessment findings and clinical knowledge. Accurate and complete documentation of fetal status and UA is especially important when IA and palpation are being used, because no paper tracing record or computer storage of these assessments is obtained as with EFM. Labour flow records or computer charting systems that prompt notations of all assessments are useful for ensuring comprehensive documentation.

Electronic Fetal Monitoring

The purpose of electronic FHR monitoring is to provide ongoing assessment of the FHR in relation to UA in order to detect potential decompensation in the fetus. This allows for timely and effective interventions to prevent fetal or newborn morbidity or mortality. EFM tracings are analyzed for characteristic patterns that suggest fetal hypoxic events and metabolic acidosis during labour. When atypical or abnormal FHR patterns are noted (depicting increased risk for hypoxia and the development of metabolic acidosis if left unresolved), interventions to resolve the atypical or abnormal FHS features, based on the clinician's interpretation of the clinical situation, should be implemented in a timely manner. While the goal of EFM is to detect impending fetal decompensation (hypoxia and metabolic acidosis) during labour and provide timely intervention, as stated earlier the use of EFM is associated with increased rates of Caesarean births and instrumental vaginal births compared to rates with IA (see Evidence-Informed Practice box: Fetal Monitoring).

EVIDENCE-INFORMED PRACTICE

Fetal Monitoring

Ask the Question

What are the optimal methods of assessing fetal well-being on admission and during labour?

Critically Analyze the Evidence

Electronic fetal heart monitoring (EFM; also known as cardiotocography [CTG]) has become standard practice in the labour and birth setting for many decades, especially in North America. It has been suggested that such monitoring is not necessary for the low-risk labour patient and may even present a risk of false abnormal readings, leading to high rates of Caesarean births.

A meta-analysis of trials measuring maternal and fetal outcomes with the use of admission CTG in comparison to IA demonstrated no evidence of benefit for the use of admission CTG for low-risk patients on admission in labour. Furthermore, the authors indicated that admission CTG probably increases Caesarean birth rates in the low risk population (Devane et al., 2017).

Another meta-analysis including 13 randomized controlled trials with a total of 37 000 participants compared the use of IA to CTG throughout labour. Compared to IA, use of CTG showed no significant improvement in overall perinatal death or cerebral palsy. Continuous CTG use was associated with an increased risk of operative vaginal birth and increased risk of Caesarean birth. CTG use was associated with half the number of newborn seizure rates compared to those with IA (Alfirevic et al., 2017).

The SOGC has issued professional guidelines for intrapartum care that do not recommend EFM for low-risk labouring patients (Dore & Ehman, 2020). EFM should be used for pregnancies at increased risk for adverse outcomes, along with fetal scalp blood sampling for either pH or lactate testing if abnormal patterns arise or persist. Use of continuous EFM is recommended when conditions associated with adverse fetal outcomes are known in the antenatal or intrapartum period (see Table 19.3).

Implications for Practice

EFM is here to stay, but it is only a screening tool (Dore & Ehman, 2020). Labouring patients and providers have come to expect the constant feedback that EFM provides. In addition, busy nurses have come to rely on the remote monitoring screens as they move from room to room. However, the risk of false alarms and the legal vulnerability of ambiguous patterns may be contributing to the soaring Caesarean birth rate, which carries its own risks. Continuous monitoring of low-risk patients restricts patient mobility, potentially prolonging labour and increasing discomfort. In high-risk situations, EFM can be a valuable tool for identifying atypical and abnormal FHR patterns indicative of fetal decompensation; however, the tracings may also be inaccurate and ambiguous, causing needless anxiety. Patients who expect routine monitoring need information about the risks and benefits of continuous monitoring in comparison to those with IA. This information can enable them to make informed decisions about their preference for monitoring their baby's heart rate in labour. The health care team may also need to become more proficient and familiar with auscultation as an assessment tool, and they must consider the information obtained as only one part of the total clinical picture.

Lauren Rivard

The two modes of EFM are (1) the external mode, which uses external **transducers** placed on the labouring person's abdomen to assess FHR and UA, and (2) the internal mode, which involves application of a spiral electrode to the fetal presenting part to assess the FHR. In addition, internal monitoring may include IUPC to assess UA and uterine resting tone. The differences between the external and internal modes of EFM are summarized in Table 19.4.

External Monitoring. Separate transducers are used to monitor the FHR and UA (Figure 19.5). The ultrasound transducer works by reflecting high-frequency sound waves off a moving interface, in this case the fetal heart and valves. It is sometimes difficult to reproduce a continuous and precise record of the FHR because artifact may be introduced by fetal and maternal movement. Prepregnancy body mass index (BMI) greater than 35 kg/m^2, occiput-posterior position of the fetus, and anterior attachment of the placenta can all cause weak or absent signals (Association of Women's Health, Obstetric and Neonatal Nurses [AWHONN], 2009). Ensuring a clear, continuous FHR and UA tracing on the monitor is an essential component of EFM. Some electronic fetal monitors have the ability to simultaneously monitor the fetal and maternal heart rate. While clinically useful, caution ensuring that the heart rate monitored is either the fetal or maternal heart is warranted. Once the area of maximal intensity of the FHR has been located, conductive gel is applied to the surface of the ultrasound transducer, and the transducer is then positioned over this area and held securely in place using an elastic belt. The FHR is printed on specially formatted monitor paper. Canada is moving forward toward a national paper speed of 3 cm/min; some areas are still using 1 or 2 cm/min. It is important to determine the paper speed prior to interpreting the EFM tracing.

The tocotransducer (tocodynamometer) measures UA transabdominally. The device is placed on the fundus (in a term pregnancy above the umbilicus) and held securely in place with an elastic belt (see Figure 19.5, *B*). UA, fetal movements, or any other changes to external pressure of the abdomen depress a pressure-sensitive surface on the side of the transducer next to the abdomen. The tocotransducer measures and records the frequency and approximate duration of contractions, but it cannot measure the intensity. If the patient has obesity, it

TABLE 19.4 External and Internal Modes of Monitoring

External Mode	Internal Mode
Fetal Heart Rate	
Ultrasound transducer: High-frequency sound waves reflect mechanical action of the fetal heart; noninvasive, does not require rupture of membranes or cervical dilation; used during both the antepartum and intrapartum periods.	*Spiral electrode:* Converts fetal ECG as obtained from the presenting part to the FHR via a cardiotachometer; can be used only when membranes are ruptured and the cervix is sufficiently dilated during the intrapartum period; electrode penetrates into the fetal presenting part by 1.5 mm and must be attached securely to ensure a good signal.
Uterine Activity	
Tocotransducer: Monitors frequency and duration of contractions by means of a pressure-sensing device applied to the maternal abdomen; used during both the antepartum and intrapartum periods. Strength of the contraction must still be assessed by palpation as done with IA.	*Intrauterine pressure catheter (IUPC):* Monitors the frequency, duration, and intensity of contractions, and resting uterine tone; two types of IUPCs: fluid-filled system and solid catheter; both measure intrauterine pressure at the catheter tip and convert the pressure into millimetres of mercury (mm Hg) on the uterine activity panel of the strip chart; both can be used only when membranes are ruptured and the cervix is sufficiently dilated during the intrapartum period.

ECG, Electrocardiogram; *FHR,* fetal heart rate; *IA,* intermittent auscultation.

may be difficult to have the tocotransducer detect the exact frequency and duration of UA.

The tocotransducer of most electronic fetal monitors is designed for assessing UA in term pregnancy; for this reason, it may not be sensitive enough to detect preterm UA. When monitoring a preterm labour, it is important to remember that the fundus may be located below the level of the umbilicus. The nurse may need to rely on the labouring patient to indicate when UA is occurring and to use palpation as an additional way of assessing contraction frequency and validating the monitor tracing. The strength of the contractions is always determined by palpation, unless an IUPC is in place.

The external transducers are applied easily by the nurse but must be repositioned at least every hour and as the labouring patient or the fetus changes position. In most cases, the use of an external monitor confines the patient to a bed or chair. Portable telemetry monitors are becoming more widely available and allow observation of the FHR and UA patterns by means of centrally located electronic display stations. These portable units provide mobility while the patient is still receiving continuous EFM monitoring.

Internal Monitoring. The technique of continuous internal FHR or UA monitoring provides a more accurate appraisal of fetal well-being during labour than external monitoring because it is not interrupted by fetal movement or affected by movement or size of the pregnant person (Figure 19.6). For this type of monitoring, the membranes must be ruptured, the cervix sufficiently dilated (at least 2 to 3 cm), and the presenting part low enough to allow placement of the spiral electrode, IUPC, or both. Internal and external modes of monitoring may be combined (i.e., internal FHR with external UA, or external FHR with internal UA) without difficulty.

With internal monitoring of the FHR a small spiral electrode is attached to the presenting part. To monitor UA internally, an IUPC is introduced into the uterine cavity alongside the fetal presenting part. The catheter has a pressure-sensitive tip that measures changes in intrauterine pressure. As the catheter is compressed during a contraction,

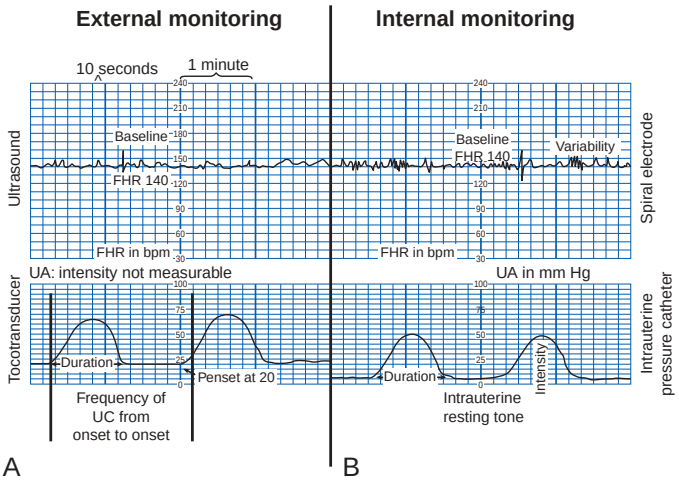

Fig. 19.7 Electronic fetal monitor display of fetal heart rate and uterine activity on monitor paper. **A:** External mode with ultrasound and tocotransducer as signal source. **B:** Internal mode with spiral electrode and intrauterine catheter as signal source. Frequency of contractions is measured from the beginning of one contraction to the beginning of the next. *bpm,* Beats per minute; *FHR*, fetal heart rate; *UA*, uterine activity; *UC*, uterine contractions. (From Miller, L., Miller, D., & Cypher, R. [2017]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [8th ed.]. Mosby.)

pressure is placed on the pressure transducer. This pressure is then converted into a pressure reading in millimetres of mercury (mm Hg). The IUPC can objectively measure UA, including the frequency, duration, and intensity of uterine contractions, as well as uterine resting tone.

The precise measurement of uterine contractions measured by an IUPC can be used to assess the adequacy of contractions for achieving progress in labour. Montevideo units (MVUs) are calculated by subtracting the baseline uterine pressure from the peak contraction pressure for each contraction that occurs in a 10-minute window and then adding together the pressures for each contraction that occurs during that period of time (Cunningham et al., 2018; Miller et al., 2017).

MVUs usually range from 100 to 250 in the first stage of labour; they may rise to 300 to 400 in the second stage. Contraction intensities of 40 mmHg or more and MVUs of 80 to 120 are generally sufficient to initiate spontaneous labour. MVUs are only used with IUPC monitoring of contractions in labour.

The FHR and UA are displayed on the monitor paper and/or computer screen, with the FHR in the upper section and UA in the lower section. Figure 19.7 contrasts the internal and external modes of electronic monitoring. Note that each small square on the monitor paper or screen horizontally represents 10 seconds; each larger box of six squares equals 1 minute (when paper is moving through the monitor at the rate of 3 cm/min).

Admission Fetal Monitor Strips

There has been much debate over the routine use of admission electronic fetal monitor strips. Although it is common practice in many hospitals to perform a 20-minute monitor strip on admission, this is not supported by evidence or recommended for low-risk pregnant patients (Dore & Ehman, 2020). The SOGC states that pregnancies at risk for adverse fetal or newborn outcomes (see Table 19.3) should have an admission FHR tracing completed, but for low-risk pregnancies there is no evidence demonstrating benefit. Admission FHR tracings are not to be used to determine whether a patient is in labour. Palpation along with IA is an effective method to determine the status of labour and the fetus.

FETAL HEART RATE PATTERNS

Characteristic FHR patterns are associated with fetal and maternal physiological processes; these patterns have been identified for many years. However, because EFM was introduced into clinical practice before consensus was reached regarding standardized terminology, variations in the description and interpretation of common FHR patterns were often great. In 1997, the National Institute of Child Health and Human Development (NICHD) published a proposed nomenclature system for EFM interpretation, including standardized definitions for FHR monitoring. In 2007, the SOGC introduced a three-tier system of FHR interpretation and categorization when using EFM (Table 19.5). This change in nomenclature provides care providers with clear and concise guidelines to communicate changes in FHR patterns.

The FHR must be assessed systematically. Assessment of the FHR, with all key components (baseline FHR, variability, and accelerations or decelerations), must include interpretation of UA. Standard terminology should be used when describing the FHR tracing, and findings should be classified (IA—normal or abnormal; EFM—normal, atypical, or abnormal), then interpreted in light of the total clinical picture, followed by a clinically appropriate response to the assessment of the findings.

Baseline Fetal Heart Rate

The intrinsic rhythmicity of the fetal heart, the central nervous system (CNS), and the fetal autonomic nervous system control the FHR. An increase in sympathetic response results in acceleration of the FHR, whereas an increase in parasympathetic response produces a slowing of the FHR. Usually, a balanced increase of sympathetic and parasympathetic response occurs during contractions, with no observable change in the baseline FHR.

Baseline FHR is the approximate mean FHR rounded to increments of 5 beats/min (bpm) during a 10-minute tracing segment; it excludes accelerations, decelerations, and periods of marked variability (Dore & Ehman, 2020; Macones et al., 2008; Miller et al., 2017). The baseline FHR must be present for at least 2 minutes (not necessarily contiguous) in any 10-minute segment or the baseline for that time period is indeterminate (Dore & Ehman, 2020; Macones et al., 2008). The baseline

TABLE 19.5 Classification of Intrapartum EFM Tracings

	Normal	Atypical	Abnormal
Uterine activity	• Normal contraction pattern	• Tachysystole may be present with normal, atypical, or abnormal tracings; monitor closely for concerning FHR characteristics	
Baseline	• 110–160 bpm	• 100–110 bpm • >160 bpm for 30 to 80 min • Rising baseline • Arrhythmia (irregular rhythm)	• <100 bpm • >160 bpm for >80 min • Erratic baseline
Variability	• 6–25 bpm (moderate) • <5 bpm for <40 min	• ≤5 bpm for 40–80 min	• ≤5 bpm for >80 min • ≥25 bpm for >10 min • Sinusoidal
Acceleration	• Spontaneous accelerations present but not required • Accelerations with scalp stimulation	• Absence of acceleration with scalp stimulation	• Usually absent (accelerations if present, do not change classification of tracing)
Decelerations	• None • Nonrepetitive uncomplicated variable decelerations • Early decelerations	• Repetitive uncomplicated variables • Nonrepetitive complicated variables • Intermittent late decelerations • Single prolonged deceleration >2 min but <3 min	• Repetitive complicated variables • Recurrent late deceleration • Single prolonged deceleration >3 min but <10 min
Interpret clinically (in light of total situation)	• No evidence of fetal compromise	• Physiological response	• Possible fetal compromise
Terminology	**Recurrent**: Decelerations occur with ≥50% of uterine contractions in any 20-minute window **Intermittent**: Decelerations occur with <50% of uterine contractions in any 20-minute segment **Repetitive**: ≥3 in a row **Nonrepetitive**: 1 or maximally 2 in a row		

bpm, Beats per minute; *FHR*, fetal heart rate.
Source: Dore, S., & Ehman, W. (2020). SOGC clinical practice guideline: No. 396—Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics & Gynaecology Canada, 42*(3), 316–348. https://doi.org/10.1016/j.jogc.2019.05.007.

rate should be recorded as a single number to lessen confusion and to allow for clarity in identifying baseline variability. However, recording practices may be determined on an individual organization level. Organizations that choose to accept a range for the FHR baseline rate (e.g., 130–140) should clearly communicate with staff and have this preference written in organizational policies and procedures. The normal FHR range at term is 110 to 160 bpm. In the preterm fetus, the baseline rate is slightly higher.

Tachycardia. Fetal **tachycardia** is a baseline FHR greater than 160 bpm that lasts for more than 10 minutes (Figure 19.8) (Dore & Ehman, 2020). Tachycardia is labelled as either "atypical" or "abnormal," depending on the length of time it occurs (see Table 19.5). It can be considered an early warning sign of potential fetal hypoxemia, especially when associated with decreasing variability and decelerations. Fetal tachycardia most commonly occurs as a result of maternal fever. Other causes of fetal tachycardia include maternal or fetal infection, maternal hyperthyroidism, fetal anemia, and maternal administration of medications (e.g., atropine, hydroxyzine) or illicit drug use (e.g., cocaine, methamphetamines). Table 19.6 lists causes, clinical significance of, and nursing interventions for fetal tachycardia.

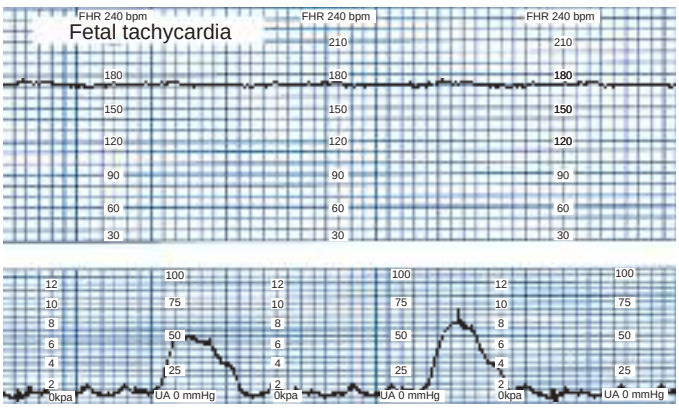

Fig. 19.8 Fetal tachycardia: Fetal heart rate (FHR) greater than 160 beats per minute (bpm). *UA*, Uterine activity.

Bradycardia. Fetal **bradycardia** is a baseline FHR less than 110 bpm for more than 10 minutes (Figure 19.9) (Dore & Ehman, 2020). In the presence of possible fetal bradycardia, it is essential to confirm the maternal pulse to differentiate it from the FHR. True bradycardia occurs rarely and is not specifically related to fetal oxygenation. It is critical to distinguish true bradycardia from a prolonged deceleration, since the causes and management of these two conditions are very different. Bradycardia is often caused by some type of fetal cardiac problem, such as structural defects involving the pacemakers or conduction system or fetal heart failure. Other causes of bradycardia include viral infections (e.g., cytomegalovirus), maternal hypoglycemia, and maternal hypothermia. The clinical significance of the bradycardia depends on the underlying cause and accompanying FHR patterns, including variability and the presence of accelerations or decelerations (Miller et al., 2017). Table 19.6 lists causes and clinical significance of and nursing interventions for bradycardia.

TABLE 19.6 Fetal Tachycardia and Bradycardia and Nursing Implications

Tachycardia	Bradycardia
Definition	
FHR >160 bpm lasting >10 min	FHR <110 bpm lasting >10 min
Possible Causes	
• Early fetal hypoxemia • Fetal cardiac arrhythmias or congenital anomalies • Maternal fever • Infection (including chorioamnionitis) • Parasympatholytic medications (atropine, hydroxyzine) • Maternal hyperthyroidism • Fetal anemia • Drugs (caffeine, cocaine, methamphetamines)	• Fetal hypoxia/acidosis • AV dissociation (heart block)—may be related to maternal connective tissue disease (e.g., lupus) • Structural defects • Viral infections (e.g., cytomegalovirus) • Medications • Maternal hypotension • Fetal heart failure • Maternal hypoglycemia • Maternal hypothermia • Maternal position
Clinical Significance	
Persistent tachycardia in the absence of periodic changes does not appear to be serious in terms of newborn outcomes (especially true if tachycardia is associated with maternal fever); tachycardia is abnormal when associated with decelerations (variable or late decelerations) or absent variability.	Baseline bradycardia alone is not specifically related to fetal oxygenation. Clinical significance of bradycardia depends on the underlying cause and accompanying FHR patterns, including variability, and the presence of accelerations or decelerations.
Nursing Interventions	
• Confirm maternal vital signs • Notify the primary health care provider and carry out health care provider's orders based on alleviating cause—this may include antipyretics, antibiotics, and cooling measures; fluid bolus; and scalp pH or lactate sampling • Intrauterine resuscitation if thought due to hypoxia (see Box 19.8)	• Confirm maternal pulse as different from FHR • Consider vaginal examination to rule out cord prolapse • May consider scalp stimulation or scalp pH or lactate sampling • Other interventions, depending on cause

AV, Atrioventricular; *bpm*, beats per minute; *FHR*, fetal heart rate.

Fetal Heart Rate Variability

Baseline *variability* of the FHR refers to fluctuations in the baseline FHR that are irregular in amplitude and frequency and are visually quantified as the amplitude of the peak to trough in bpm. Variability is determined over a 10-minute segment of baseline, excluding accelerations and decelerations (AWHONN, 2009; Dore & Ehman, 2020; Miller et al., 2017). Distinctions are no longer made between short-term (beat-to-beat) or long-term variability because in actual practice they are visually determined as a unit (Miller et al., 2017).

Variability is classified as follows:

- Absent: Amplitude range is undetectable (0 to 2 bpm).
- Minimal: Amplitude range is detectable but less than or equal to 5 bpm.
- Moderate: Amplitude range is 6 to 25 bpm.
- Marked: Amplitude range is greater than 25 bpm.

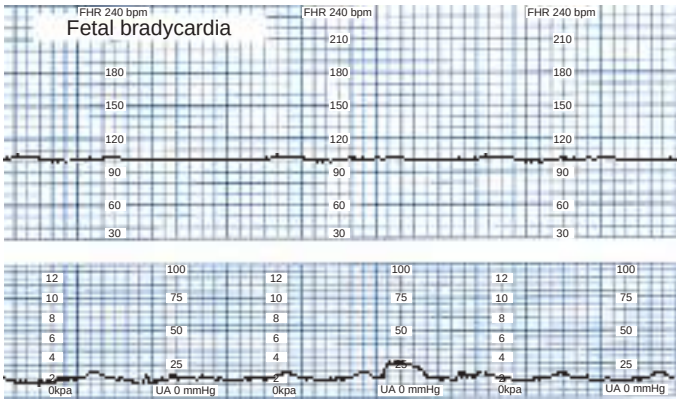

Fig. 19.9 Fetal bradycardia: Fetal heart rate (FHR) less than 110 beats per minute (bpm). *UA*, Uterine activity.

Minimal or absent FHR variability (Figure 19.10, *A* and *B*) can result from fetal hypoxemia and metabolic acidemia. Other conditions potentially associated with minimal or absent variability include fetal sleep, fetal tachycardia, medications, prematurity, congenital anomalies, fetal anemia, cardiac arrhythmias, infection, and pre-existing neurological injury (Miller et al., 2017). Table 19.7 contrasts key differences between increased and decreased variability and the clinical implications of each.

Moderate variability is considered normal (see Figure 19.10, *C*). Its presence is highly predictive of a normal fetal acid–base balance (absence of fetal metabolic acidemia) at the time of its presence (Dore & Ehman, 2020). Moderate variability indicates that FHR regulation is not affected significantly by fetal sleep cycles, tachycardia, prematurity, congenital anomalies, pre-existing neurological injury, or CNS depressant medications (Macones et al., 2008; Miller et al., 2017).

The significance of marked variability (see Figure 19.10, *D*) is unclear. Possible explanations include a normal variant or an exaggerated autonomic response to interruption of fetal oxygenation (Macones et al., 2008; Miller et al., 2017).

A sinusoidal FHR pattern is not included in the definition of FHR variability. A sinusoidal FHR pattern is a smooth, wavelike undulating pattern of the FHR with a cycle frequency of 3 to 5 waves/min that persists for 20 minutes or more (Figure 19.11). Although the pathophysiological mechanisms are unclear, this uncommon pattern classically occurs with severe fetal anemia (Dore & Ehman, 2020; Miller et al., 2017). Variations of the sinusoidal pattern (pseudosinusoidal FHR patterns) have been described in association with chorioamnionitis, fetal sepsis, and administration of opioids (Miller et al., 2017).

Periodic and Episodic Changes in Fetal Heart Rate

Changes in FHR from baseline are categorized as periodic or episodic. *Periodic* changes are those that occur with uterine contractions. *Episodic* changes are those that are not associated with uterine contractions. These patterns include accelerations and decelerations (Macones et al., 2008).

Accelerations. An **acceleration** of the FHR is defined as a visually apparent, abrupt (onset to peak less than 30 seconds) increase in FHR above the baseline rate (Dore & Ehman, 2020) (Figure 19.12). The peak is at least 15 bpm above the baseline and the acceleration lasts 15 seconds or longer, with the return to baseline in less than 2 minutes. Before 32 weeks of gestation, the definition of an acceleration is a peak of 10 bpm or more above the baseline and duration of at least 10 seconds. An acceleration that lasts longer than 2 minutes but less than 10 minutes in length is considered a *prolonged* acceleration. An

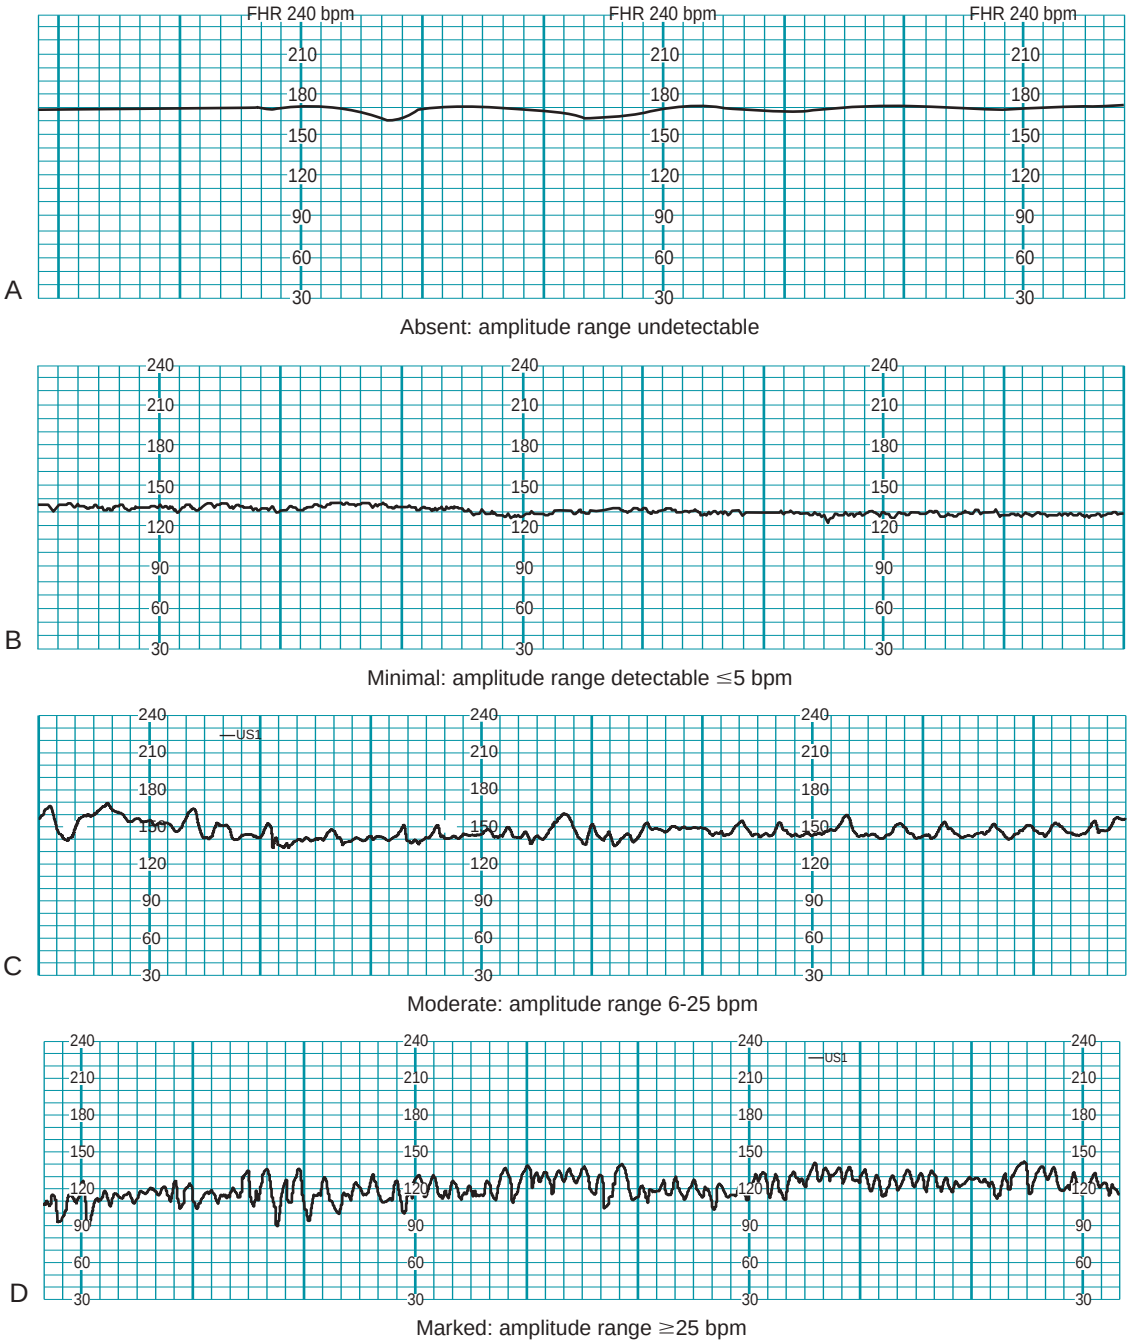

Fig. 19.10 Classification of fetal heart rate (FHR) variability. **A:** Absent: amplitude range undetectable. **B:** Minimal: amplitude range detectable ≤5 beats/min. **C:** Moderate: amplitude range 6–25 beats/min. **D:** Marked: amplitude range ≥25 beats/min. (From Miller, L., Miller, D., & Cypher, R. [2017]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [8th ed.]. Mosby.)

acceleration of the FHR that lasts more than 10 minutes is considered a change in baseline rate (Miller et al., 2017).

Accelerations can be either periodic or episodic. They may occur in association with fetal movement or spontaneously. If accelerations do not occur spontaneously, they can be elicited by fetal scalp stimulation (Dore & Ehman, 2020). Accelerations are considered an indication of fetal well-being. Their presence is highly predictive of a normal fetus with an intact oxygenated sympathetic nervous system (Canadian Perinatal Programs Coalition [CPPC], 2020). However, the lack of an acceleration with digital fetal scalp stimulation does not predict fetal compromise (Dore & Ehman, 2020). To perform digital fetal scalp stimulation, gently stroke the fetal scalp for 15 seconds during a vaginal examination when the FHR is at baseline. It is important to note that digital fetal scalp stimulation should not be used as a resuscitative intervention and should therefore be avoided during a FHR deceleration. Box 19.3 lists causes and clinical significance of and nursing interventions for accelerations.

Decelerations. A deceleration (caused by dominance of a parasympathetic response) may be benign or abnormal. FHR decelerations are

TABLE 19.7 Increased and Decreased Variability and Clinical Significance

Increased Variability	Decreased Variability
Potential Causes	
• Hypoxic events (e.g., uterine tachysystole) • Hyperoxygenation • Fetal cardiac dysrhythmias • Normal maturation • Increased parasympathetic activity • Illicit drug use • Fetal stimulation	• Hypoxia/acidosis • Severe fetal anemia • CNS depressants • Maternal smoking • Fetal sleep cycles • Congenital abnormalities • Fetal cardiac dysrhythmias • Maternal temperature elevation • Hypovolemia
Clinical Significance	
Significance of marked variability not known; rule out artifact; if thought to be due to hypoxia, maximize fetal oxygenation. Marked variability persisting for 10 minutes or more is abnormal and requires urgent action, such as fetal scalp pH or lactate sampling or emergent delivery.	Benign when associated with periodic fetal sleep states, which last approximately 40 minutes; if caused by drugs, variability usually increases as drugs are excreted; minimal or absent variability for >80 minutes is considered a sign of potential fetal acidemia.
Nursing Intervention	
If birth is not indicated, continuously observe FHR tracing for other abnormal characteristics that may develop, including increasing baseline, prolonged decelerations, changes in variability to minimal or absent, and development of complicated variable decelerations or late decelerations.	Rule out nonhypoxic etiologies; intervention is not warranted if associated with fetal sleep states or temporarily associated with CNS depressants; if thought to be due to hypoxia, maximize fetal oxygenation, consider performing fetal scalp stimulation to elicit an acceleration of the FHR, determine duration of time FHR has experienced absent or minimal variability, notify primary health care provider, prepare for birth if indicated by primary health care provider.

categorized as early, late, variable, or prolonged (Figure 19.13 and further discussion below). They are described by their visual relation to the onset and end of a contraction and by the nature of their descent, either gradual or abrupt. Clinically, decelerations are also characterized by their general shape. In the SOGC guideline, "repetitive" decelerations

BOX 19.3 Accelerations

Cause

Spontaneous fetal movement

Fetal stimulation from:

- Vaginal examination
- Electrode application
- Fetal scalp stimulation

Fetal reaction to external sounds

Uterine activity

Fundal pressure

Abdominal palpation

Brief occlusion of umbilical vein only

Clinical Significance

Normal pattern: Acceleration with fetal movement signifies fetal well-being, representing fetal alertness or arousal states.

Nursing Interventions

None required

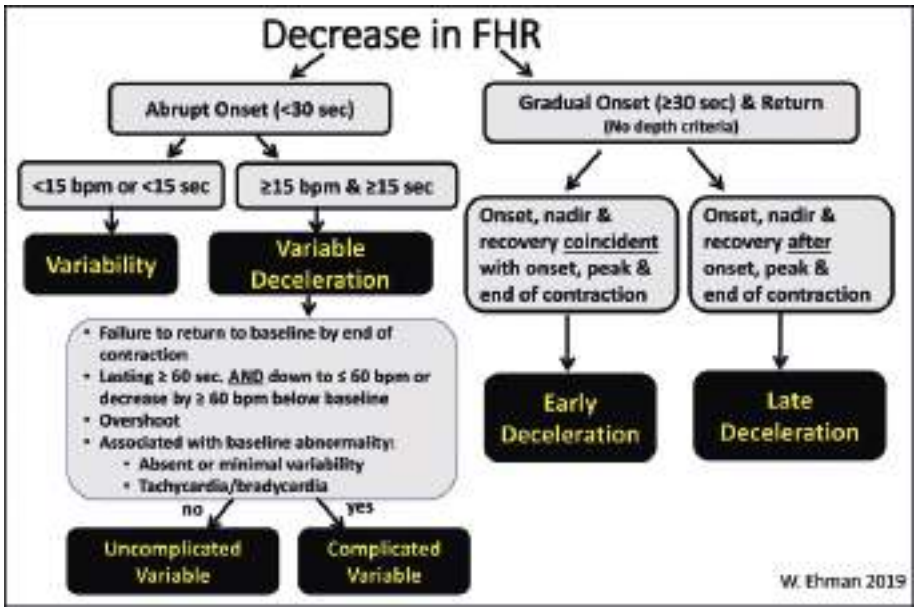

Fig. 19.13 Differentiating fetal heart rate (FHR) decelerations. (From Dore, S., & Ehman, W. [2020]. SOGC clinical practice guideline: No. 396—Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics and Gynaecology Canada, 42*[3], 316–348. https://doi.org/10.1016/j.jogc.2019.05.007.)

are defined as greater than three decelerations in a row (Dore & Ehman, 2020). In the 2008 (NICHD) Workshop on EFM documentation, decelerations are defined as "recurrent" if they occur with greater than or equal to 50% of uterine contractions in any 20-minute window (Dore & Ehman, 2020; Macones et al., 2008).

Early decelerations. An **early deceleration** of the FHR is a visually apparent, usually symmetrical, **gradual** decrease (onset to lowest point [nadir] greater than or equal to 30 seconds) in the FHR and return to baseline associated with a uterine contraction (Figures 19.14 and 19.15) (CPPC, 2020). Usually occurring in the context of moderate variability, early decelerations are thought to be caused by transient fetal head compression, which leads to a slowing of the FHR due to vagal reflex (Dore & Ehman, 2020). Early decelerations are considered normal and generally benign (Dore & Ehman, 2020; Miller et al., 2017). The onset, **nadir**, and recovery of the deceleration usually correspond to the beginning, peak, and end of the contraction, respectively. For this reason, an early deceleration is sometimes referred to as the "mirror image" of a contraction.

Although uncommon, when early decelerations are present, they usually occur during the first stage of labour when the cervix is dilated 4 to 7 cm. However, they are sometimes seen during the second stage when the patient is pushing.

Early decelerations are thought to be benign, thus interventions are not necessary. Identification of early decelerations enables the health care provider to distinguish them from late or variable decelerations, which may lead to atypical or abnormal FHR patterns and for which interventions are appropriate. Box 19.4 lists causes, clinical significance of, and nursing interventions for early decelerations.

Late decelerations. A **late deceleration** of the FHR is a visually apparent **gradual** (onset to nadir greater than or equal to 30 seconds) decrease in and return to baseline FHR associated with uterine contractions (Dore & Ehman, 2020; Macones et al., 2008). In most cases, the onset, nadir, and recovery of the deceleration occur after the beginning, peak, and end of the contraction, respectively. The deceleration begins after the contraction has started, and the lowest point of the deceleration occurs after the peak of the contraction. The deceleration usually does not return to baseline until after the contraction is over (Figures 19.16 and 19.17). Traditionally, late decelerations have been attributed to uteroplacental insufficiency. However, in reality a number of factors can disrupt oxygen transfer to the fetus, even with mild uterine contractions and a normally functioning placenta (Miller et al., 2017). Potential causes and clinical significance of and nursing interventions for late decelerations are described in Box 19.5.

Rarely, fetal oxygenation can be interrupted sufficiently to result in metabolic acidemia. For this reason, persistent and repetitive late decelerations should be considered an ominous sign when they are uncorrectable, especially if they are associated with absent or minimal variability and tachycardia (Dore & Ehman, 2020; Miller et al., 2017).

Episodic gradual decelerations. *Episodic gradual deceleration* is a term new in the SOGC's 2020 *Fetal Health Surveillance: Intrapartum Consensus Guideline* (Dore & Ehman, 2020). These decelerations are similar in shape to both early and late decelerations where the onset

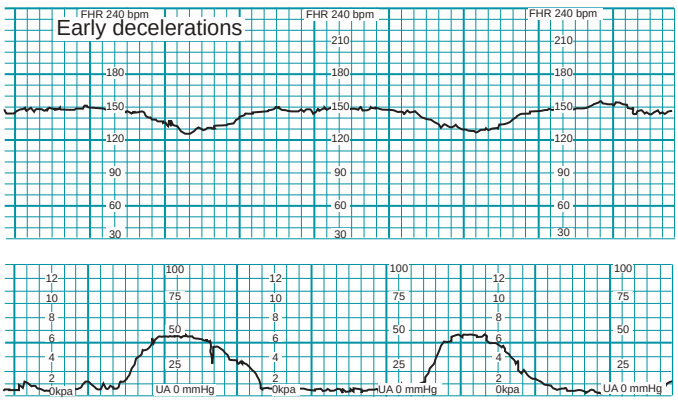

Fig. 19.14 Electronic fetal monitor tracing showing early decelerations. *FHR,* Fetal heart rate; *UA,* uterine activity. (From Miller, L., Miller, D., & Cypher, R. [2017]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [8th ed.]. Mosby.)

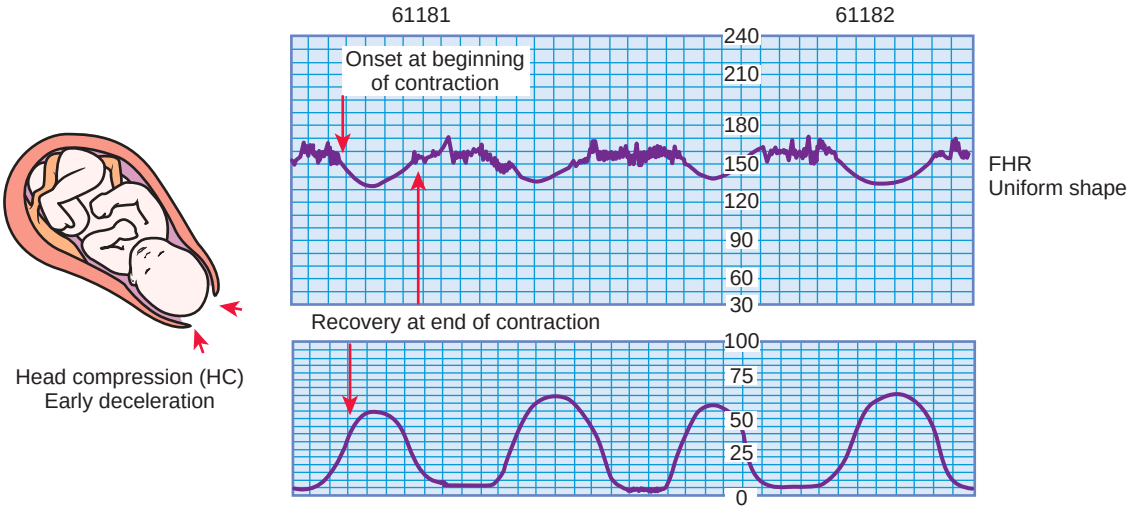

Fig. 19.15 Line drawing illustrating early decelerations. *FHR,* Fetal heart rate. (From Tucker, S. M. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. Mosby.)

BOX 19.4 Early Decelerations

Cause

Head compression resulting from the following:

- Uterine contractions
- Malposition
- Unengaged presenting part
- Vaginal examination
- Fundal pressure
- Placement of internal spiral electrode
- Cephalopelvic disproportion (CPD); usually seen early in labour

Clinical Significance

Normal pattern: not associated with fetal hypoxemia, acidemia, or low Apgar scores. If thought to be due to CPD, monitor labour progress. If seen in association with atypical or abnormal baseline features, early decelerations may have acid–base implications for the fetus.

Nursing Interventions

None required

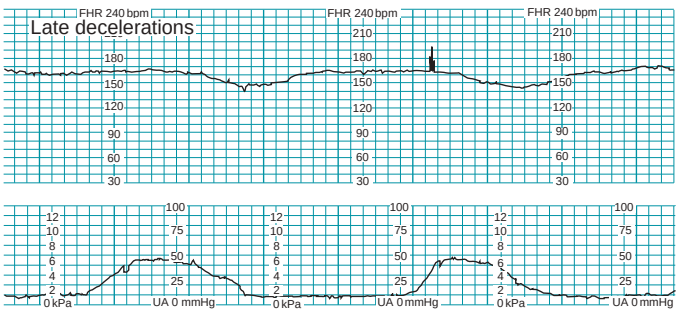

Fig. 19.16 Electronic fetal monitor tracing showing late decelerations. *FHR,* Fetal heart rate; *UA,* uterine activity. (From Miller, L., Miller, D., & Cypher, R. [2017]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [8th ed.]. Mosby.)

and return to the baseline FHR is gradual (greater than or equal to 30 seconds from onset to nadir). This term is used to describe gradual decelerations when they are occurring without identifiable UA either by palpation or with IUPC.

Variable decelerations. Variable decelerations are the most common type of deceleration seen in labour. They are defined as a visually **abrupt** (onset to nadir less than 30 seconds) decrease in the FHR below baseline. The FHR decreases at least 15 bpm below baseline and the deceleration lasts for at least 15 seconds but less than 2 minutes from the time of onset (Figures 19.18 and 19.19). They can occur during or between contractions (CPPC, 2020; Macones et al., 2008).

Variable decelerations are thought to reflect an autonomic reflex response to umbilical cord compression, which interrupts oxygen transfer to the fetus (Dore & Ehman, 2020, Miller et al., 2017). Box 19.6 lists causes and clinical significance of and nursing interventions for variable decelerations.

The appearance of variable decelerations differs from those of early and late decelerations, which closely approximate the shape of the corresponding uterine contraction. Instead, variable decelerations often have a U, V, or W shape, are characterized by an abrupt (less than 30 seconds) descent to the nadir of the deceleration, and return to the FHR baseline (see Figure 19.19). Variable decelerations are further classified as uncomplicated or complicated variable decelerations.

Uncomplicated variable decelerations are characterized by their abrupt decrease in the FHR and the sudden (abrupt) return to baseline. These variables may or may not be accompanied by an acceleratory response of the FHR prior to and immediately following the deceleration of the FHR—these accelerated portions of the fetal heart are part of the deceleration and are commonly called "shoulders." The accelerations or "shoulders" are a compensatory response to compression of the umbilical vein. Despite the appearance of an acceleration, this physiological response to compression of the umbilical vein does not in and of itself indicate the presence of fetal well-being as the presence of spontaneous accelerations would. Uncomplicated variable decelerations rarely alter the fetal pH and have little clinical significance. When uncomplicated variable decelerations are present in the FHR tracing, they may be classified as either normal, atypical, or abnormal depending on the frequency of the decelerations and other characteristics of the FHR baseline.

Complicated variables are more likely to affect fetal well-being. The FHR tracing is classified as abnormal if complicated variable

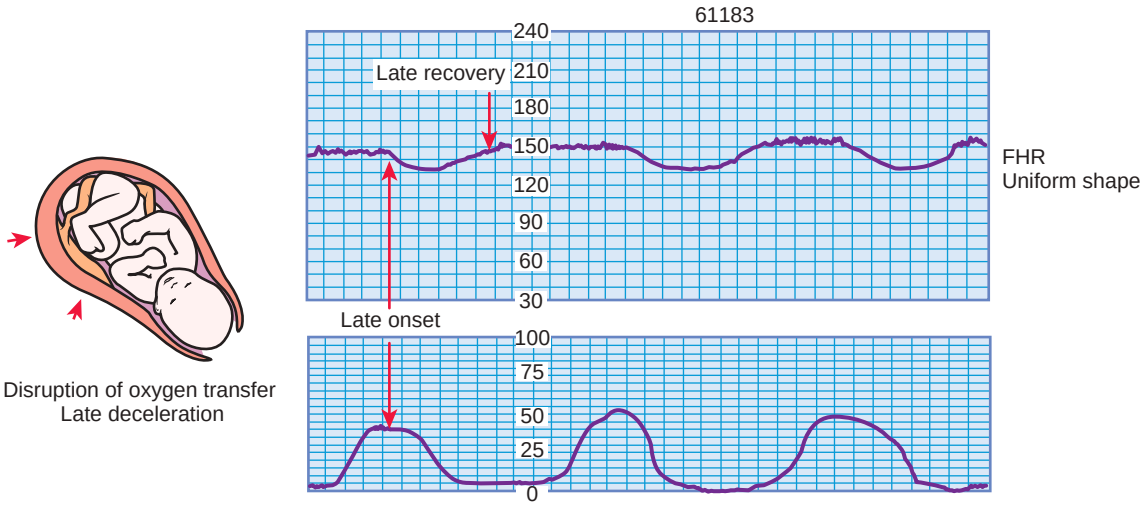

Fig. 19.17 Line drawing illustrating late decelerations. *FHR,* Fetal heart rate. (Modified from Tucker, S. M. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. Mosby.)

BOX 19.5 Late Decelerations

Cause

Uteroplacental insufficiency caused by the following:

Acute Conditions	Chronic Conditions
• Uterine tachysystole	• Maternal comorbidities (e.g., diabetes, collagen disease, hypertensive disorders)
• Maternal hypotension related to epidural or spinal anaesthesia	• Post-term (>42 weeks' gestation) pregnancy
• Maternal supine positioning	• Reduced maternal P_{O_2}
• Reduced maternal P_{O_2}	• Poor placental development/ malformation
• Acute placental disruption (i.e., abruption, previa)	• Premature placental aging (i.e., intrauterine growth restriction)
• Intra-amniotic infection	
• Vasoconstriction	
• Maternal hypo/hyperventilation	

Clinical Significance

An FHR tracing is classified as atypical if the late decelerations are seen occasionally and as abnormal if the late decelerations are occurring with greater than 50% of contractions in any 20 minute window. Late decelerations are associated with fetal hypoxemia, acidemia, and low Apgar scores; they are considered ominous if persistent and uncorrectable with intrauterine resuscitation, especially when associated with fetal tachycardia and loss of variability.

Nursing Interventions

When occasional late decelerations are detected, change maternal position (lateral), check maternal vital signs, communicate with the team, document and continue to observe closely. When late decelerations are repetitive, intrauterine resuscitation should be initiated (see Box 19.8).

decelerations are repetitive (three or more in a row) (Dore & Ehman, 2020). These decelerations can deplete the fetal reserve and lead to fetal hypoxemia. Complicated variable decelerations include the following:

- Failure to return to baseline by the end of the contraction
- Deceleration lasting greater than or equal to 60 seconds AND down to less than or equal to 60 bpm OR decreased by greater than or equal to 60 bpm below baseline
- Overshoot of 20 bpm for 20 seconds after deceleration

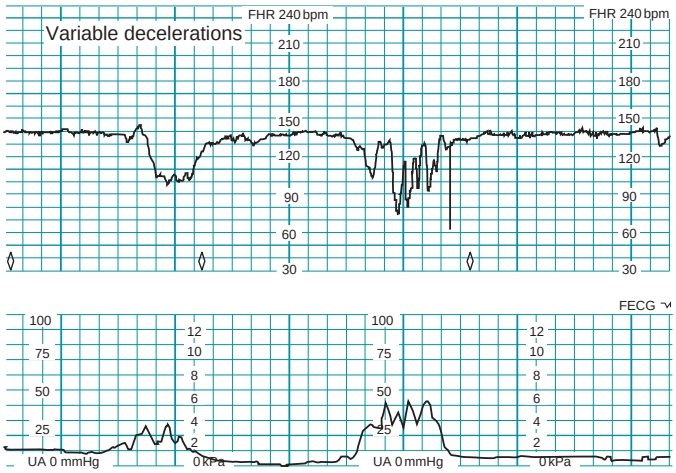

Fig. 19.18 Electronic fetal monitor tracing showing variable decelerations. *FHR,* Fetal heart rate; *FECG,* fetal electrocardiogram; *UA,* uterine activity. (From Miller, L., Miller, D., & Cypher, R. [2017]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [8th ed.]. Mosby.)

- Variable deceleration in the presence of minimal or absent baseline variability
- Baseline tachycardia or bradycardia (Dore & Ehman, 2020)

Prolonged decelerations. A *prolonged deceleration* is a visually apparent decrease (may be either gradual or abrupt) of at least 15 bpm below the baseline and lasting more than 2 minutes but less than 10 minutes from onset to return to baseline (Figure 19.20). A deceleration lasting more than 10 minutes is considered a baseline change (Macones et al., 2008) and requires immediate intrauterine resuscitative measures and a teamwork approach to management, communication, and documentation of the situation. Prolonged decelerations occur when the mechanisms responsible for late or variable decelerations last for an extended period (more than 2 minutes). Examples of conditions that can cause an interruption in the fetal oxygen supply long enough to produce a prolonged deceleration include maternal hypotension, cervical examination, uterine tachysystole or rupture, extreme placental insufficiency, cord entanglement, and prolonged cord compression or prolapse (Miller, 2017; Miller et al., 2017).

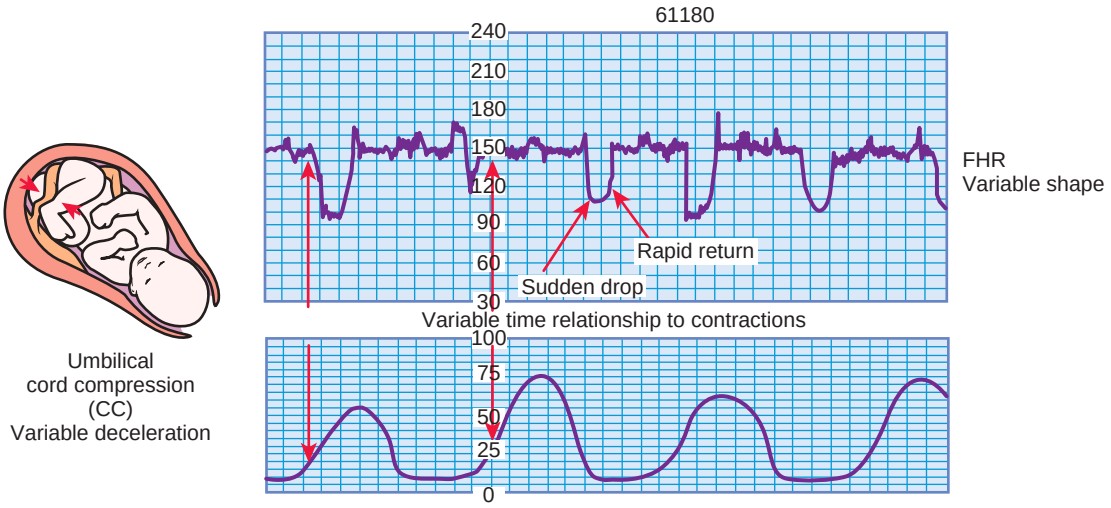

Fig. 19.19 Line drawing illustrating variable decelerations. *FHR,* Fetal heart rate. (From Tucker, S. M. [2004]. *Pocket guide to fetal monitoring and assessment* [5th ed.]. Mosby.)

BOX 19.6 Variable Decelerations

Cause

Umbilical cord compression caused by the following:

- Oligohydramnios
- Maternal position with cord between fetus and maternal pelvis (occult umbilical cord prolapse)
- Cord around fetal neck (nuchal cord), arm, leg, or other body part
- Short cord
- Knot in cord
- Prolapsed umbilical cord
- Decreased amniotic fluid

Clinical Significance

Variable decelerations occur in most labours and are usually correctable. Complicated variable decelerations require critical analysis and timely decision making, including intrauterine resuscitation and confirmation of fetal well-being, either directly or indirectly (fetal scalp stimulation or fetal scalp blood sampling for pH or lactate) (Dore & Ehman, 2020). Preparation for an expeditious birth may be necessary.

Nursing Interventions

- Change patient position (side to side, knee chest).
- Consider need for intrauterine resuscitation (particularly if variables are complicated) (see Box 19.8).
- Notify primary care provider.
- Assess for possible cord prolapse.
- Assist with scalp stimulation, scalp pH or lactate, or amnioinfusion (see discussion later in chapter), if ordered.
- Alter pushing technique (e.g., open glottis, shorter pushes).
- Assist with birth (vaginal assisted or Caesarean) if pattern cannot be corrected.

The presence and severity of hypoxia are thought to correlate with the depth and duration of the prolonged deceleration, how long it takes for the FHR to return to baseline, how much variability is lost during the deceleration, and whether or not rebound tachycardia and decreased variability are seen following the deceleration (Miller, 2017).

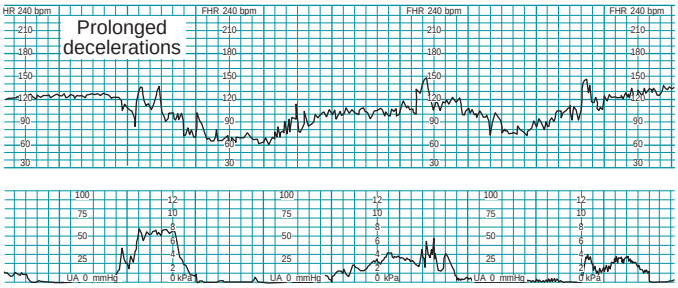

Fig. 19.20 Prolonged decelerations. *FHR,* Fetal heart rate; *UA,* uterine activity. (From Miller, L., Miller, D., & Cypher, R. [2017]. *Mosby's pocket guide to fetal monitoring: A multidisciplinary approach* [8th ed.]. Mosby.)

! NURSING ALERT

Nurses should notify the primary care provider immediately and initiate appropriate intrauterine resuscitation when they identify a prolonged deceleration.

Nursing Care

The primary goals of obstetrical nursing care are to have healthy fetal and maternal outcomes. Knowledge of fetal status and standards for care determine the interventions implemented. All planning and interventions must take into account the total clinical picture. The planning process includes meeting the needs of the patient and family, answering questions, and explaining nursing interventions.

Although the use of EFM can be comforting to many parents, it can be a source of anxiety to others. The nurse needs to be particularly sensitive to the emotional, informational, and physical comfort needs of the labouring person and their family and respond appropriately (Figure 19.21 and Box 19.7). See the Nursing Care Plan, Fetal Monitoring during Labour on the Evolve site.

Electronic Fetal Monitoring Pattern Recognition. Nurses take into consideration the total clinical picture to determine whether an FHR pattern is normal, atypical, or abnormal. They evaluate these factors on the basis of the presence of other obstetrical complications, progress in labour, and use of analgesia or anaesthesia. Further consideration of the estimated time to birth is also important.

Fig. 19.21 Nurse explains electronic fetal monitoring as ultrasound transducer monitors the fetal heart rate. (Courtesy Julie Perry Nelson.)

BOX 19.7 Patient and Family Teaching When Intermittent Auscultation or Electronic Fetal Monitor Is Used

The following guidelines relate to patient teaching:

- Explain the purpose of monitoring is to identify fetal well-being in labour.
- Explain each procedure.
- Provide the rationale for labouring patient's positions other than supine.
- Explain that fetal status can be assessed safely using intermittent auscultation (IA) or explain the need for electronic fetal monitoring (EFM) if there are risk factors for adverse perinatal outcomes. The patient should be encouraged to decide what type of monitoring they prefer.
- If using EFM, explain that the lower tracing on the monitor strip paper shows uterine activity (UA); the upper tracing shows the fetal heart rate (FHR).
- Reassure the labouring patient and their partner that prepared childbirth techniques can be implemented without difficulty.
- Using palpation, note peak of contraction; knowing that contraction will not get stronger and is half over is usually helpful. Note diminishing intensity.
- Reassure the labouring patient and partner that the use of internal monitoring does not restrict movement unless medically indicated. Portable telemetry monitors allow the FHR and uterine contraction patterns to be monitored and may increase ambulation during labour.
- Reassure the labouring patient and partner that the use of monitoring does not imply fetal jeopardy.

Considering these factors, the nurse must determine which interventions are appropriate, based on sound clinical judgement of a complex, integrated process.

- *Normal*—Characteristics are within normal parameters.
- *Atypical*—Further vigilant assessment is required, especially when combined features are present. The nurse must determine the significance and cause of the FHR features and correct any reversible causes, initiate intrauterine resuscitation, call for help, determine the duration of the effect and reserve tolerance of the fetus, and consider whether further fetal evaluation (scalp stimulation and/or fetal blood sampling [FBS] for pH or lactate) is indicated or may be of value. The nurse must also consider the need to expedite birth if the FHR tracing abnormalities persist or the fetus continues to deteriorate further (Dore & Ehman, 2020).
- *Abnormal*—Action is required. Review the overall clinical situation, assessing for potential causes that are reversible. Initiate appropriate intrauterine resuscitation and call for help. Determine the duration of the effect and reserve tolerance of the fetus, consider FBS, mobilize additional teams, including pediatrics and anaesthesiology, and consider expediting birth (vaginal or Caesarean birth) unless there is evidence of normal oxygenation by FBS assessment for either pH or lactate.

LEGAL TIP: Fetal Monitoring Standards

Nurses who care for patients who require EFM during childbirth are legally responsible for maintaining an interpretable monitor strip, correctly interpreting FHR patterns, initiating appropriate nursing interventions based on those patterns, documenting the outcomes of those interventions, and communication with the primary health care provider. Perinatal nurses are responsible for the timely notification of the primary health care provider in the event of atypical or abnormal FHR patterns or contraction patterns (i.e., patterns that indicate the need for intervention or expedited birth). Perinatal nurses also are responsible for initiating collaborative resolution (the institutional chain of command) should differences in opinion arise among health care providers about the interpretation of the FHS findings and the interventions required.

Nursing management of atypical or abnormal patterns. The six essential components of the FHR tracing that must be evaluated regularly are UA, the baseline FHR, baseline variability, accelerations, decelerations, and changes or trends in the FHR over time. Whenever one of these essential components of the FHS findings is assessed as atypical or abnormal, corrective measures must be taken immediately. The purpose of these actions is to improve fetal oxygenation (Miller et al., 2017). The term *intrauterine resuscitation* is sometimes used to refer to specific interventions initiated when an atypical or abnormal FHS patterns is noted. Basic corrective measures include instituting maternal position changes, stopping or decreasing oxytocin if it is infusing, and checking maternal vital signs to differentiate FHR from maternal heart rate and to determine if the labouring person is hypotensive or hypovolemic. If the person is pushing, the nurse may need to modify or pause pushing efforts. The nurse may also need to improve hydration with an intravenous bolus, if appropriate and indicated (e.g. maternal hypotension, hypovolemia or hypoxia), maintaining awareness of overall fluid balance of the pregnant person. The nurse must also rule out cord prolapse, consider tocolysis in the event of tachysystole with FHR changes, consider amnioinfusion in the presence of repetitive (three or more in a row) complicated decelerations, and provide supportive care to reduce the pregnant person's anxiety. Administration of oxygen by mask should be reserved for situations of hypoxia and hypovolemia of the pregnant person (Dore & Ehman, 2020). These interventions are implemented to improve uterine and intervillous space blood flow and increase oxygenation and cardiac output of the pregnant person (Miller et al., 2017). Box 19.8 lists basic interventions to improve maternal and fetal oxygenation status.

Nurses must assign priorities to interventions in order to maximize the efficacy of the intrauterine resuscitation. The purpose of intrauterine resuscitation is to improve uterine blood flow, improve umbilical blood flow, optimize maternal–fetal oxygenation, and decrease UA (Dore & Ehman, 2020). Decisions regarding which intrauterine resuscitation measure should be undertaken first are based on the clinical situation, gestational age, resources available, the stage of labour, and additional risk factors that are present (Dore & Ehman, 2020).

Some interventions are specific to the FHR pattern. Nursing interventions appropriate for the management of tachycardia and bradycardia are given in Table 19.6, and those appropriate for the management of increased or decreased variability are given in Table 19.7. No specific nursing interventions are required for the

BOX 19.8 Management of Atypical or Abnormal Fetal Heart Rate Pattern

Intrauterine resuscitation:
- Stop or decrease oxytocin.
- Change patient position (to left or right lateral).
- Check labouring patient's vital signs, including differentiation of the pulse from the FHR.

Modify breathing or pushing techniques during second stage:
- Use open-glottis rather than Valsalva-style pushing.
- Use fewer pushing efforts during each contraction or make individual pushing efforts shorter.
- Push only with every second or third contraction.
- Push only with contractions (with use of regional anaesthesia) or the urge to push.

If indicated—Improve patient hydration with an IV fluid bolus (e.g., maternal hypovolemia and/or hypoxia); be aware of patient's fluid balance.

Perform vaginal examination to rule out cord prolapse and assess progress.

Consider IV tocolysis in the presence of tachysystole with atypical or abnormal FHS findings.

Consider amnioinfusion (see discussion later in chapter) in the presence of complicated variable decelerations.

Provide supportive care to the labouring patient and family to reduce anxiety and lessen catecholamine impact.

Consider administration of oxygen (8 to 10 L/min) by mask, only when maternal hypoxia and/or hypovolemia is suspected or confirmed. Oxygen administration is reserved for maternal resuscitation, not fetal resuscitation.

Notify primary health care provider.

FHR, Fetal heart rate; *FHS,* fetal health surveillance; *IV,* intravenous.
From Dore, S., & Ehman, W. (2020). SOGC clinical practice guideline: No. 396—Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics and Gynaecology Canada, 42*(3), 316–348. https://doi.org/10.1016/j.jogc.2019.05.007.

management of FHR accelerations or early decelerations (see Boxes 19.3 and 19.4). However, late and complicated variable decelerations require aggressive intervention (see Boxes 19.5 and 19.6). Based on the FHR response to these interventions, the primary health care provider decides whether additional interventions should be instituted or whether immediate vaginal or Caesarean birth should be performed.

Patient and Family Teaching. Part of the perinatal nurse's role includes acting as a partner with the labouring patient and their family to achieve a high-quality birthing experience (see Community Focus box). In addition to providing teaching and support for the patient and family or support people regarding the labour and birth process, breathing techniques, use of equipment, and pain management techniques, the nurse can help with two factors that have an effect on fetal status: pushing and positioning.

COMMUNITY FOCUS

Education About Electronic Fetal Monitoring

Interview childbirth educators from two different types of childbirth preparation classes regarding what they teach expectant parents about electronic fetal monitoring. Do the educators regard it to be "normal"? Do they discuss its advantages and disadvantages, or do they just describe it as a routine intervention? Do they discuss choice in labour (i.e., are parents able to select auscultation rather than electronic monitoring)? Intermittent rather than continuous monitoring? What implications does this information have for your practice as a labour and birth nurse?

Positioning during labour. Supine hypotension is caused by the weight and pressure of the gravid uterus on the ascending vena cava when the pregnant patient is in a supine position. The supine position decreases venous return to the heart and cardiac output and subsequently reduces blood pressure. If the labouring person's blood pressure is low, it decreases intervillous space blood flow during uterine contractions and results in fetal hypoxemia. This is reflected on the fetal monitor as an atypical or abnormal FHS pattern; usually this begins with variable decelerations, followed by decreasing variability, and ultimately may result in late decelerations or complicated variable decelerations. The nurse should instruct the labouring patient to avoid using the supine position, if possible. The patient should be encouraged to maintain an upright, side-lying, or semi-Fowler position with a lateral tilt to the uterus. Either the right or left lateral position effectively enhances uteroplacental blood flow.

Discouraging the Valsalva manoeuvre. The Valsalva manoeuvre can be described as the process of making a forceful bearing-down attempt while holding one's breath with a closed glottis and tightening the abdominal muscles. This process stimulates the parasympathetic division of the autonomic nervous system, producing a vagal response that results in a decrease of the labouring person's heart rate and blood pressure. Prolonged pushing in this manner can decrease placental blood flow, alter the labouring patient's and fetus's oxygenation, decrease the fetal pH and Po_2, increase the fetal Pco_2, and increase the likelihood of fetal hypoxemia, as reflected in FHR pattern changes.

During the second stage of labour, when the patient needs to push, an alternative to breath holding with a closed glottis is to perform the open-mouth and open-glottis breathing-pushing technique. The nurse can instruct the patient to keep their mouth and glottis open and let air escape from the lungs during the pushing process. This may result in an audible grunting sound and will prevent doing the Valsalva manoeuvre (see Chapter 17).

ADDITIONAL METHODS OF ASSESSMENT AND INTERVENTION

A major shortcoming of EFM is its high rate of false-positive results. Even the most abnormal patterns are poorly predictive of newborn morbidity. Therefore, EFM assessment of the FHR should be viewed as a screening test that signals when atypical or abnormal features are present, warranting the use of other diagnostic tests (when available) to evaluate fetal status and intervene as needed. Fetal scalp blood sampling (for lactate or pH) is sometimes employed to evaluate the fetus further; amnioinfusion is sometimes used to decrease the physiological stress of UA that has resulted in an atypical or abnormal FHR pattern. Umbilical cord blood acid–base determination is a postpartum assessment technique that is useful as an adjunct to the Apgar score in assessing the immediate condition of the newborn.

Fetal Scalp Blood Sampling

Fetal scalp blood sampling involves obtaining a capillary fetal blood sample in a fetus more than 34 weeks of gestation. It is obtained through a small incision in the fetal scalp, taken through the dilated cervix after the membranes have ruptured. It is an adjunct to EFM when the pattern is difficult to interpret or is atypical or abnormal and birth is not imminent. The capillary sample is tested for pH or lactate. Results will guide the primary health care provider on whether to expedite birth, reassess within 30 minutes, or allow labour to continue (Table 19.8).

Fetal scalp blood sampling is limited by many factors, including the requirement for cervical dilation and ruptured membranes, technical difficulty of the procedure, and the need for repetitive pH or lactate determinations. Fetal scalp lactate blood sampling may be easier to

TABLE 19.8 Fetal Blood Sampling

FETAL SCALP BLOOD SAMPLING—PH AND LACTATE VALUES

pH Value	Lactate Value*	Interpretation
≥7.25	<4.2	Normal—repeat sampling in 30 minutes if FHR tracing abnormalities persist
7.21–7.24	4.2–4.8	Borderline—repeat sampling in 30 minutes or consider birth if significant decrease in pH or increase in lactate
≤7.20	>4.8	Abnormal—birth indicated

*Lactate values are applicable only to the Nova Biomedical Stat Strip lactate meter—currently the only lactate meter available in Canada.
Source: Dore, S., & Ehman, W. (2020). SOGC clinical practice guideline: No. 396—Fetal health surveillance: Intrapartum consensus guideline. *Journal of Obstetrics and Gynaecology Canada, 42*(3), 316–348. https://doi.org/10.1016/j.jogc.2019.05.007.

obtain than the sample required for pH testing, as only a very small sample is required. The guideline for determination of fetal status is determined by the type of meter used. Values included in Table 19.8 are applicable to the Nova Biomedical Stat Strip Lactate meter, which is available for clinical use in Canada.

Umbilical Cord Acid–Base Determination

In assessing the immediate condition of the newborn after birth, a sample of cord blood is a useful adjunct to the Apgar score. The SOGC strongly recommends that both umbilical arterial and venous cord gases be measured after all births, as they may help in providing appropriate care to the newborn and in planning subsequent management (Dore & Ehman, 2020). Umbilical arterial values reflect fetal condition and thus are considered by some as most relevant; umbilical venous blood values reflect placental function (Miller et al., 2017). Umbilical cord gas measurements reflect the acid–base status of the newborn at birth, a measurement not reflected in the Apgar score (Table 19.9). If only one sample is possible, it should be arterial, since arterial samples are the best indicator of fetal oxygenation at birth. If acidemia is present, the type—respiratory, metabolic, or mixed—is determined by analyzing the blood gas values (Table 19.10).

Amnioinfusion

Amnioinfusion is infusion of room- or body-temperature isotonic fluid (usually normal saline or lactated Ringer's solution) into the uterine cavity when the volume of amniotic fluid is low (Miller et al., 2017). Without the buffer of amniotic fluid, the umbilical cord can easily become compressed during contractions or with fetal movement,

TABLE 19.9 Approximate Normal Values for Cord Blood

Cord Blood	pH	PCO_2 (mm Hg)	HCO_3 (MMOL/L)	Base Excess (MMOL/L)
Artery	7.20–7.34	39.2–61.4	18.4–25.6	−5.5–0.1
Vein	7.28–7.40	32.8–48.6	18.9–23.9	−4.4–0.4

diminishing the flow of blood between the fetus and placenta. The purpose of amnioinfusion is to relieve intermittent umbilical cord compression that results in repetitive complicated variable decelerations and transient fetal hypoxemia by restoring the intrauterine fluid volume to a normal or near-normal level (Miller et al., 2017).

Amnioinfusion may be used in cases of labouring patients with an abnormally small amount of amniotic fluid (*oligohydramnios*) or no amniotic fluid (*anhydramnios*), or in cases where there are repetitive variable decelerations that are gradually becoming more complicated in nature. Oligohydramnios or anhydramnios may occur in cases of uteroplacental insufficiency, premature rupture of membranes, or spontaneous or artificial rupture of membranes at term.

Routine amnioinfusion for meconium-stained amniotic fluid without the presence of variable decelerations is no longer recommended (Miller et al., 2017). Risks of amnioinfusion include overdistension of the uterine cavity and increased uterine tone. Fluid is administered through an IUPC by either gravity flow or an infusion pump. Usually a bolus of fluid is administered over 20 to 30 minutes; then the infusion is slowed to a maintenance rate. Likely no more than 1 000 mL of fluid will need to be administered. Ideally, the fluid is warmed to body temperature for the preterm fetus by infusing it through a blood warmer (Miller et al., 2017).

Intensity and frequency of uterine contractions should be assessed continually during the procedure. The recorded uterine resting tone during amnioinfusion appears higher than normal because of resistance to outflow and turbulence at the end of the catheter. Uterine resting tone should not exceed 40 mm Hg during the procedure, and the nurse should continue to palpate the uterine fundus in addition to monitoring contractions with the IUPC. The amount of fluid return must be estimated and documented during amnioinfusion to prevent overdistension of the uterus. The volume of fluid returned should be approximately the same as the amount infused (Miller et al., 2017).

DOCUMENTATION

Clear, concise, and complete documentation in the patient's medical record is essential. As recommended by the SOGC, all fetal health assessments, the plan of action, and the clinical actions taken must be accurately documented (Dore & Ehman, 2020). When describing FHR tracings, it is essential to document the complete FHS assessment, including UA, the baseline FHR, variability, the presence of accelerations and decelerations, and the interpretation of the FHS findings (such as normal or abnormal IA, or normal, atypical, or abnormal EFM). The nurse then needs to interpret the FHS findings in light of the total clinical picture and respond appropriately. This includes instituting appropriate intrauterine resuscitation (if necessary), team communication, and documentation of all clinical action taken and the FHR or uterine response to the interventions implemented. FHR data and interpretation should be documented at least hourly in the latent phase of the first stage of labour (every 15 minutes if oxytocin is infusing), every 15 minutes in the active phase of the first stage of labour, and every 5 to 15 minutes

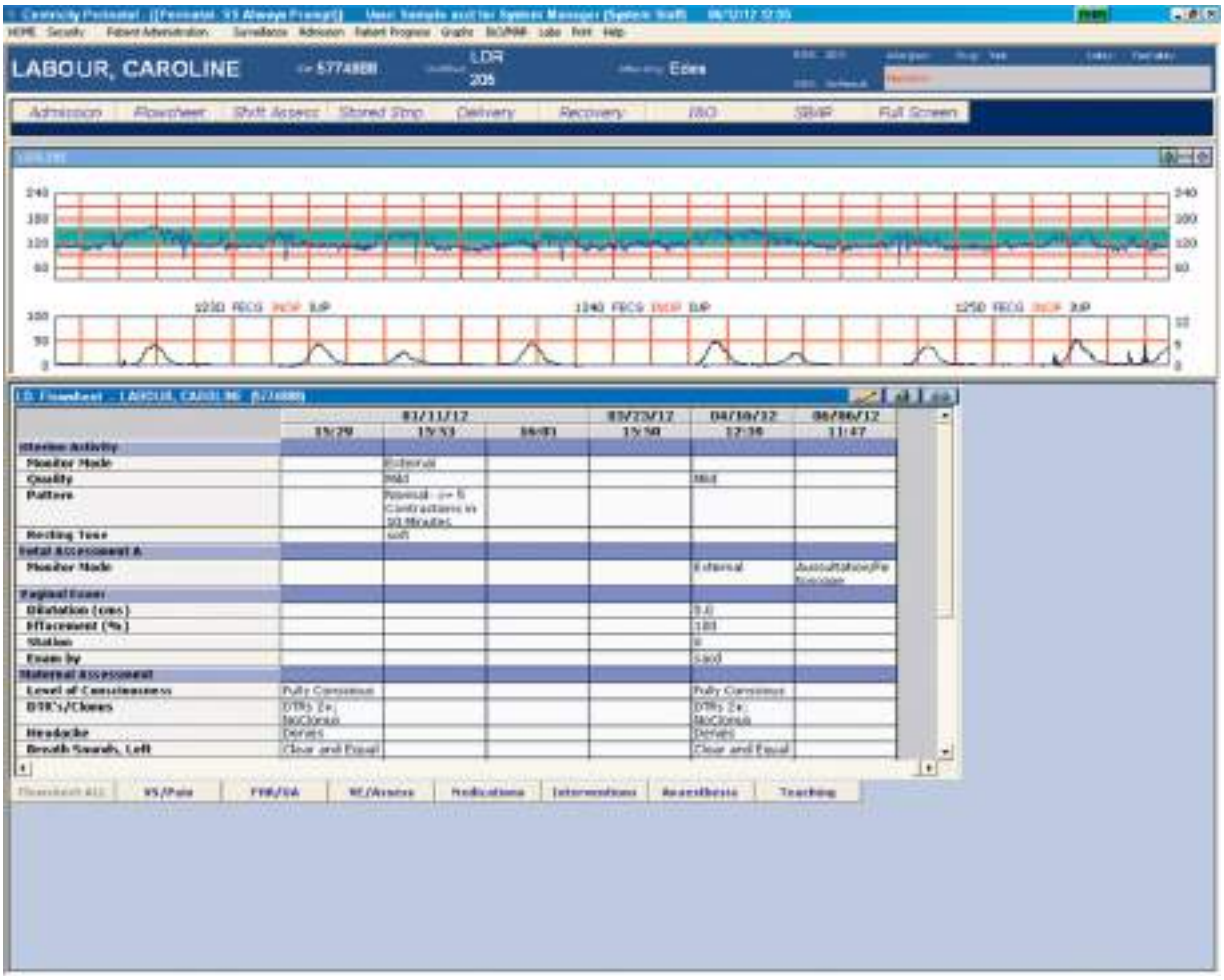

Fig. 19.22 With integration of the fetal monitor tracing into the electronic medical record, the nurse can view the fetal tracing while charting. (Courtesy General Electric Healthcare Technologies, Barrington, IL.)

in the active phase of the second stage of labour depending on whether the fetus is being monitored by IA or EFM (Dore & Ehman, 2020). More and more hospitals are moving to use of the electronic medical records and computer charting. With computerized charting, each required component usually appears on the screen so that it will be addressed routinely. Computerized charting often includes forced choices that greatly increase the use of standardized FHR terminology by all members of the health care team. Electronic documentation also has space for comments on the EFM record, which are archived with the medical record (Figure 19.22). As much as possible, duplicate documentation should be avoided. The nurse needs to follow the documentation standards for fetal surveillance as outlined by hospital policies and procedures. Regardless of the documentation method, it is important that the time on the fetal monitor and the time the nurse uses to chart progress notes or other documentation are synchronous.

An important point in fetal surveillance documentation is that caregivers use proper descriptive terminology. It is important to avoid such terms as *asphyxia*, *hypoxia*, and *fetal distress*, as these terms are imprecise and nonspecific and lack standard definitions (CPPC, 2020). The SOGC recommends that all intrapartum obstetrical care providers (nurses, physicians, and midwives) be required to commit to education in FHS and maintain up-to-date competence with formal educational reviews every 2 years (Dore & Ehman, 2020).

KEY POINTS

- Fetal well-being during labour is gauged by the response of the FHR to UA.
- Essential components of the FHS include the UA (contraction) pattern, baseline FHR, variability, accelerations, decelerations, classification, and changes or trends over time.
- FHR cannot be accurately assessed without accurate knowledge of UA assessed through palpation or an IUPC.
- The monitoring of fetal well-being includes FHR assessment, watching for meconium-stained amniotic fluid, and assessment of maternal vital signs and UA.
- It is the responsibility of the nurse to assess FHR and patterns, implement independent nursing interventions, and report atypical and abnormal patterns to the primary health care provider.
- The SOGC has established and published health care provider standards and guidelines for intrapartum FHS.
- The emotional, informational, and comfort needs of the patient and their family must be addressed when the mother and their fetus are being monitored.
- Documentation is initiated and updated according to institutional protocol.

Labour and Birth at Risk

Jodie Bigalky
Originating US Chapter by *Kitty Cashion*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Differentiate between preterm birth and low birth weight.
2. Identify major risk factors associated with preterm labour.
3. Analyze current interventions to prevent spontaneous preterm labour.
4. Discuss the use of tocolytics and antenatal glucocorticoids in preterm labour.
5. Design a nursing care management plan for patients with preterm premature rupture of the membranes (PPROM).
6. Describe the care of a patient experiencing post-term pregnancy.
7. Identify the care of a patient who experiences labour dystocia.
8. Summarize the nursing care management for a trial of labour, induction and augmentation of labour, forceps- and vacuum-assisted birth, a Caesarean birth, and trial of labour after a Caesarean birth (TOLAC).
9. Discuss obstetrical emergencies and their appropriate management.

When complications arise during labour and birth, perinatal morbidity and mortality risks increase. Some complications may be anticipated, especially if the pregnant patient is identified as high risk during the antepartum period; others are unexpected or unforeseen. It is crucial for nurses to understand the normal birth process in order to prevent and detect deviations from normal labour and birth and promptly implement nursing measures when complications arise. Optimum care of the labouring person, the fetus, or both, as well as of the family, is possible only when the perinatal nurse and other members of the obstetrical team use their knowledge and skills in a concerted effort to provide competent and compassionate care. This chapter focuses on the challenges associated with preterm labour and birth, dystocia, post-term pregnancy, and obstetrical emergencies.

PRETERM LABOUR AND BIRTH

Preterm labour is defined as cervical changes and regular uterine contractions occurring between 20 and 37 weeks of pregnancy. **Preterm birth** is any birth that occurs before the completion of 37 weeks of pregnancy. Complications related to preterm birth contribute to high morbidity and mortality rates in newborns and infants (Shah et al., 2018). The rate of preterm birth worldwide is approximately 11% and is associated with newborn morbidity and mortality (Newnham et al., 2014). In 2014, the overall preterm birth rate for Canada was 8.1%, although the rate of births that occur before the completion of 32 weeks of pregnancy was only 1.2% (Public Health Agency of Canada [PHAC], 2017).

The majority of all preterm births are termed **late preterm** because they occur between 34 and 37 weeks of gestation. Late preterm infants are at increased risk for early death and long-term health issues when compared with infants who are born full term. Although late preterm babies do experience significant health challenges, the great majority of infant deaths and the most serious morbidity occur among the 16% of all preterm infants who are born before 32 weeks of gestation.

Preterm Birth Versus Low Birth Weight

Although they have distinctly different meanings, the terms *preterm birth* or *prematurity* and *low birth weight* are often used interchangeably. *Preterm birth* describes length of gestation (i.e., less than 37 weeks regardless of the weight of the infant), whereas *low birth weight* describes only weight at the time of birth (i.e., 2 500 g or less). Because birth weight is far easier to determine than gestational age, in many settings and publications *low birth weight* has been used as a substitute term for *preterm birth*. Preterm birth, however, is a more dangerous health condition for an infant because less time in the uterus correlates with immaturity of body systems. **Low-birth-weight infants** can be preterm but are not necessarily preterm. Low birth weight can be caused by conditions other than preterm birth, such as intrauterine growth restriction (IUGR), a condition of inadequate fetal growth not necessarily correlated with initiation of labour. Pregnant patients who have various complications of pregnancy that interfere with uteroplacental perfusion, such as gestational hypertension or poor nutrition, may give birth to a baby at term who is at low birth weight because of

IUGR. However, infants born at a preterm gestation can weigh more than 2 500 g at birth, such as infants born to patients with diabetes who have poorly controlled blood glucose levels. Currently, thanks to advances in pregnancy dating, outcomes related to gestational age can be distinguished with greater frequency from outcomes related to birth weight (Simhan et al., 2018).

Spontaneous Versus Indicated Preterm Birth

Preterm birth is divided into two categories: spontaneous and indicated. *Spontaneous preterm birth* occurs after an early initiation of the labour process and comprises nearly 75% of all preterm births in North America. Conditions such as preterm labour with intact membranes, preterm premature rupture of membranes (preterm PROM), cervical insufficiency, or amnionitis often result in preterm birth (Simhan et al., 2018).

Indicated preterm births are iatrogenic, because they occur as a means to resolve maternal or fetal risk related to continuing the pregnancy. About 25% of all preterm births in North America are indicated because of medical or obstetrical conditions that affect the pregnant patient, the fetus, or both (Simhan et al., 2018). Box 20.1 lists some common causes of indicated preterm births.

The remainder of this section deals with spontaneous preterm labour and birth.

Spontaneous Preterm Labour and Birth Risk Factors

The incidence of preterm birth in Canada is increasing, with many of the social determinants of health, including poverty, lack of education, living in a disadvantaged geographical area, and lack of access to prenatal care, identified as risk factors (Lim et al., 2018). The preterm birth rate is also higher among patients younger than 18 years of age or older than 35 years (Lim et al., 2018). Major risk factors for spontaneous preterm birth are listed in Box 20.2. In addition, the risk for preterm birth appears to be genetically related. For example, pregnant patients who were themselves born prematurely have an increased risk for giving birth prematurely (Buhimschi et al., 2018). Researchers have developed many risk scoring systems in an attempt to determine which patients might go into labour prematurely. No risk scoring system has been very successful in lowering the preterm birth rate; however, many patients with no identifiable risk factors give birth prematurely (Lim et al., 2018; Simhan et al., 2018). Assisted human reproduction, which is associated with increased rates of multifetal pregnancies, and practice changes that favour early birth in complicated pregnancies have contributed to increasing preterm birth rates (Lim et al., 2018; Simhan et al., 2018). It is important that all patients be educated about prematurity, not only in early pregnancy but also in the preconception period. Unless all patients are included in prevention efforts, a widespread reduction in preterm birth rates cannot be expected.

Infection in the mother is associated with preterm labour. Patients in spontaneous preterm labour with intact membranes commonly have organisms normally found in the lower genital tract present in their amniotic fluid, placenta, and membranes (Buhimschi et al., 2018). How the organisms gain access to the amniotic cavity is not well understood. Urinary tract and intra-abdominal (e.g., appendicitis) infections have also been related to preterm birth (Buhimschi et al., 2018). Patients with periodontal disease have also been shown to have an increased risk for preterm birth, although the evidence to support this link is weak (Buhimschi et al., 2018). Recommendations for all pregnant patients include regular dental care before and during pregnancy, oral assessment as part of prenatal health care, and good oral hygiene measures.

Preterm labour may also be caused by congenital structural abnormalities of the uterus, which can affect the cervix, the body of the uterus, or both. Implantation of the placenta on a uterine septum may lead to preterm birth as a result of placental separation and hemorrhage. Patients who experience unexplained vaginal bleeding after the first trimester of pregnancy also have an increased risk for preterm birth.

BOX 20.1 Common Causes of Indicated Preterm Birth

- Pre-existing or gestational diabetes
- Chronic hypertension
- Pre-eclampsia
- Obstetrical disorders or risk factors in the current or a previous pregnancy
  - Placental disorders (abruption or previa)
  - Cholestasis
- Medical disorders
  - Seizures
  - Thromboembolism
  - Connective tissue disorders
  - Maternal HIV or herpes infection
- Obesity
- Smoking
- Advanced maternal age
- Fetal disorders
  - Chronic (IUGR) or acute (abnormal NST or BPP) fetal compromise
  - Excessive (polyhydramnios) or inadequate (oligohydramnios) amount of amniotic fluid
  - Fetal hydrops, ascites, blood group alloimmunization
  - Birth defects
  - Fetal complications of multifetal gestation (e.g., growth deficiency, twin-to-twin transfusion syndrome)

BPP, Biophysical profile; *HIV,* human immunodeficiency virus; *IUGR,* intrauterine growth restriction; *NST,* nonstress test.

Data from Buhimschi, C. S., Mesiano, S., & Muglia, L. J. (2018). Pathogenesis of spontaneous preterm birth. In R. Resnik, C. J. Lockwood, T. R. Moore, et al. (Eds.). *Creasy & Resnik's Maternal-fetal medicine: Principles and practice* (8th ed.). Elsevier; Simhan, H., Iams, J., & Romero, R. (2017). Preterm labor and birth. In S. Gabbe, R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

BOX 20.2 Risk Factors for Spontaneous Preterm Labour

- History of previous spontaneous preterm birth between 16 and 36 weeks of gestation
- Family history of preterm labour
- African descent
- Genital tract infection
- Uterine anomaly
- Use of assisted human reproduction
- Cigarette smoking, substance misuse
- Periodontal disease
- Multifetal gestation
- Bleeding of uncertain origin in pregnancy
- Low prepregnancy weight
- Low socioeconomic status
- Lack of access to prenatal care
- High levels of personal stress in one or more domains of life

Data from Simhan, H. H., Berghella, V., & Iams, J. D. (2018). Prevention and management of preterm parturition. In R. Resnik, C. J. Lockwood, T. R. Moore, et al. (Eds.). *Creasy & Resnik's Maternal-fetal medicine: Principles and practice* (8th ed.). Elsevier; Simhan, H., Iams, J., & Romero, R. (2017). Preterm labor and birth. In S. Gabbe, R. Niebyl, J. L. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

The risk rises as the number of bleeding episodes increases. Intrauterine inflammation is associated with infection, uterine vascular compromise, and decidual hemorrhage and may contribute to preterm labour. Stress in the pregnant patient or fetus, uterine overdistension, and a decrease in progesterone are other factors that may play a part in initiating preterm labour. It has becoming increasingly clear that preterm labour is caused by multiple pathological processes that eventually result in uterine contractions, cervical changes, and membrane rupture (Buhimschi et al., 2018).

Predicting Spontaneous Preterm Labour and Birth

Fetal Fibronectin Test. Fetal fibronectin (fFN) is a biochemical marker that may be used as a diagnostic test for preterm labour. It is a glycoprotein "glue" found in plasma and produced during fetal life. fFN normally appears in cervical and vaginal secretions early in pregnancy and then again in late pregnancy. The test is performed by collecting fluid from the patient's vagina using a swab during a speculum examination. The presence of fFN during the late second and early third trimesters of pregnancy may be related to placental inflammation, which is thought to be one cause of spontaneous preterm labour. However, the presence of fFN is not very sensitive as a predictor of preterm birth. The test's sensitivity may be better earlier in pregnancy. Often the test is used to predict who will *not* go into preterm labour, because preterm labour is very unlikely to occur in patients with a negative result. In one study in Ontario, it was determined there was a small but statistically significant reduction in the rate of hospital admissions for preterm labour following the introduction of fFN testing. In most cases, patients with a negative fFN test can be monitored as outpatients, avoiding unnecessary interventions, hospitalizations, or maternal transport to a hospital with a higher level of neonatal care (Fell et al., 2014; Mahomed et al., 2019).

Cervical Length. Another possible predictor of imminent preterm labour is endocervical length. Changes in cervical length occur before uterine activity, so cervical measurement can be used to identify patients in whom the labour process has begun. However, because preterm cervical shortening occurs over a period of weeks, neither digital nor ultrasound cervical examination is very sensitive at predicting imminent preterm birth (Simhan et al., 2018). Patients whose cervical length is greater than 30 mm are unlikely to give birth prematurely even if they have symptoms of preterm labour (Simhan et al., 2018).

A combined approach to predicting preterm birth has been found to increase sensitivity and negative predictive value. Combining the evaluation of fFN levels and ultrasound measurement of cervical length was found to increase the ability to identify those at risk for preterm labour within the next 7 days as well as better identify those at low risk (DeFranco et al., 2013).

Nursing Care

Assessment. Prenatal care should focus on performing ongoing holistic risk assessment, encouraging pregnant patients to participate in health-promoting activity (e.g., good nutrition, exercise, stress management), and implementing appropriate medical and psychosocial interventions. The onset of preterm labour is often insidious and can be easily mistaken for normal discomforts of pregnancy. Nursing care should be individualized for each patient on the basis of their assessment findings (see Nursing Care Plan: Patients at Risk for Preterm Labour, available on Evolve).

Interventions

Prevention. Primary prevention strategies that address risk factors associated with preterm labour and birth are less costly in human and financial terms than the high-tech and often lifelong care required by preterm infants and their families. Programs aimed at health promotion and disease prevention that encourage healthy lifestyles for the population in general and persons of childbearing age in particular should be developed to prevent preterm labour and birth. Preconception counselling and care for patients, especially those with a history of preterm birth, may help in identifying correctable risk factors and provide a means to encourage patients to participate in health-promoting activities. Smoking cessation, for example, has been shown to prevent preterm labour and birth (Simhan et al., 2018).

Preterm birth can be prevented in some patients by administering prophylactic progesterone supplementation. Both daily vaginal suppositories or creams and weekly intramuscular injections of 17-alpha hydroxyprogesterone caproate have been shown to decrease the rate of preterm birth by about 40% in women with a history of prior preterm birth or with a short (less than 15 mm to 20 mm length) cervix before 24 weeks of gestation. A short cervix, rather than a history of previous preterm birth, is the most appropriate reason for beginning vaginal progesterone therapy. Supplementation begins at 16 weeks and continues until 36 weeks of gestation. Progesterone supplementation is not recommended for use in nulliparous patients and does not affect the rate of preterm birth in patients with multiple gestations. Exactly how progesterone works to prevent preterm birth is unclear (Brizot et al., 2015; Feng et al., 2018).

One of the most important nursing interventions aimed at preventing preterm birth is the education of pregnant patients about the early symptoms of preterm labour (Box 20.3). If a patient knows the warning signs and symptoms of preterm labour and seeks care early enough, prevention of preterm birth may be possible, and if labour is not stopped, transport to an appropriate care facility may be planned. Nurses can provide patient education regarding symptoms of regular contractions or cramping between 20 and 37 weeks of gestation and should inform the pregnant patient that these symptoms are not normal discomforts of pregnancy and that contractions, cramping, or back pain that does not go away, becomes regular in timing, or increases in intensity should prompt the patient to contact their primary health care provider. Pregnant patients also must be taught the significance of these symptoms of preterm labour and what to do should they occur (see Patient Teaching box: What to Do If Symptoms of Preterm Labour Occur). Waiting too long to see a health care provider could result

BOX 20.3 Signs and Symptoms of Preterm Labour

Uterine Activity
- Uterine contractions more frequent than every 10 minutes, persisting for 1 hour or more
- Uterine contractions painful or painless

Discomfort
- Lower abdominal cramping similar to gas pains; may be accompanied by diarrhea
- Dull, intermittent low back pain (below the waist)
- Painful, menstrual-like cramps
- Suprapubic pain or pressure
- Pelvic pressure or heaviness; feeling that "baby is pushing down"
- Urinary frequency

Vaginal Discharge
- Change in character and amount of usual discharge: thicker (mucoid) or thinner (watery), bloody, brown or colourless, increased amount, odour
- Rupture of amniotic membranes

in inevitable preterm birth without the benefit of treatments that may improve outcomes.

PATIENT TEACHING

What to Do If Symptoms of Preterm Labour Occur

- Stop what you are doing.
- Empty your bladder.
- Drink two to three glasses of water or juice.
- Lie down on your side for 1 hour.
- Palpate for contractions.
- If symptoms continue, call your health care provider or go to the hospital.
- If symptoms go away, resume light activity but not what you were doing when the symptoms began.
- If symptoms return, call your health care provider or go to the hospital.
- If any of the following symptoms occur, call your health care provider or go to the hospital immediately:
  - Uterine contractions every 10 minutes or less for 1 hour or more
  - Vaginal bleeding
  - Fluid leaking from the vagina

Early recognition and diagnosis. Although preterm birth often is not preventable, early recognition of preterm labour is still essential to implement interventions that have been demonstrated to reduce infant morbidity and mortality. These interventions include the following (American College of Obstetricians & Gynecologists [ACOG], 2016; Simhan et al., 2017):

- Transferring the labouring patient before birth to a hospital equipped to care for their preterm infant
- Administering antibiotics during labour to prevent newborn group B streptococcal infection
- Administering antenatal corticosteroids to patients at risk for preterm labour to prevent or reduce neonatal and infant morbidity and mortality from health conditions including respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and other causes
- Administering magnesium sulphate to patients giving birth before 34 weeks of gestation, to reduce the incidence of cerebral palsy in their infants (Magee et al., 2019)
- Administering tocolytic therapy for short-term prolongation of pregnancy (up to 48 hours) to allow for administration of antenatal steroids

Although transport of the patient who is in preterm labour to a tertiary centre helps ensure a better health outcome for the patient and the newborn, it also has a downside. Patients may be transported to centres far from home, making visits by family and friends difficult and increasing the anxiety of the patient and the family. Attention to the needs of the patient and family before, during, and after the transport is essential to comprehensive nursing care.

The diagnosis of preterm labour is based on three major diagnostic criteria (ACOG, 2016):

1. Gestational age between 20 and 36+6 weeks
2. Regular uterine activity, accompanied by a change in cervical effacement, dilation, or both
3. Initial presentation with regular contractions and cervical dilation of at least 2 cm

If the presence of fFN is used as another diagnostic criterion, a sample of cervical mucus for testing should be obtained by sterile speculum exam. Vaginal swab collection is no longer recommended. The presence of vaginal bleeding or ruptured membranes or a history of intercourse within the past 24 hours can also reduce the accuracy of the test results.

The pregnant, preterm patient with an irritable uterus but no documented cervical change is not in preterm labour, although they should be carefully evaluated during follow-up care to determine whether they have progressed to active preterm labour (e.g., effacement, dilation, or both). Misdiagnosis of preterm labour can lead to inappropriate use of pharmacological agents that can be dangerous to the health of the labouring patient, the fetus, or both.

Activity restriction. Bed rest, hydration, and limited work were often recommended to reduce the risk for preterm birth in patients at risk for giving birth prematurely. There is no evidence, however, to support the effectiveness of these interventions, and they should not be routinely recommended. In fact, both bed rest and excessive hydration can cause potentially harmful complications in the labouring person. Research indicates that bed rest causes adverse physical effects, including risk for thrombus formation, muscle atrophy, osteoporosis, cardiovascular deconditioning, and endocrine system changes (Simhan et al., 2017). In many instances, these symptoms are not resolved by 6 weeks postpartum. In addition, bed rest affects patients and their families psychologically, emotionally, socially, and financially. Box 20.4 lists the adverse effects of bed rest. Many health care providers now recommend only modified activity restriction, if at all.

Suppression of uterine activity. Should preterm labour occur, patients are usually admitted to the hospital for assessment, fetal monitoring, cervical and vaginal cultures, and assessment of cervical status, amniotic fluid leakage, and temperature (an increase can be an early sign of chorioamnionitis). **Tocolytics** are medications given to arrest labour after uterine contractions and cervical change have occurred. No medications have been approved for use as tocolytics in Canada. Medications marketed for other purposes, such as for treatment of asthma or hypertension or as anti-inflammatory or analgesic agents, are used on an "off-label" basis (i.e., medications known to be effective for a specific purpose though not specifically developed and tested for this purpose) to suppress preterm labour (Simhan et al., 2018). No tocolytic has been shown to reduce the rate of preterm birth. Rather, the rationale for giving these

BOX 20.4 Adverse Effects of Bed Rest

Maternal Effects (Physical)

- Weight loss, indigestion, loss of appetite
- Muscle wasting, weakness; aching muscles
- Potential for thrombus formation and thromboembolism
- Bone demineralization and calcium loss
- Decreased plasma volume and cardiac output
- Increased clotting tendency; risk for thrombophlebitis
- Alteration in bowel function; constipation
- Sleep disturbance, fatigue
- Prolonged postpartum recovery

Maternal Effects (Psychosocial)

- Loss of control associated with role reversals
- Dysphoria—anxiety, depression, hostility, and anger
- Guilt associated with difficulty adhering to activity restriction and inability to meet role responsibilities
- Boredom, loneliness
- Emotional lability (mood swings); difficulty concentrating
- Increased stress

Effects on Support System

- Stress associated with role reversals, increased responsibilities, and disruption of family routines
- Financial strain associated with loss of maternal income
- Fear and anxiety regarding well-being of the mother and fetus

medications is to delay birth long enough to allow time for transport of the patient and for corticosteroids to reach maximum benefit to reduce newborn morbidity and mortality. Studies of individual medications used for tocolysis rarely contain information about whether delaying birth improved infant outcomes (Simhan et al., 2018). Contraindications for tocolytic therapy are listed in Box 20.5. Box 20.6 describes nursing care for patients receiving tocolytic therapy.

BOX 20.5 Contraindications to Tocolysis

Maternal

Severe pre-eclampsia or severe gestational hypertension
Significant vaginal bleeding
Intrauterine infection (chorioamnionitis)
Cardiac disease
Medical or obstetrical condition that contraindicates continuation of pregnancy

Fetal

Gestational age of 37 weeks or more
Fetal demise
Lethal fetal anomaly
Evidence of acute or chronic fetal compromise

Data from Simhan, H., Iams, J., & Romero, R. (2017). Preterm birth. In S. Gabbe, J. Niebyl, J. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Saunders.

BOX 20.6 Nursing Care for a Patient Receiving Tocolytic Therapy

- Explain to the patient and their family the purpose and adverse effects of the tocolytic medication(s) ordered.
- Position patient in lateral position to enhance placental perfusion and reduce pressure on the cervix.
- Monitor vital signs, including lung sounds and respiratory effort, fetal heart rate and pattern, and labour status according to hospital protocol and professional standards.
- Assess labouring patient and fetus for signs of adverse reactions related to the tocolytic medication(s) being administered (see Medication Guide: Tocolytic Therapy for Preterm Labour).
- Determine labouring patient's fluid balance by measuring intake and output.
- Provide psychosocial support to the patient and their family as well as opportunities for them to express feelings and concerns.
- Offer comfort measures as required.
- Encourage diversional activities and relaxation techniques.

NURSING ALERT

To date, there are no medications approved by the Health Protection Branch of Health Canada to arrest preterm labour, although some medications are prescribed for this purpose. Nurses need to be aware of the use of off-label medications.

Nifedipine (Adalat), a calcium channel blocker, is a tocolytic agent that can suppress contractions. Because of its ease of administration and low incidence of significant maternal and fetal adverse effects, the use of nifedipine is increasing and it is usually the first choice of tocolytic. The medication is rapidly absorbed after oral administration. Adverse effects in the patient include headache, flushing, dizziness, and nausea; are generally mild; and relate primarily to the hypotension and reflex tachycardia that occur with administration. The decrease in blood pressure that occurs may be helpful for patients who are also diagnosed with gestational hypertension or pre-eclampsia (see Medication Guide: Tocolytic Therapy for Preterm Labour).

Indomethacin (Indocin), a nonsteroidal anti-inflammatory drug (NSAID), has been shown in some trials to suppress preterm labour by blocking the production of prostaglandins. Serious adverse effects in the pregnant patient are uncommon, and indomethacin is usually well tolerated. However, serious fetal or newborn adverse effects have caused major concerns about its use as a tocolytic. Therefore, limiting the use of indomethacin to a short duration of treatment in patients with preterm labour at less than 32 weeks of gestation is recommended (Simhan et al., 2018) (see Medication Guide).

Magnesium sulphate inhibits uterine contractions and decreases intracellular calcium levels. Magnesium sulphate produces few serious maternal or newborn complications, and clinicians are familiar with its use. However, although magnesium sulphate is still frequently used, a recent meta-analysis of tocolytic agents found that it is not effective when given for tocolysis and is used more appropriately for fetal neuroprotection (see Medication Guide and discussion below) (Simhan et al., 2018).

SAFETY ALERT

Because using a calcium channel blocker can result in orthostatic hypotension and dizziness, it is essential to instruct patients taking this type of medication to slowly change position from supine to upright and then sit before standing until any dizziness disappears. In addition, it is important to maintain adequate fluid balance to reduce the drop in blood pressure that can occur with the medication-related vasodilation.

MEDICATION GUIDE

Tocolytic Therapy for Preterm Labour

Medication and Action	Dosage and Route	Adverse Effects	Nursing Considerations
Nifedipine (Adalat)* Calcium channel blocker; relaxes smooth muscles, including the uterus, by blocking calcium entry	Loading dose: 20 mg PO Maintenance dosage: 10–20 mg PO 3 to 4 times daily adjusted according to uterine activity (however, the ideal dose has not been established)	Maternal (most effects are mild) • Hypotension • Dizziness • Headache • Nausea • Flushing Fetal • No known adverse effects	• Do not use sublingual route. • Use with caution with antihypertensives because severe hypotension can result. • Avoid concurrent use with magnesium sulphate because skeletal muscle blockade can result. • Assess patient and fetus according to agency protocol, being alert for adverse reactions. • Its use is contraindicated in patients with preload-dependent cardiac lesion (e.g., aortic insufficiency).

Indomethacin* Relaxes uterine smooth muscle by inhibiting prostaglandins	Loading dose: 50 mg rectally or 50–100 mg PO; then 25–50 mg PO q6h for 48 hr	Maternal (common) • Nausea and vomiting • Heartburn Less common, but more serious • GI bleeding • Prolonged bleeding time • Thrombocytopenia • Asthma in aspirin-sensitive patients Fetal • Constriction of ductus arteriosus • Oligohydramnios, caused by reduced fetal urine production • Newborn pulmonary hypertension	• Long-acting formulations decrease incidence of adverse effects • Used only if gestational age is less than 32 weeks • Administer for 48 hr or less. • Do not use in patients with renal or hepatic disease, active peptic ulcer disease, poorly controlled hypertension, asthma, or coagulation disorders. • It can mask fever in a labouring patient. • Assess labouring patient and fetus according to agency policy; be alert for adverse effects. • Determine amniotic fluid volume and function of fetal ductus arteriosus before initiating therapy and within 48 hr of discontinuing therapy; assessment is critical if therapy continues for more than 48 hr. • Administer with food to decrease GI distress. • After birth, monitor for signs of postpartum hemorrhage. • It should be used with caution in patients who are volume depleted or who are already hypotensive.
Magnesium sulphate CNS depressant; relaxes smooth muscles, including uterus	IV fluid should contain 40 g in 1 000 mL, piggyback to primary infusion, and administer using pump. Loading dose: 4 g over 30 min Maintenance dose: 1 g/hr Use for stabilization only. Discontinue within 24–48 hr at the maintenance dose or if intolerable adverse effects occur.	Maternal • Hot flushes, sweating, burning at IV insertion site, nausea and vomiting, dry mouth, drowsiness, blurred vision, diplopia, headache, ileus, generalized muscle weakness, lethargy, dizziness • Hypocalcemia • Dyspnea • Transient hypotension • Some reactions may subside when loading dose is completed. Intolerable • Respiratory rate fewer than 12 breaths/min • Pulmonary edema • Absent DTRs • Chest pain • Severe hypotension • Altered level of consciousness • Extreme muscle weakness • Urine output less than 25–30 mL/hr or less than 100 mL/4 hr Fetal (uncommon) • Decreased breathing movement • Reduced FHR variability • Abnormal NST	• Assess patient and fetus to obtain baseline before beginning therapy and then before and after each incremental change; follow frequency of agency protocol. • Discontinue infusion and notify health care provider if intolerable adverse effects occur. • Ensure that calcium gluconate 1 g (10 mL of 10% solution) or calcium chloride (normal dose is 500 mg IV infused over 30 min) is available for emergency administration to reverse magnesium sulphate toxicity. • It should not be given to patients with myasthenia gravis. • Total IV intake should be limited to 125 mL/hr.

DTR, Deep tendon reflex; *FHR*, fetal heart rate; *GI*, gastrointestinal; *IV*, intravenous; *NST*, nonstress test; *PO*, by mouth.
*__Caution:__ Not approved by Health Canada for preterm labour (off-label use).

Promotion of fetal lung maturity. Antenatal glucocorticoids are given as intramuscular injections to the patient at risk for preterm labour or already in preterm labour, to accelerate fetal lung maturity by stimulating fetal surfactant production. They are now considered one of the most effective and cost-efficient interventions for preventing morbidity and mortality associated with preterm labour. Antenatal glucocorticoids have been shown to significantly reduce the incidence of respiratory distress syndrome, intraventricular hemorrhage, necrotizing enterocolitis, and death in newborns, without increasing the risk for infection in either the pregnant patient or the newborn (Mercer & Chien, 2018). All pregnant patients between 24 and 34+6 weeks of gestation should be given a single course of antenatal glucocorticoids when preterm birth is threatened and

expected within 7 days, unless evidence indicates that glucocorticoids will have an adverse effect on the pregnant patient or birth is imminent. In general, patients who are candidates for tocolytic therapy are also candidates for antenatal glucocorticoids (Mercer & Chien, 2018; Skoll et al., 2018). The regimen for administration of antenatal glucocorticoids is given in the Medication Guide: Antenatal Glucocorticoid Therapy with Betamethasone or Dexamethasone.

MEDICATION GUIDE

Antenatal Glucocorticoid Therapy With Betamethasone or Dexamethasone

Action*
- Stimulates fetal lung maturation by promoting release of enzymes that induce production or release of lung surfactant. Glucocorticoids have similar maturational effects on other organs, including the brain, kidneys, and gut.

Indication
- To prevent or reduce severity of newborn respiratory distress syndrome by accelerating lung maturity in fetuses between 24 and 34+6 weeks of gestation when birth is expected within 7 days. Infants born to a parent who received antenatal glucocorticoids are also less likely to experience intraventricular hemorrhage, necrotizing enterocolitis, or newborn death.

Dosage and Route
- Betamethasone: 12 mg intramuscular (IM) for 2 doses 24 hours apart
- Dexamethasone: 6 mg IM for 4 doses 12 hours apart

Maternal Effects
- Transient (lasting 72 hours) increase in white blood cell (WBC) and platelet counts
- Hyperglycemia

Fetal Effects
- Transient (typically lasting 48 to 72 hours after the last dose) decrease in fetal breathing and body movements

Nursing Considerations
- Give deep IM injection in ventral gluteal or vastus lateralis muscle.
- Medication *must* be given by IM injection; oral administration is *not* an acceptable alternative.
- Injection is painful.
- Medication should *not* affect the pregnant patient's blood pressure.
- Assess blood glucose levels. Pregnant patients with diabetes whose blood sugar levels have previously been well controlled may require increased insulin doses for several days.

***Note:** Health Canada has not approved these medications for this use (i.e., this is an off-label use for obstetrics).

Elsevier; Skoll, A., Boutin, B., Bujold, E., et al. (2018). SOGC clinical practice guideline: Antenatal corticosteroid therapy for improving neonatal outcomes. *Journal of Obstetrics and Gynaecology Canada, 40*(9), 1219–1239. doi:10.1016/j.jogc.2018.04.018.

NURSING ALERT

All pregnant patients between 24 and 34+6 weeks of gestation who are at risk for preterm birth within 7 days should receive treatment with a single course of antenatal glucocorticoids. Because optimal benefit to the fetus begins 24 hours after the first injection, timely administration is essential.

Management of inevitable preterm birth. When preterm birth appears inevitable (i.e., is expected to occur within the next 24 hours), magnesium sulphate may be administered to reduce or prevent newborn neurological morbidity (e.g., cerebral palsy). The current recommendation is that magnesium sulphate for neuroprotection be given to patients who are at least 24 but less than or equal to 33+6 weeks of gestation at the time birth is expected to occur. How magnesium sulphate works to provide neuroprotection is not well understood. Although it is likely that the neuroprotective effects are the result of residual concentrations of the medication in the newborn's system, data are insufficient to determine the precise maternal dose necessary to confer the benefit (Simhan et al., 2018). Currently, the dose of magnesium sulphate administered for neuroprotection is the same as that given for tocolysis (see Medication Guide: Tocolytic Therapy for Preterm Labour). If antenatal magnesium sulphate has been started for fetal neuroprotection, tocolysis should be discontinued. Magnesium sulphate should be discontinued if birth is no longer imminent or after a maximum of 24 hours of therapy has been administered (Magee et al., 2019). See Evidence-Informed Practice Box: Magnesium Sulphate for Neuroprotection Against Cerebral Palsy.

EVIDENCE-INFORMED PRACTICE

Magnesium Sulphate for Neuroprotection Against Cerebral Palsy

Ask the Question

For patients anticipating preterm birth, can any prenatal treatment protect the premature newborn from cerebral palsy?

Search for the Evidence

Search Strategies: English research-based publications since 2011 on magnesium sulphate, neuroprotection, preterm, premature were included.

Databases Used: Cochrane Collaborative Database, CINAHL, PubMed, UpToDate, and the professional websites for SOGC and ACOG

Critical Appraisal of the Evidence

Among the many challenges for a premature baby is the risk for cerebral palsy, the most common motor disability in children. Alert clinicians noticed that newborns whose mothers had been given magnesium sulphate for tocolysis or pre-eclampsia were less likely to have cerebral palsy. Further research confirmed its benefit and safety.
- Magnesium sulphate facilitates vasodilation, reduces inflammation, and reduces calcium uptake into cells. It may delay cellular injury or death and increases blood flow to the brain (Merrill, 2013).

Continued

- Although magnesium sulphate is no longer recommended for stopping preterm labour, the Society of Obstetricians and Gynaecologists of Canada (SOGC) still recommends magnesium sulphate for neuroprotection against cerebral palsy in patients anticipating imminent preterm birth from the age of viability to 33 +6 weeks of gestation (Magee et al., 2019). The American College of Obstetricians and Gynecologists (ACOG) and the Society for Maternal-Fetal Medicine (SMFM) (2016) recommend the use of magnesium sulphate in patients less than 32 weeks of gestation.
- If antenatal magnesium sulphate has been started for fetal neuroprotection based on a clinical diagnosis of imminent preterm birth, tocolysis is no longer indicated and should be discontinued (Magee et al., 2019).
- Administering magnesium sulphate requires intravenous infusion and close monitoring. Monitoring of maternal serum magnesium levels is not required when magnesium sulphate is administered solely for fetal neuroprotection, unless both a maintenance infusion is used and there is evidence of renal impairment (Magee et al., 2019).
- A cost-effectiveness analysis reveals that giving neuroprotective magnesium sulphate to patients with threatened preterm birth saves $1.5 million for every case of cerebral palsy that is averted (Bickford et al., 2013).
- A knowledge translation strategy (including national practice guidelines, online e-learning modules, educational rounds, and evaluation of barriers and feasibility) was associated with an 84% increase in optimal magnesium sulphate use (De Silva et al., 2018).

Apply the Evidence: Nursing Implications

- Magnesium sulphate should be given in settings where staff are familiar with its use, monitoring is available, and emergency resuscitation and ventilation equipment is available.
- Typical use in patients in active preterm labour or with preterm premature rupture of membranes is a 4-g loading dose given over 30 to 60 minutes, followed by the maintenance dose of 1 g/hour, given until birth or for up to 24 hours, whichever comes first. Other tocolytics are discontinued.
- Prior to the loading dose, the nurse obtains baseline vital signs and checks patellar reflexes. These assessments are repeated at 10 minutes after initiation and at the end of the loading dose. During the maintenance dose, vitals are repeated hourly, reflexes every 2 hours, and continuous electronic fetal monitoring is recommended.
- Signs of magnesium toxicity include a decrease in respirations of 4 breaths per minute from the baseline rate or to less than 12 per minute; a systolic blood pressure drop of 15 mm Hg from the baseline; diminished reflexes; decreased urinary output; or fetal heart rate abnormalities. If these are noted, the nurse should stop the infusion and notify the health care provider. Calcium gluconate should be available nearby as an antidote.
- To improve safety, the infusion should be given via infusion device in prepackaged concentrations clearly labelled as loading and maintenance doses and double-checked by another nurse.
- Newborn hypermagnesemia, although rare, can present as apnea, respiratory depression, lethargy, poor feeding, and hyporeflexia. Neonatal resuscitation support should be available.

Pat Mahaffee Gingrich

Labour that has progressed to a cervical dilation of 4 cm is likely to lead to preterm birth. If birth appears imminent, preparations to care for a small, immature newborn should be made. Patients in preterm labour may rapidly progress to birth and a very small fetus may be born through a partially dilated cervix. Also, malpresentation (e.g., breech presentation) occurs much more frequently in preterm than in term fetuses. Therefore, nurses must be prepared to handle the emergency birth of a preterm infant, from either cephalic or breech presentation, without the patient's obstetrical health care provider being present. Personnel skilled in neonatal resuscitation should be present at the time of birth. Equipment, supplies, and medications used for neonatal resuscitation should be gathered in advance and prepared for immediate use. If birth occurs in a hospital that is not prepared to provide continuing care for a preterm newborn, plans should be made for transfer of the baby to a higher level of care as soon as possible after stabilization.

Fetal and early neonatal loss. Preterm birth or the presence of congenital anomalies or genetic disorders incompatible with life are major reasons for intrauterine fetal demise (stillbirth) or early neonatal death. In many of these situations, the parents will have already been told that the fetus has died or that the baby has a condition that is incompatible with life and will most likely die very soon after birth. Sometimes, however, the fetal death will be unexpected, diagnosed only after the patient has been admitted to the labour and birth unit. Whatever the case, labour and birth nurses must be prepared to provide sensitive care to these patients and their families.

If fetal or early neonatal death is expected, the parents and members of the health care team need to discuss the situation before the birth and decide on a management plan that is acceptable to everyone. Despite counselling about the likelihood of a poor outcome, some parents want "everything possible," including Caesarean birth for an abnormal fetal heart rate (FHR) tracing, done for the baby. If such intervention is not desired, usually the FHR will not be monitored during labour.

Another major decision is whether to attempt neonatal resuscitation and to what lengths resuscitation should go. Sometimes the feasibility of neonatal resuscitation cannot be determined until the baby's size and physical appearance have been assessed. If the baby is too small, too immature, or too malformed for effective resuscitation, palliative care can be provided instead. The baby is kept warm and comfortable, either at the parent's bedside, in the nursery, or at home, depending on the parents' desires, until death occurs. Parents can choose to view and hold the baby as they wish.

After the birth, the patient should be given the opportunity to decide if they want to stay on the maternity unit or be moved to another hospital unit. They may prefer to be away from the sound of crying babies and exposure to other families who have had healthy infants. However, postpartum care and grief support may not be as good on another hospital unit where the staff are not experienced in postpartum and bereavement care.

Whether death occurs in utero or after birth, parents are faced with the same needs. See Chapter 24 for additional information on providing care for families experiencing a perinatal loss.

PREMATURE RUPTURE OF MEMBRANES

Premature rupture of membranes (PROM) is the spontaneous rupture of the amniotic sac and leakage of amniotic fluid beginning before the onset of labour at any gestational age. **Preterm premature rupture of membranes (preterm PROM or pPROM)** (i.e., membranes rupture before the completion of 37 weeks of gestation) is associated with approximately 10% of all preterm births. The frequency of preterm PROM appears to have decreased over the past decade (Mercer, 2017). Preterm PROM most likely results from pathological weakening of the amniotic membranes, caused by inflammation, stress from uterine contractions, or other factors that cause increased intrauterine pressure. Infection of the urogenital tract is a major risk factor associated with preterm PROM (Mercer, 2017; Mercer & Chien, 2018); Box 20.7 lists other risk factors. PROM or preterm PROM is diagnosed after the patient reports either a sudden gush of fluid or a slow leak of fluid from the vagina.

Chorioamnionitis is the most common maternal complication of preterm PROM, making it a major complication of pregnancy (see later discussion). Other less common but serious maternal complications include placental abruption, retained placenta and hemorrhage requiring dilation and curettage (D&C), sepsis, and death. Fetal complications from preterm PROM are related primarily to intrauterine infection, cord prolapse, umbilical cord compression associated with oligohydramnios, and placental abruption. Another possible fetal complication when preterm PROM occurs before 20 weeks of gestation is pulmonary hypoplasia (Mercer, 2017; Mercer & Chien, 2018).

Nursing Care

Management of PROM is determined for each patient on the basis of an assessment of the estimated risk for maternal, fetal, and newborn complications if pregnancy is allowed to continue or immediate labour and birth are attempted. At term, because infection is the greatest risk for the labouring person, the fetus, and the newborn, birth is the best option. Labour will most likely be induced if it does not begin spontaneously soon after PROM occurs, although some patients are given the option of waiting 24 hours to determine if labour will begin on its own (Mercer, 2017; Mercer & Chien, 2018).

BOX 20.7 Risk Factors for Preterm Premature Rupture of Membranes (Preterm PROM)

- History of prior preterm birth, especially if associated with preterm PROM
- History of cervical surgery or cerclage (suture to keep cervix closed)
- Urinary or genital tract infection
- Short (<25 mm) cervical length in the second trimester identified by transvaginal ultrasound
- Preterm labour or symptomatic contractions in the current pregnancy
- Uterine overdistension
- Second- and third-trimester bleeding
- Pulmonary disease
- Connective tissue disorders
- Low socioeconomic status
- Low body mass index
- Nutritional deficiencies (copper and ascorbic acid)
- Cigarette smoking

Data from Mercer, B. (2017). Premature rupture of the membranes. In S. Gabbe, J. Niebyl, J. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

Active pursuit of labour and birth, rather than expectant management, is usually recommended for patients who experience preterm PROM between 34 and 36 weeks of gestation, although a recent multicentre study found that conservative management that continued until 37 weeks of gestation was associated with less newborn hypoglycemia and hyperbilirubinemia. Therefore, conservative management of preterm PROM that occurs at 34 to 37 weeks of gestation might be an option if the risk for intrauterine infection is considered to be low (Mercer, 2017).

Preterm PROM before 32 weeks of gestation is often managed expectantly or conservatively because the risks to the fetus and newborn associated with preterm birth are considered to be greater than the risks of infection. Patients will likely be hospitalized in an attempt to prolong the pregnancy and allow additional time for fetal maturation, unless intrauterine infection, significant vaginal bleeding, placental abruption, advanced labour, or atypical or abnormal fetal assessment is assessed (Mercer, 2017). Conservative management may require transfer to a hospital that is prepared to provide 24-hour neonatal resuscitation and intensive care. Ideally transfer should occur early in the course of care, before birth becomes imminent or complications arise. Nursing support of the patient and family is critical at this time. They are often anxious about the health of the baby, and the pregnant patient may fear being responsible in some way for the membrane rupture. The nurse can reassure the patient that in most cases the cause of PROM is unknown (Mercer, 2017). Other nursing interventions include encouraging expression of feelings and concerns, providing information, and making referrals as needed.

Conservative management of preterm PROM includes frequent use of a nonstress test (NST) and **biophysical profile (BPP)** to determine fetal health status and estimate amniotic fluid volume (AFV) (see Chapter 13). The patient with PROM also should be taught how to count fetal movements daily, because a slowing of fetal movement has been shown to be a precursor to severe fetal compromise. Most pregnant patients should feel six movements in 2 hours; if they do not, further antenatal testing (NST, BPP, or both) is required (Liston et al., 2018). In addition, the patient will be monitored for signs of labour, placental abruption, and the development of intrauterine infection.

The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends one course of antenatal corticosteroid be administered to patients at 24 to 34+6 weeks gestation (Skoll et al., 2018) (see discussion above). Also, a 7-day course of broad-spectrum antibiotics (e.g., ampicillin/amoxicillin and erythromycin) will be administered. Antibiotic treatment has been shown to prolong the time between membrane rupture and birth, decrease the incidence of chorioamnionitis, and reduce infections and gestational age-dependent complications in the newborn, such as the need for oxygen or surfactant therapy and intraventricular hemorrhage (Mercer, 2017; Yudin et al., 2017).

Administering magnesium sulphate for fetal neuroprotection to patients with preterm PROM who are less than 34 weeks of gestation who are thought to be at imminent risk for giving birth prematurely is recommended (Magee et al., 2019) (see earlier discussion for more information on magnesium sulphate administration for this reason).

Vigilance for signs of infection is a major part of nursing care and patient education after preterm PROM. The patient must be taught how to keep the genital area clean and that nothing should be introduced into the vagina. Signs of infection (e.g., fever, foul-smelling vaginal discharge, maternal and fetal tachycardia) should be reported immediately to the primary health care provider. If chorioamnionitis develops, the patient is placed on broad-spectrum antibiotics and labour will be induced.

CHORIOAMNIONITIS

Chorioamnionitis, bacterial infection of the amniotic cavity, is a major cause of complications for both mothers and newborns at any gestational age. It occurs in approximately 1 to 5% of term births but in

as many as 25% of preterm births (Duff & Birsner, 2017). Other terms for this condition include *amnionitis* and *intrapartum infection*. Chorioamnionitis is usually diagnosed by the clinical findings of maternal fever, maternal and fetal tachycardia, uterine tenderness, and foul odour of amniotic fluid (Duff, 2018).

Chorioamnionitis most often occurs after membranes rupture or labour begins, as organisms that are part of the normal vaginal flora ascend into the amniotic cavity. Many of the risk factors for chorioamnionitis are associated with a long labour, such as prolonged membrane rupture, multiple vaginal examinations, and use of internal FHR and contraction monitoring modes (Duff, 2018). Other risk factors include young maternal age, low socioeconomic status (which may be associated with no or minimal prenatal care), nulliparity, and pre-existing infections of the lower genital tract (Duff & Birsner, 2017).

Patients with chorioamnionitis can develop bacteremia. They are also more likely to have labour dystocia, which can result in the need for Caesarean birth (see later discussion). If Caesarean birth is necessary, wound infection or pelvic abscess is a possible complication.

Risks to the newborn include pneumonia, bacteremia, and sepsis. Death is more likely to occur in preterm than in term newborns (Duff, 2018). There is increasing evidence that intrauterine infection is associated with increased risks for respiratory distress syndrome, periventricular leukomalacia, and cerebral palsy. It is thought that intrauterine infection leads to fetal infection that eventually produces a fetal inflammatory response syndrome with resulting pulmonary and central nervous system damage (Duff, 2018).

In order to prevent complications to the pregnant patient and newborn, prompt treatment with intravenous (IV) broad-spectrum antibiotics and birth of the fetus are necessary. Ampicillin or penicillin and gentamicin are the antibiotics most often used to treat chorioamnionitis during labour. After Caesarean birth, an antibiotic that provides coverage for anaerobic organisms, such as clindamycin or metronidazole (Flagyl), should be added. One additional dose of a combination of broad-spectrum antibiotics (e.g., ampicillin and gentamicin) given postpartum is usually sufficient treatment for patients with chorioamnionitis (Duff, 2018).

The increased use of intrapartum antibiotic prophylaxis during labour in patients who are group B streptococci positive has decreased the incidence of chorioamnionitis. Other measures that have proven to be effective in decreasing the frequency of chorioamnionitis are active management of labour (see later discussion); induction of labour, rather than expectant management, following rupture of membranes at term; and use of prophylactic antibiotics in selected patients with preterm PROM (Duff, 2018).

POST-TERM PREGNANCY, LABOUR, AND BIRTH

A *post-term* or *postdate pregnancy* is one that extends beyond the end of week 42 of gestation, or more than 294 days from the first day of the last menstrual period (LMP). The rate of post-term pregnancies in Canada decreased from 0.5 to 0.3 per 100 live births from 2005 to 2014 (PHAC, 2017). Many pregnancies are misdiagnosed as prolonged. The use of first-trimester ultrasound for pregnancy dating has confirmed that the first day of the LMP, traditionally used for pregnancy dating, is much less reliable as a predictor of true gestational age. Therefore, use of the LMP alone for pregnancy dating tends to greatly overestimate the number of post-term gestations (Rampersad & Macones, 2017). Ideally, every pregnant person should be offered a first-trimester dating ultrasound; however, if the availability of obstetrical ultrasound is limited, it is reasonable to use a second-trimester scan to assess gestational age (Butt & Lim, 2019).

The exact cause of post-term pregnancy is still unknown. However, it is clear that the timing of labour is determined by complex interactions among the fetus, the placenta and membranes, the uterine myometrium, and the cervix. For example, placental sulphatase deficiency causes low estrogen production. Patients with this disorder generally do not go into spontaneous labour. This is an example of a genetic cause for post-term pregnancy that supports the important role of the placenta in labour initiation. Risk factors for post-term pregnancy include a first pregnancy, prior post-term pregnancy, a male fetus, obesity, and a genetic predisposition (Rampersad & Macones, 2017).

Post-Term Risks

A number of factors related to post-term pregnancy, including labour dystocia, severe perineal injuries, chorioamnionitis, endomyometritis, postpartum hemorrhage, and Caesarean birth, are associated with significant risk for morbidity during the intrapartum period (Rampersad & Macones, 2017; Sheibani & Wing, 2017). Each intervention, such as induction of labour with prostaglandins or oxytocin, forceps- or vacuum-assisted birth, and Caesarean birth, carries its own set of risks. The patient also may experience psychological reactions such as anxiety as they pass their estimated date of birth (Rampersad & Macones, 2017).

Another complication associated with post-term pregnancy is abnormal fetal growth. Although the risk for having a small-for-gestational-age infant is increased, only 10 to 20% of post-term fetuses are undernourished. The risk for macrosomia increases as gestational age advances. Macrosomia occurs when the placenta continues to provide adequate nutrients to support fetal growth after 40 weeks of gestation. Macrosomic infants have an increased risk for operative birth and shoulder dystocia, leading to fetal injury (Rampersad & Macones, 2017).

Other fetal risks associated with post-term gestation are related to the intrauterine environment. Decreased amniotic fluid (less than 400 mL), or **oligohydramnios**, is a common finding in post-term pregnancy. Because of the decreased amount of amniotic fluid, there is a potential for cord compression resulting in abnormal FHR patterns and subsequent Caesarean birth (Rampersad & Macones, 2017). Other potential complications include meconium-stained amniotic fluid, increased chance of meconium aspiration, low Apgar scores, and convulsions in the newborn (Rampersad & Macones, 2017). Postmature infants may have decreased subcutaneous fat and lack vernix and lanugo (Rampersad & Macones, 2017).

Collaborative Care

Because of the increased risk for stillbirth, antepartum fetal assessment beginning at 41 weeks of gestation should be considered (Delaney & Roggensack, 2017). Antepartum assessments for post-term pregnancy may include daily fetal movement counts, NSTs, AFV assessments, contraction stress tests, BPPs, and Doppler flow measurements (see Chapter 13). The patient and family should be fully informed about the tests, including why they are being performed and the meaning of the results obtained in terms of the health of the pregnant patient and the fetus.

Studies have shown a significantly increased rate of perinatal mortality after 41 weeks of gestation (Sheibani & Wing, 2017). Currently, it is recommended that birth occur after 42 weeks and by 42+6 weeks of gestation to decrease the risk for perinatal morbidity and mortality (ACOG, 2009/2019; Rampersad & Macones, 2017). Patients should be offered induction of labour between 41 and 42 weeks, as this intervention may reduce perinatal mortality and meconium aspiration syndrome without increasing the Caesarean birth rate (Delaney & Roggensack, 2017). Pregnant patients who choose to delay induction past 41 weeks should, at a minimum, undergo an NST and AFV assessment twice weekly (Delaney & Roggensack, 2017).

During the post-term period, the pregnant patient should be encouraged to assess fetal activity daily, assess for signs of labour, and keep appointments with their obstetrical health care provider (see Patient Teaching box: Post-Term Pregnancy). The patient and family should be encouraged to express their feelings about the prolonged pregnancy (e.g., frustration, anger, impatience, fear)

and reassured that these feelings are normal. At times, the emotional and physical strain of a post-term pregnancy may seem overwhelming.

PATIENT TEACHING

Post-Term Pregnancy

- Perform daily fetal movement counts.
- Assess for signs of labour.
- Call your primary health care provider if your membranes rupture or if you perceive a decrease in or no fetal movement.
- Keep appointments for fetal assessment tests or cervical checks.
- Go to the hospital soon after labour begins.

If the patient's cervix is favourable, expectant management can be followed, but labour is usually induced with oxytocin. If the cervix is not favourable, fetal surveillance is continued and a cervical ripening agent (e.g., prostaglandin E_2) may be administered, followed by oxytocin induction (Rampersad & Macones, 2017).

During labour, the fetus of a patient with a post-term pregnancy should be continuously monitored electronically for a more accurate assessment of the fetal heart rate and pattern (Dore & Ehman, 2020). Inadequate fluid volume leads to compression of the cord, which results in a transient fetal hypoxia that is reflected in variable or prolonged deceleration patterns. If oligohydramnios is present, **amnioinfusion** may be performed to restore AFV, to maintain a cushioning of the cord. See Chapter 19 for additional information on amnioinfusion.

DYSTOCIA

Dystocia is defined as abnormally slow progress of labour; it is caused by various conditions related to the five P's of labour (**p**assenger, **p**assageway, **p**owers, **p**osition of the labouring patient, and **p**sychological response) (see Chapter 16). *Dystocia* is defined as greater than 4 hours of less than 0.5 cm per hour of cervical dilation in active labour or greater than 1 hour of active pushing with no descent of the presenting part and is a common reason for Caesarean birth (Lee et al., 2016). Dystocia can be caused by any of the following:

- Ineffective uterine contractions or bearing-down efforts (the powers); the most common cause of dystocia
- Alterations in the pelvic structure, including abnormalities of the labouring patient's bony pelvis or soft-tissue abnormalities of the reproductive tract (the passageway)
- Fetal causes, including abnormal presentation or position, anomalies, excessive size, and number of fetuses (the passenger)
- Position of patient during labour and birth
- Psychological responses of the patient to labour that are related to past experiences, preparation, culture and heritage, and support system

These five factors are interdependent. In assessing the patient for labour dystocia, the nurse must consider the ways in which they interact and influence labour progress. Dystocia should be suspected when there is an alteration in the characteristics of uterine contractions, a lack of progress in the rate of cervical dilation, or a lack of progress in fetal descent and expulsion.

Abnormal Uterine Activity (Alteration in Power)

Dystocia can occur due to abnormal uterine contractions that prevent the normal progress of cervical dilation, effacement (primary powers), or descent (secondary powers). Dysfunction of uterine contractions can be further described as being *hypertonic* or *hypotonic*.

Latent Phase Disorders. A common labour disorder that occurs during the latent phase of first-stage labour is hypertonic uterine dysfunction. The patient experiencing hypertonic uterine dysfunction often is an anxious first-time patient who is having painful and frequent contractions that are ineffective in causing cervical dilation or effacement to progress. These contractions usually occur in the latent stage (cervical dilation of less than 4 cm) and are usually uncoordinated. The force of the contraction may be in the midsection of the uterus rather than in the fundus; therefore, the uterus is unable to apply downward pressure to push the presenting part against the cervix. The uterus may not relax completely between contractions. Some patients may spend several days in protracted latent labour.

Patients with hypertonic uterine dysfunction may be exhausted and express concern about loss of control because of the intense pain they are experiencing and the lack of progress. They can be managed expectantly, because most patients will eventually enter the active phase of labour. Another management approach is to provide therapeutic rest, through taking a warm bath or shower and with the administration of analgesics such as morphine to inhibit uterine contractions, reduce pain, and encourage sleep (Sheibani & Wing, 2017). After several hours of rest, these patients are likely to awaken in active labour with a normal uterine contraction pattern.

Active Phase Disorders. Active-phase labour disorders can be divided into either protraction disorders, where progress in labour is slower than normal, or arrest disorders, where there is no progress in labour (Sheibani & Wing, 2017). The most common cause of an active-phase protraction disorder is inadequate uterine activity (hypotonic uterine dysfunction) (Sheibani & Wing, 2017). The labouring patient initially makes normal progress into the active stage of labour, then the contractions become weak and inefficient or stop altogether. The uterus is easily indented, even at the peak of contractions. Intrauterine pressure during the contraction is insufficient for progress of cervical effacement and dilation. Cephalopelvic disproportion (CPD) (see later discussion) and fetal malposition are other common causes of active-phase labour protraction disorders. Examples of fetal malposition are an extended (rather than flexed) fetal head, brow, or face presentation, and occiput posterior presentation (Sheibani & Wing, 2017).

Evaluation of arrest during the first stage of labour includes an assessment of uterine activity; fetal presentation, position, and station; and estimated fetal weight. If findings are normal, labour augmentation measures may be implemented (e.g., ambulation, hydrotherapy, rupture of membranes, nipple stimulation, or oxytocin infusion). Most labouring patients respond to these interventions by resuming progression of cervical dilation and are able to give birth vaginally (Sheibani & Wing, 2017).

Alteration in Secondary Powers. Secondary powers, or bearing-down efforts, may be compromised when large amounts of analgesic medications are given. Anaesthesia may also block the bearing-down reflex and, as a result, alter the effectiveness of voluntary bearing-down efforts. Exhaustion resulting from lack of sleep or long labour and fatigue resulting from inadequate hydration and food intake reduce the effectiveness of the patient's voluntary bearing-down efforts. Position of the patient during pushing can work against the forces of gravity and decrease the strength and efficiency of the contractions.

Table 20.1 summarizes the characteristics of dystocia related to ineffective contractions (power).

Abnormal Labour Patterns. Six abnormal labour patterns were identified and classified by Friedman (1989) according to the nature of cervical dilation and fetal descent. These patterns are (1) prolonged latent phase, (2) protracted active-phase dilation, (3) secondary arrest: no change, (4) protracted descent, (5) arrest of descent, and (6) failure

TABLE 20.1 Dystocia Related to Inadequate Primary and Secondary Powers

PRIMARY POWERS (ABNORMAL UTERINE ACTIVITY)		SECONDARY POWERS
Hypertonic Uterus	**Hypotonic Uterus**	**Inadequate Voluntary Expulsive Forces**
Description		
Usually occurs early in latent phase labour; cause is unknown, may be related to fear and tension	Cause is usually cephalopelvic disproportion or fetal malposition	Involves abdominal and levator ani muscles Occurs in second stage of labour; cause may be related to nerve block anaesthetic, analgesia, exhaustion
Change in Pattern of Progress		
Pain is out of proportion to intensity of contractions and to effectiveness of contractions in effacing and dilating the cervix. Contractions increase in frequency and are uncoordinated. Uterus is contracted between contractions, cannot be indented.	Contractions decrease in frequency and intensity. Uterus is easily indented even at peak of contractions. Uterus is relaxed between contractions (normal).	No voluntary urge to push or bear down or inadequate or ineffective pushing
Potential Maternal Effects		
Loss of control related to intensity of pain and lack of progress Exhaustion Fear regarding unexpected nature of labour	Infection Exhaustion Stress regarding change in progress	Spontaneous vaginal birth more difficult; assisted birth possible
Potential Fetal Effects		
Fetal asphyxia with meconium aspiration	Fetal infection Fetal and newborn death	Fetal asphyxia
Care Management		
Initiate therapeutic rest measures. Administer analgesic (e.g., morphine) if membranes are intact and pelvic adequacy is confirmed. Relieve pain to permit mother to rest. Assist with measures to enhance rest and relaxation (e.g., hydrotherapy, massage, music, distracting activities).	Rule out cephalopelvic disproportion. Augment labour with oxytocin. Perform amniotomy. Assist with measures to enhance the progress of labour (e.g., position changes, ambulation, hydrotherapy).	Encourage mother to bear down with contractions; assist with relaxation between contractions. Position mother in favourable position for pushing. Reduce epidural infusion rate. Assist with forceps- or vacuum-assisted birth. Prepare for Caesarean birth if abnormal fetal status occurs.

of descent. These abnormal patterns may result from a variety of causes, including ineffective uterine contractions, pelvic contractures, CPD, abnormal fetal presentation or position, early use of analgesics, nerve block analgesia or anaesthesia, and anxiety and stress. Abnormal progress can be identified by plotting cervical dilation and fetal descent on a labour graph (partogram) at various intervals after the onset of labour and comparing the resulting curve with the expected labour curve for a nulliparous or multiparous labour. If a labouring patient exhibits an abnormal labour pattern, the obstetrical health care provider should be notified.

Studies done within the past two decades indicate that the contemporary pattern of labour progression is different from what Friedman observed in the 1950s. In general, modern labour progresses at a slower rate for both nulliparous and multiparous patients. The active labour phase now begins at 4 cm cervical dilation and lasts twice as long as what Friedman described. It is common for more than 2 hours to pass in the active phase of labour without cervical dilation. Patient characteristics have changed considerably since Friedman's work was published. In general, patients giving birth now are older and heavier, and both of these factors are associated with longer labours (Lee et al., 2016).

Health care providers must be careful when diagnosing a labour pattern as prolonged and when intervening on the basis of this diagnosis. Criteria defining the differences between prelabour, latent, and active labour should be established. Evaluation of a patient's labour status in the hospital or unit admission areas is helpful in preventing the premature implementation of labour interventions such as administration of systemic opioid analgesics or induction of epidural analgesia or anaesthesia. If a patient is found to be in prelabour or latent (early) labour, they can be sent home or remain in the admission area until labour becomes active. If possible, patients should not be admitted to the labour and birth unit until they are in active labour.

Alterations in Pelvic Structure (Passageway)

Pelvic Dystocia. Pelvic dystocia can occur whenever there are contractures of the pelvic diameters that reduce the capacity of the bony pelvis, including the inlet, midpelvis, outlet, or any combination of these planes. Pelvic contractures may be caused by congenital abnormalities, maternal malnutrition, neoplasms, or lower spinal disorders. An immature pelvic size predisposes some adolescent patients to pelvic dystocia. Pelvic deformities may also be the result of motor vehicle accidents or other accidents or trauma.

Soft Tissue Dystocia. Soft tissue dystocia results from obstruction of the birth passage by an anatomical abnormality other than that involving the bony pelvis. The obstruction may result from placenta previa

that partially or completely obstructs the internal os of the cervix. Other causes such as leiomyomas (uterine fibroids) in the lower uterine segment, ovarian tumours, and a full bladder or rectum may prevent the fetus from entering the pelvis. Occasionally, cervical edema occurs during labour when the cervix is caught between the presenting part and the symphysis pubis or when the patient begins bearing-down efforts prematurely, thereby inhibiting complete dilation. Sexually transmitted infections (e.g., human papillomavirus) can alter cervical tissue integrity and thus interfere with adequate effacement and dilation.

Fetal Causes (Passenger)

Dystocia of fetal origin may be caused by anomalies, excessive fetal size and malpresentation, malposition, or multifetal pregnancy. Complications associated with dystocia of fetal origin include newborn asphyxia, fetal injuries or fractures, and vaginal lacerations in the labouring patient. Although spontaneous vaginal birth is possible in these instances, a forceps-assisted, vacuum-assisted birth or Caesarean birth often is necessary.

Anomalies. Gross ascites, large tumours, and open neural tube defects such as myelomeningocele and hydrocephalus are fetal anomalies that can cause dystocia. The anomalies affect the relationship of the fetal anatomy to the pelvic capacity of the labouring patient, with the result that the fetus is unable to descend through the birth canal.

Cephalopelvic Disproportion. Cephalopelvic disproportion (CPD), also called *fetopelvic disproportion*, is disproportion between the size of the fetus and the size of the pelvis of the labouring patient. With CPD, the fetus cannot fit through the pelvis to be born vaginally. Although CPD is often related to excessive fetal size or macrosomia (i.e., 4 000 g or more), the challenge in many cases is malposition of the fetal presenting part rather than true CPD. CPD cannot be accurately predicted (Sheibani & Wing, 2017).

Malposition. The most common fetal malposition is persistent occipitoposterior position (i.e., right occipitoposterior [ROP] or left occipitoposterior [LOP]) (see Figure 16.2), occurring in about 15% of all labours during the latent phase of the first stage of labour. About 5% of all fetuses are in this position at birth (Sheibani & Wing, 2017). Labour, especially the second stage, is prolonged; the labouring patient typically feels severe back pain from the pressure of the fetal head (occiput) pressing against the sacrum. See Box 17.10 for suggested measures to relieve back pain and promote rotation of the fetal occiput to an anterior position, which will facilitate birth.

Malpresentation. Malpresentation (the fetus presentation is something other than cephalic, or head first) is another commonly reported complication of labour and birth. Breech presentation is the most common form of malpresentation, occurring in approximately 3 to 4% of all labours (Lanni et al., 2017). The three types of breech presentation are shown in Figure 20.1 and include

- Frank breech (thighs flexed, knees extended)
- Complete breech (thighs and knees flexed)
- Footling breech (when one foot [single footling] or both feet [double footling] present before the buttocks)

Breech presentations are associated with multifetal gestation, preterm birth, anomalies in the fetus and in the pregnant patient, hydramnios, and oligohydramnios. High rates of breech presentation are also noted in fetuses with certain genetic disorders (e.g., trisomies 13, 18, and 21, Potter's syndrome [renal agenesis], and myotonic dystrophy). Fetuses with neuromuscular disorders have a high rate of

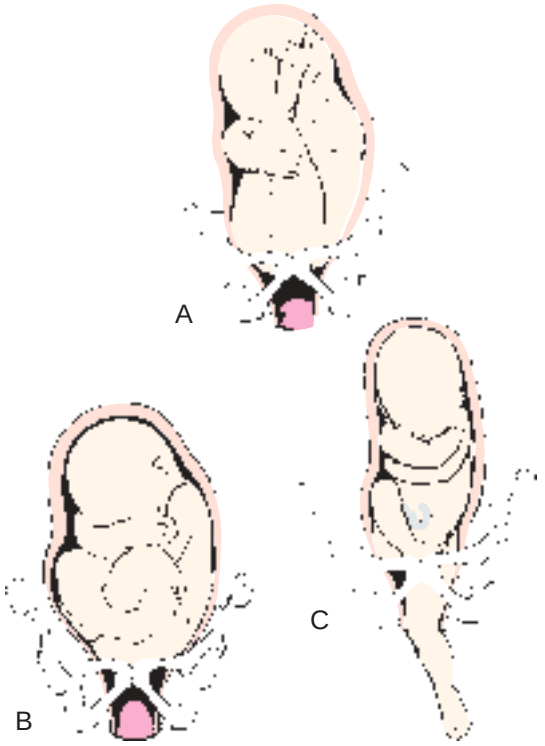

Fig. 20.1 Breech presentation. **A:** Frank breech. **B:** Complete breech. **C:** Single footling breech. (From Gilbert, E. [2011]. *Manual of high risk pregnancy & delivery* [5th ed.]. Mosby.)

breech presentation, perhaps because they are less capable of movement within the uterus. Abnormal AFV (both increased and decreased) also contributes to more breech presentations because it affects fetal mobility. Breech presentation is diagnosed by abdominal palpation (e.g., Leopold manoeuvres; see Box 17.7) and vaginal examination and usually is confirmed by an ultrasound scan (Lanni et al., 2017; Thorp & Laughon, 2018).

During labour, the descent of the fetus may be slow because the breech is not as effective a dilating wedge as the fetal head. There is risk of prolapse of the umbilical cord if the membranes rupture in early labour. The presence of meconium in amniotic fluid is not necessarily a sign of fetal compromise because it results from pressure on the fetal abdominal wall as it traverses the birth canal. Assessment of fetal heart rate and pattern should be used to determine whether the passage of meconium is an expected finding associated with breech presentation or is an abnormal sign associated with fetal hypoxia. The fetal heart tones of infants in a breech position are best heard at or above the umbilicus of the labouring patient.

Vaginal birth is accomplished by mechanisms of labour that manipulate the buttocks and lower extremities as they emerge from the birth canal (Figure 20.2). Risks associated with vaginal birth from a breech presentation include prolapse of the umbilical cord (especially in single or double footling breech presentations) and trapping of the aftercoming fetal head (especially with preterm infants). Safe vaginal birth from a breech presentation largely depends on the experience, judgement, and skill of the health care provider who assists the birth. Criteria for attempting a vaginal birth from a breech presentation are as follows (Thorp & Laughon, 2018):

- Frank or complete breech presentation
- Estimated fetal weight between 2 000 and 3 800 g
- Gynecoid maternal pelvis
- Flexed fetal head

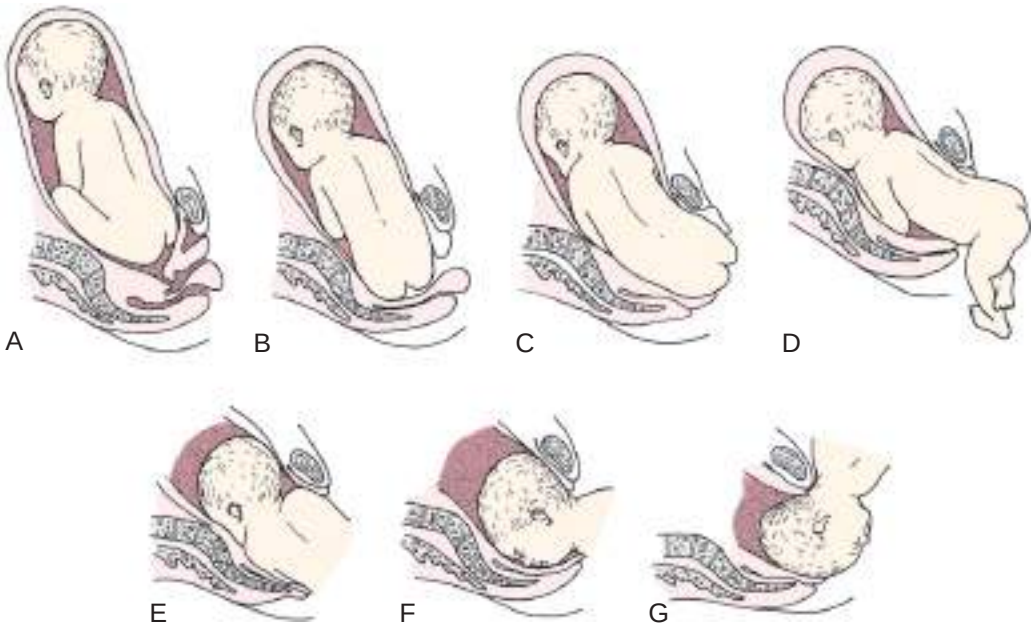

Fig. 20.2 Mechanism of labour in breech presentation. **A:** Breech before onset of labour. **B:** Engagement and internal rotation. **C:** Lateral flexion. **D:** External rotation or restitution. **E:** Internal rotation of shoulders and head. **F:** Face rotates to sacrum when occiput is anterior. **G:** Head is born by gradual flexion during elevation of fetal body.

A patient who labours with a fetus in a breech presentation needs to be assessed frequently for adequate progress in labour. Although Caesarean birth reduces the risks to the fetus, the risks are increased to the labouring patient. Patients whose breech presentation occurs late in pregnancy need to be informed about the options for birth, including the risks associated with each option (Kotaska & Menticoglou, 2019). External cephalic version (ECV) (see later discussion later in chapter) may be tried to turn the fetus to a vertex presentation.

Face and brow presentations are uncommon and are associated with fetal anomalies, pelvic contractures, and CPD. Vaginal birth is possible if the fetus flexes to a vertex presentation, although forceps often are used. Caesarean birth is indicated if the presentation persists, if there is an abnormal fetal heart rate and pattern, or if labour stops progressing.

Caesarean birth is usually necessary for a fetus in a transverse lie (i.e., shoulder) presentation, although ECV may be attempted after 36 to 37 weeks of gestation (Thorp & Laughon, 2018).

Position of the Labouring Patient

The functional relationships among the uterine contractions, the fetus, and the patient's pelvis are altered by the position of the labour patient. The position can provide a mechanical advantage or disadvantage to the mechanisms of labour by altering the effects of gravity and the body-part relationships that are important to the progress of labour. For example, the hands-and-knees position facilitates rotation from a posterior occiput position more effectively than does the lateral position (Lawrence et al., 2013). Ambulation in latent labour has been demonstrated to decrease the duration of labour and the incidence of interventions such as Caesarean birth and epidural analgesia. As a result, patients should be encouraged to be upright and mobile during latent labour (Lawrence et al., 2013). Upright positions such as sitting and squatting facilitate fetal descent during pushing and shorten the second stage of labour (Gupta et al., 2017). See Box 17.10 for suggested positions to enhance fetal descent. Limiting movement of labouring patients or restricting labour to the recumbent or lithotomy position may compromise progress. The incidence of dystocia in patients confined to these positions is increased, resulting in increased need for augmentation of labour, the use of forceps, and incidence of vacuum-assisted or Caesarean birth.

Psychological Responses

Hormones and neurotransmitters released in response to stress (e.g., catecholamines) can cause dystocia. Sources of stress vary for each labouring patient, although pain and the absence of a support person are two recognized factors. Confinement to bed and restriction of movement can be a source of psychological stress that compounds the physiological stress caused by immobility in the unmedicated labouring patient. When anxiety is excessive, it can inhibit cervical dilation and result in prolonged labour and increased pain perception. Anxiety also causes increased levels of stress-related hormones (e.g., beta-endorphin, adrenocorticotropic hormone, cortisol, and epinephrine). These hormones act on the smooth muscles of the uterus; increased levels can cause dystocia by reducing uterine contractility. The continuous supportive presence of a nurse or doula may help to decrease the stress felt by the labouring patient.

Nursing Care

Patients who have labour dystocia require nursing assessment to ensure their own well-being and the well-being of the fetus. Electronic fetal monitoring (EFM) should be used to assess for atypical or abnormal FHR patterns. Ultrasound scanning can be used to identify potential labour complications related to the fetus (e.g., abnormal fetal position) or pelvis of the pregnant patient. Risk assessment is a continuous process in the labouring patient. By reviewing the patient's past labour or labours and observing their physical and psychological responses to the current labour, any factors that might contribute to dysfunctional labour can be identified. Nursing diagnoses, expected outcomes of care, and interventions are then established for each patient on the basis of assessment findings. Many interventions for dystocia (e.g., ECV, cervical ripening, induction or augmentation of labour, and operative procedures [forceps- or vacuum-assisted birth, Caesarean birth]) are implemented collaboratively with other members of the health care

team. Commonly performed interventions are discussed in detail in the Obstetrical Procedures section.

LEGAL TIP: Standard of Care—Labour and Birth Complications

- Document all assessment findings, interventions, and the patient's responses in the medical record according to unit protocols, procedures, and policies and professional standards.
- Assess whether the patient (and the family, if appropriate) is fully informed about the procedures for which they are consenting.
- Provide full explanations regarding what is happening and what needs to be done to help them and their fetus.
- Maintain safety in administering medications and treatments correctly.
- Have telephone orders signed as soon as possible.
- Provide care at the acceptable standard (e.g., according to unit protocols and professional standards).
- Continue monitoring of the patient and fetus until birth according to the policies, procedures, and protocols of the birthing facility, even after a decision to carry out Caesarean birth is made.

PRECIPITOUS LABOUR

Precipitous labour is defined as labour that lasts less than 3 hours from the onset of contractions to the time of birth. This abnormal labour pattern occurs in approximately 3% of all births. Precipitous birth alone is usually not associated with significant maternal morbidity or mortality (Cunningham et al., 2018).

Precipitous labour may result from hypertonic uterine contractions that are tetanic in intensity. Conditions often associated with this type of uterine contractions include placental abruption, uterine tachysystole, and recent cocaine use. Complications in the labouring patient can include uterine rupture, lacerations of the birth canal, amniotic fluid embolus (anaphylactoid syndrome of pregnancy), and postpartum hemorrhage. Fetal complications include hypoxia caused by decreased periods of uterine relaxation between contractions and, in rare instances, intracranial trauma related to rapid birth. These complications may result in adverse perinatal outcomes (Cunningham et al., 2018).

Patients who have experienced precipitous labour often describe feelings of disbelief that their labour began so quickly, alarm that their labour progressed so rapidly, panic about the possibility that they would not make it to the hospital on time to give birth, and, finally, relief when they arrived at the hospital. In addition, patients have expressed frustration when nurses would not believe them when they reported their readiness to push. Progress can be so rapid in some patients that they may have difficulty remembering the details of their childbirth. They should be provided with an opportunity to discuss their labour and birth with caregivers who were present.

OBESITY

Intrapartum and Postpartum Risks

Patients with obesity require care that is adapted to accommodate the challenges posed by their increased weight and size. Persons with obesity are more likely to begin pregnancy with pre-existing medical conditions such as chronic hypertension and type 2 diabetes (see Chapter 15 for discussion of care during pregnancy). While pregnant, they can develop pregnancy-associated hypertensive disorders, or gestational diabetes may be diagnosed. Patients with obesity also have an increased incidence of post-term pregnancy. All of these risk factors can increase the likelihood that labour will be induced (Picklesimer & Dorman, 2013). Uterine contractility may be altered in patients with obesity and higher doses of oxytocin may be required (Heavey, 2011; Zhang et al., 2007). Fetal monitoring poses another challenge, as there can be an inability to obtain interpretable fetal heart rate patterns or monitor uterine contractions (ACOG, 2013). There is an increased risk of shoulder dystocia due to fetal macrosomia. The risk of Caesarean birth is also greater in patients with obesity; the risk is 20% for body mass index (BMI) less than 30 and 47.4% for BMI greater than 40 (ACOG, 2013). This increased risk could be due to a prolonged active phase of labour as well as CPD or fetal **macrosomia**. In addition to being more prone to needing Caesarean birth in general, obese patients are also more likely to require emergency Caesarean birth.

During the postpartum period patients with obesity are at risk for thromboembolism and wound disruption and infection after Caesarean birth (Picklesimer & Dorman, 2013). They also have a higher risk for postpartum hemorrhage because of an increased likelihood of induction, resulting in prolonged labour, birth of a macrosomic infant, and caregiver difficulty with locating the uterine fundus to provide effective fundal massage (Baird et al., 2017).

Nursing Care

Nursing care of obese patients during labour and birth can be challenging for a number of reasons. Sometimes standard furniture such as beds, chairs, and operating tables are not large enough to accommodate the patient's size. Extra-large furniture may not fit through a standard doorway, so room renovation may be necessary. Some hospitals have created rooms specifically designed to accommodate patients with obesity. Continuous external FHR and contraction monitoring may be extremely difficult if not impossible to perform. When labour has progressed, it may be helpful to use an internal spiral electrode to monitor the FHR and an intrauterine pressure catheter (see Chapter 19) to monitor the contractions (Maxwell et al., 2019). Special equipment, such as extra-large blood pressure cuffs, is necessary to properly assess the patient's condition.

During labour, respiratory challenges may occur in patients with obesity, so nurses need to monitor oxygen saturation levels along with performing thorough respiratory assessments. Care should focus on efforts to minimize oxygen consumption and maximize pulmonary function. It may be difficult to palpate the fetus; ultrasonographic examination may be necessary to confirm fetal position. It is important to encourage the labouring patient to reposition themselves frequently in order to provide maternal comfort and promote fetal descent.

Epidural analgesia administered during the first stage of labour can bring about decreased demand on the metabolic and respiratory systems and improved oxygenation, because pain causes the catecholamine levels to increase, which in turn causes cardiac output to increase. Effective epidural analgesia slows this increase in catecholamine levels. Epidural administration can be difficult in the obese patient; often multiple attempts are necessary to successfully place the epidural needle. It is often difficult to locate the midline and identify the epidural space. It is also difficult to position the person; sitting is often the best position.

Routine procedures may require more time and effort to accomplish for a patient with obesity. The extra time required can slow essential interventions and increase risks to the mother and fetus, such as when an emergency Caesarean birth is necessary. Establishing IV access, for example, may require multiple attempts, sometimes by multiple providers.

IV opioids may be used during the first stage of labour; however, the doses and effects must be monitored carefully because persons with obesity can be extremely sensitive to the respiratory depressant effects of opioids. Combined spinal epidural anaesthesia is an alternative to epidural anaesthesia. This option is now available in the morbidly obese pregnant patient because there is an appropriately sized long needle manufactured for this purpose.

In the patient with obesity who must give birth by Caesarean, an epidural block is preferred over general anaesthesia. Moving the patient from a labour room to the operating room and transferring from a bed to the operating table can require the assistance of additional personnel or special equipment, especially if regional anaesthesia is already in place. Surgery may be further delayed by anaesthetic complications, such as difficulty establishing an epidural or spinal block.

Issues associated with general anaesthesia in patients with obesity include potential difficulties during intubation, a hypertensive effect of laryngoscopy and intubation, and aspiration and pulmonary complications. A spinal block may be used if there is insufficient time to induce an epidural block. Uterine displacement to prevent aortocaval compression is more difficult to achieve in the supine position needed for Caesarean birth. If the patient is extremely obese, a wedge may not be able to elevate one hip enough to prevent compression. In this case, it may be necessary to lift the abdominal fat pad off the abdomen manually until the peritoneal cavity has been entered.

Postoperatively, patients with obesity are at increased risk for blood clot formation. In the immediate recovery period, use of sequential compression devices (SCD boots) helps to decrease the chance for thrombus formation. Some patients may also be given low-molecular-weight heparin prophylactically to prevent thromboembolism (Chan et al., 2014; Maxwell et al., 2019). In the postpartum period, patients should also be encouraged to begin ambulating as soon as possible.

Wound healing may be delayed and dehiscence may occur as well as infection after Caesarean birth (Heavey, 2011; Picklesimer & Dorman, 2013). Keeping the incision clean and dry to prevent wound infection and promote healing is another postoperative challenge. Many obese patients have a pannus (large roll of abdominal fat) that overlies a lower abdominal transverse skin incision made just above the pubic area. The pannus causes the area to remain moist, which encourages infection development. Patients should be taught to wash the incision with soap and water several times a day, thoroughly drying the area afterward. Sutures or staples used to close the skin incision are generally left in place longer than usual to avoid possible wound disruption when they are removed. Sometimes the skin and subcutaneous layers of the incision are left open to heal by secondary intention to avoid possible dehiscence. If this course of action is chosen, the patient and other family members must be taught how to do dressing changes and wound care. Patients with obesity also have a higher risk for postpartum hemorrhage because of an increased likelihood of induction, resulting in prolonged labour, birth of a macrosomic infant with a corresponding large placental implantation site, and caregiver difficulty with locating the uterine fundus to provide effective fundal massage (Denison et al., 2018). Patients with obesity may have more difficulty breastfeeding and will require extra support for positioning the newborn.

MULTIFETAL PREGNANCY

Multifetal pregnancy is the gestation of twins, triplets, quadruplets, or more infants. In 2018, there were 11 761 multiple-gestation births in Canada, accounting for about 3.1% of total births (Statistics Canada, 2021). Multiple gestations have been partially attributed to the use of fertility-enhancing medications and procedures and the older age of childbearing patients. Compared with younger patients, those age 35 years and older are more likely to have a multifetal pregnancy. The rate of triplet and higher-order multiple pregnancies has been steadily declining, likely due to refinements in the treatments used for infertility, particularly limiting the number of embryos transferred during in vitro fertilization (IVF) procedures (Malone & D'Alton, 2018; Newman & Unal, 2017).

Multiple births are associated with more complications (i.e., dystocia) than are single births. The higher incidence of fetal and newborn complications and higher risk for perinatal mortality stem primarily from the birth of low-birth-weight infants resulting from preterm birth and IUGR (or both), in part related to placental dysfunction and twin-to-twin transfusion. Fetuses may experience distress and asphyxia during the birth process as a result of cord prolapse and the onset of placental separation with the birth of the first fetus (Malone & D'Alton, 2018). As a result, the risk for long-term conditions, such as cerebral palsy, is higher among multiple births.

In addition, fetal complications such as congenital anomalies and abnormal presentations can lead to dystocia and an increased incidence of Caesarean birth. For example, in only 40 to 45% of all twin pregnancies do both fetuses present in the vertex position, the most favourable one for vaginal birth. In 35 to 40% of the pregnancies, one twin may present in the vertex position and the other in a breech or transverse lie presentation (Malone & D'Alton, 2018).

In the absence of other indications for Caesarean birth, vaginal birth should be planned when both fetuses present in the vertex position, regardless of gestational age. Should the second fetus present as breech or transverse, the type of birth will depend on the size of the second twin, the presence of a growth discrepancy, and the availability of skilled obstetrical staff (Malone & D'Alton, 2018).

The health of the patient may be compromised by an increased risk for hypertension, anemia, and hemorrhage associated with uterine atony, placental abruption, and multiple or adherent placentas. Duration of the phases and stages of labour may vary from that experienced with singleton births.

Teamwork and planning are essential in the management of childbirth in multiple pregnancies, especially those of the higher-order multiples. The nurse plays a key role in coordinating the activities of the highly skilled health care providers involved. Early detection and effective care of pregnant patients and the fetal and newborn complications associated with multiple births are essential to achieving a positive outcome for labouring patients and their babies. The position of the patient and the provision of active support are used to enhance labour progress and placental perfusion. Stimulation of labour with oxytocin, epidural anaesthesia, forceps and vacuum assistance, and internal or external cephalic version may be used to accomplish the vaginal birth of twins. Caesarean birth is most likely with higher-order multiple births. Each newborn may have its own team of health care providers present at the birth. Emotional support that includes expression of feelings and full explanations of events as they occur and of the status of the labouring patient and the fetuses and newborns is important for reducing the anxiety and stress that the patient and family can experience. See Additional Resources at the end of the chapter for websites that may provide helpful information to families having a multiple birth.

OBSTETRICAL PROCEDURES

Version

Version is the turning of the fetus from one presentation to another. It may be performed externally or internally by the obstetrical health care provider.

External Cephalic Version. External cephalic version (ECV) is used in an attempt to turn the fetus from a breech or shoulder presentation to a vertex presentation for birth. It may be attempted in a labour and birth setting at 36 to 37 weeks of gestation. ECV is accomplished by the exertion of gentle, constant pressure on the abdomen (Figure 20.3). At this gestational age, the success rate for ECV is approximately 65% and the risk for Caesarean birth is reduced by 50% (Thorp & Laughon, 2018).

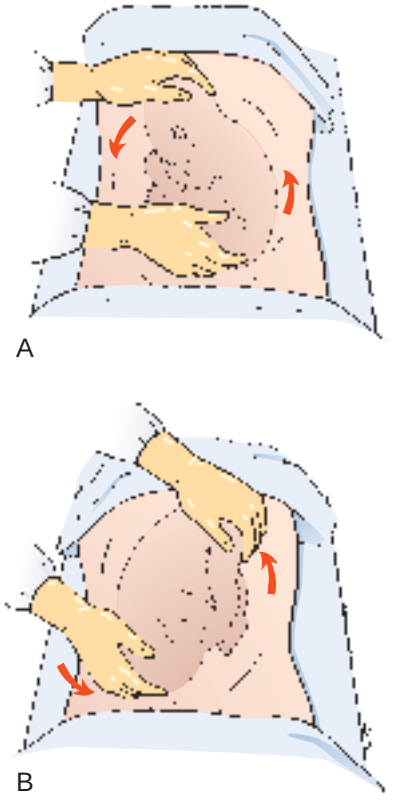

Fig. 20.3 External version of fetus from breech to vertex presentation. This must be achieved without force. **A:** Breech is pushed up out of pelvic inlet while the head is pulled toward inlet. **B:** The head is pushed toward inlet while breech is pulled upward.

ECV performed at term to avoid breech birth is a beneficial form of care and may decrease the rate of primary Caesarean births. Before ECV is attempted, ultrasound scanning is done to:

- Determine the fetal position
- Locate the umbilical cord
- Rule out placenta previa
- Detect multiple gestation, oligohydramnios, or fetal abnormalities
- Measure fetal dimensions

An NST is performed to confirm fetal well-being, or the fetal heart rate and pattern are monitored for a period of time (10 to 20 minutes). Informed consent needs to be obtained. Contraindications to ECV include the following (Hofmeyr, 2021; Lanni et al., 2017):

- Contraindication to labour or vaginal birth
- Uterine anomalies
- Placenta previa or placental abruption
- Multiple gestation
- Oligohydramnios
- Evidence of uteroplacental insufficiency
- A nuchal cord (identified by ultrasound)
- Obvious CPD

ECV is most successful in a multiparous patient who has a normal amount of amniotic fluid and whose fetus is not yet engaged in the pelvis (Cunningham et al., 2018).

During an attempted ECV, the nurse continuously monitors the fetal heart rate and pattern, especially for bradycardia and variable decelerations; checks the patient's vital signs; and assesses the patient's level of comfort because the procedure may cause discomfort. After the procedure is completed, the nurse needs to continue to monitor vital signs and uterine activity to assess for vaginal bleeding until the patient's condition is determined to be stable. Fetal heart rate and pattern monitoring should continue for at least 1 hour. Patients who are Rh negative should receive Rh immune globulin because the manipulation can cause fetomaternal bleeding (Thorp & Laughon, 2018).

Internal Version. With internal version, the fetus is turned by the health care provider, who inserts a hand into the uterus and changes the presentation to cephalic (head) or podalic (foot). Internal version is rarely used, although it is most often used in twin gestations to assist with birth of the second fetus. The safety of this procedure has not been documented; maternal and fetal injuries are possible. The nurse's role is to monitor the status of the fetus and support the labouring patient.

Induction of Labour

Induction of labour is the chemical or mechanical initiation of uterine contractions before their spontaneous onset for the purpose of bringing about the birth. Labour may be induced either electively or for indicated reasons. Induction of labour is one of the most commonly performed obstetrical procedures. The number of induced labours has not changed considerably in the last few decades and comprises approximately 22% of all births. In British Columbia, post-term pregnancies (>41 +0 weeks) represented 34% of the total inductions in British Columbia (Leduc et al., 2013). When undertaken for appropriate reasons and by appropriate methods, induction is useful and benefits both mothers and newborns (Leduc et al., 2013). It is likely that the rate of elective inductions is increasing more rapidly than the rate of indicated inductions.

Induction of labour is indicated if continuing the pregnancy could be dangerous for either the patient or the fetus and if no contraindications exist to artificial rupture of the membranes (amniotomy) or augmenting uterine contractions with oxytocin. Before labour induction, gestational age should be determined and any potential risks to mother and fetus evaluated. Patients must be fully counselled regarding risks, benefits, and alternatives of labour stimulation methods as part of the process for shared decision making (ACOG, 2009/2016; Thorp & Laughon, 2018). Box 20.8 lists indications and contraindications for labour induction.

An elective induction is one in which labour is initiated without a medical indication. Methods to ripen the cervix (e.g., application of prostaglandins or intracervical insertion of a balloon catheter) enhance the likelihood of successful induction. Many of these elective inductions are purely for the convenience of the patient or their primary health care provider. At times, however, labour may be electively induced to allay the patient's fears and anxieties associated with prior perinatal losses or to ensure that experienced multispecialty personnel are available to handle anticipated complications in the parent or newborn immediately after birth (Sheibani & Wing, 2017).

The major risks associated with elective labour induction at term are possible increased rates of Caesarean birth, newborn morbidity, and cost (Sheibani & Wing, 2017), although new evidence suggests that induction of labour in low-risk nulliparous women has been shown to decrease risk for Caesarean birth without increasing adverse perinatal outcomes (Grobman et al., 2018). At this time, the SOGC strongly recommends not inducing patients unless there is a medical indication or until they are at least 41 weeks of gestation without any other indications (Leduc et al., 2013).

Chemical, mechanical, physical, and alternative methods are used to ripen the cervix and induce labour. IV oxytocin and amniotomy are the most common methods used to induce labour. Success rates for induction of labour are higher when the condition of the cervix is favourable

BOX 20.8 Indications and Contraindications for Labour Induction

High Priority
- Pre-eclampsia >37 weeks
- Significant maternal disease not responding to treatment
- Significant but stable antepartum hemorrhage
- Chorioamnionitis
- Suspected fetal compromise
- Term prelabour rupture of membranes (PROM) with maternal group B streptococcus (GBS) colonization

Other Indications
- Postdates (>41+0 weeks) or post-term (>42+0 weeks) pregnancy
- Uncomplicated twin pregnancy >38 weeks
- Diabetes mellitus (glucose control may dictate urgency)
- Alloimmune disease at or near term
- Intrauterine growth restriction
- Oligohydramnios
- Gestational hypertension >38 weeks
- Intrauterine fetal death
- PROM near or at term (GBS negative)
- Logistical issues (history of fast labour, distance from the hospital)
- Intrauterine demise in previous pregnancy (to allay anxiety)

Unacceptable Indications
- Suspected fetal macrosomia
- Absence of fetal or maternal indication
- Caregiver or patient convenience

Source: Leduc, D., Biringer, A., Lee, L., et al. (2013). SOGC clinical practice guideline: Induction of labour. *Journal of Obstetrics and Gynaecology Canada, 35*(9), S1–S20.

or inducible. Cervical ripeness is the most important predictor of successful induction. A rating system such as the Bishop score (Table 20.2) can be used to evaluate inducibility. For example, a score of 8 or more on this 13-point scale indicates that the cervix is soft, anterior, 50% or more effaced, and dilated 2 cm or more and that the presenting part is engaged. When the Bishop score totals 7 or more, induction of labour is usually successful (Leduc et al., 2013; Sheibani & Wing, 2017). The Bishop score should be documented before the use of methods to ripen the cervix or induce labour.

Cervical Ripening Agents

Chemical agents. Preparations of prostaglandins E_1 (PGE_1) and E_2 (PGE_2) have been shown to be effective when used before induction to "ripen" (soften and thin) the cervix (see Medication Guides: Prostaglandin E_1; Misoprostol and Prostaglandin E_2: Dinoprostone).

TABLE 20.2 Bishop Score

	SCORE			
	0	1	2	3
Dilation (cm)	Closed	1–2	3–4	≥5
Effacement (%)	0–30	40–50	60–70	≥80
Station (cm)	−3	−2	−1, 0	+1, +2
Cervical consistency	Firm	Medium	Soft	
Cervix position	Posterior	Midposition	Anterior	

In some cases, patients spontaneously begin labouring after the administration of prostaglandin, thereby eliminating the need to administer oxytocin to induce labour. Additional advantages of prostaglandin use for cervical ripening include decreased oxytocin induction time and a decrease in the amount of oxytocin required for successful induction (Sheibani & Wing, 2017). PGE_1 is associated with a higher risk for uterine tachysystole with abnormal fetal heart rate and pattern changes and passage of meconium into the amniotic fluid. Most of these adverse outcomes are associated with higher-dose protocols (ACOG, 2009/2019; Sheibani & Wing, 2017). The benefits of PGE_1 include its stability at room temperature, rapid onset of action, multiple potential routes of administration, and low cost. These potential benefits make it an attractive alternative to PGE_2. However, updated guidelines are needed to promote the safe and effective use of PGE_1 for induction of labour (Chatsis & Frey, 2018). PGE_2 in the form of a vaginal insert (dinoprostone [Cervidil]), although more expensive than PGE_1, has the major advantage of easy removal should adverse reactions, including uterine tachysystole, occur.

MEDICATION GUIDE

Prostaglandin E_2 (PGE_2): Dinoprostone (Cervidil Insert; Prepidil Gel)

Action
- PGE_2 ripens the cervix, making it softer and causing it to begin to dilate and efface; it stimulates uterine contractions.

Indications
- PGE_2 is used for preinduction cervical ripening (to ripen the cervix before oxytocin induction of labour when the Bishop score is 6 or less) and to induce labour or abortion (abortifacient agent).
- It is not recommended for use if the patient has a history of previous Caesarean birth or other major uterine surgery.

Dosage and Route

Cervidil Insert
- Dosage is 10 mg of dinoprostone, designed to be gradually released (approximately 0.3 mg/hour) over 12 hours. Insert is placed transvaginally into the posterior fornix of the vagina. The insert is removed after 12 hours or at the onset of active labour or earlier if tachysystole or abnormal fetal heart rate and patterns occur.

Prepidil Gel
- Dosage is 0.5 mg of dinoprostone in a 2.5-mL syringe. Gel is administered through a syringe into the vaginal canal just below the internal cervical os. Dose may be repeated every 6 hours as needed for cervical ripening up to a maximum cumulative dose of 1.5 mg (3 doses) in a 24-hour period.

Adverse Effects
- Potential adverse reactions include headache, nausea and vomiting, diarrhea, fever, hypotension, tachysystole (greater than five contractions in 10 minutes, averaged over a 30-minute window with or without alteration of fetal heart rate or pattern), and fetal passage of meconium.

Nursing Considerations
- Explain the procedure to the patient and family. Ensure that informed consent has been obtained per agency policy.
- Assess the patient and fetus before each insertion and during treatment, following agency protocol for frequency. Assess vital signs and health status of patient being induced, fetal heart rate and pattern, and status of pregnancy, including indications for cervical ripening or induction of labour, signs of labour or impending labour, and the Bishop score. Recognize that an

abnormal fetal heart rate and pattern; fever, infection, vaginal bleeding, or hypersensitivity; and regular, progressive uterine contractions contraindicate the use of dinoprostone.
- Avoid use in patients with asthma, glaucoma, and hypotension or hypertension.
- Use with caution if the patient has cardiac, renal, or hepatic disease, anemia, jaundice, diabetes, epilepsy, or genitourinary infections.
- Bring the Prepidil gel to room temperature just before administration. Do not force the warming process by using a warm-water bath or other source of external heat such as microwave because heat may cause inactivation.
- Keep the Cervidil insert frozen until just before insertion. No warming is needed.
- Have the patient void before insertion.
- Assist the patient in maintaining a supine position with lateral tilt or a side-lying position for at least 30 minutes after insertion of gel or for 2 hours after placement of insert.
- Allow the patient to ambulate after a recommended period of bed rest and observation.
- Prepare to pull the string to remove the insert if significant adverse effects occur. There is no effective way to remove the gel from the vagina if uterine tachysystole occurs.
- Delay initiation of oxytocin for induction of labour for 6 hours after last instillation of gel or at least 30 to 60 minutes after removal of the insert. Follow agency protocol for induction if ripening has occurred and labour has not begun.
- Document all assessment findings and administration procedures.

Wolters Kluwer/Lippincott Williams & Wilkins; Leduc, D., Biringer, A., Lee, L., et al. (2013). SOGC clinical practice guideline: Induction of labour. *Journal of Obstetrics and Gynaecology Canada, 35*(9), S1–S18.

MEDICATION GUIDE

Prostaglandin E_1 (PGE_1): Misoprostol

Action
- PGE_1 ripens the cervix, making it softer and causing it to begin to dilate and efface; it stimulates uterine contractions.

Indications
- PGE_1 is used for preinduction cervical ripening (ripen the cervix before oxytocin induction of labour when the Bishop score is 4 or less) and for inducement of labour or abortion (abortifacient agent); it has not yet been approved by Health Canada for cervical ripening or labour induction (i.e., this is an unlabelled use for obstetrics).
- It should not be used if the patient has a history of previous Caesarean birth or other major uterine surgery.

Dosage and Administration
- Misoprostol is available either as a 100-mcg or 200-mcg tablet. Therefore, tablets must be broken to prepare the correct dose. This preparation should take place in the pharmacy to ensure accurate doses.
- Initial dose is 50 mcg orally with a drink of water (ensure that it is swallowed quickly to avoid sublingual absorption) or 25 mcg vaginally. Insert intravaginally into the posterior vaginal fornix using the tips of index and middle fingers, without the use of a lubricant. Repeat every 4 hours up for to 6 doses in a 24-hour period or until an effective contraction pattern is established (three or more uterine contractions in 10 minutes), the cervix ripens (Bishop score of 8 or greater), or significant adverse effects occur.

Adverse Effects
- Higher doses (e.g., 50 mcg every 6 hours) are more likely to result in adverse reactions such as nausea and vomiting, diarrhea, fever, uterine tachysystole with or without an abnormal fetal heart rate and pattern, or fetal passage of meconium. The risk for adverse reactions is reduced with lower dosages and longer intervals between doses.

Nursing Considerations
- Explain the procedure to the patient and family; ensure that informed consent has been obtained per agency policy.
- Assess the patient and fetus before each insertion and during treatment, following agency protocol for frequency. Assess vital signs and health status of labouring patient, fetal heart rate and pattern, and status of pregnancy, including indications for cervical ripening or induction of labour, signs of labour or impending labour, and the Bishop score. Recognize that an atypical or abnormal fetal heart rate and pattern; maternal fever, infection, vaginal bleeding, or hypersensitivity; and regular, progressive uterine contractions contraindicate the use of misoprostol.
- Avoid giving aluminum hydroxide and magnesium-containing antacids along with misoprostol.
- Use with caution in patients with renal failure because the medication is eliminated through the kidneys.
- Misoprostol is contraindicated in patients with previous Caesarean birth because of an increased risk of uterine rupture.
- Have the patient void before insertion.
- Assist the patient in maintaining a supine position with a lateral tilt or a side-lying position for 30 to 40 minutes after vaginal insertion.
- Prepare to swab the vagina to remove unabsorbed vaginal medication using a saline-soaked gauze wrapped around fingers if significant adverse effects occur.
- Initiate oxytocin for induction of labour no sooner than 4 hours after the last dose of misoprostol was administered, following agency protocol, if ripening has occurred and labour has not begun.
- Document all assessment findings and administration procedures.

Data from Hill, W., & Harvey, C. (2013). Induction of labor. In N. Troiano, C. Harvey, & B. Chez (Eds.), *AWHONN's high risk & critical care obstetrics* (3rd ed.). Clinical aspects of normal and abnormal labor. In R. Resnik, C. J. Lockwood, T. R. Moore, et al. (Eds.), *Creasy & Resnik's Maternal-fetal medicine: Principles and practice* (8th ed.). Elsevier.

Mechanical and physical methods. Mechanical dilators ripen the cervix by stimulating the release of endogenous prostaglandins. Balloon catheters (e.g., Foley catheter) can be inserted through the intracervical canal to ripen and dilate the cervix and are often used in patients attempting a trial of labour following a previous Caesarean birth. The catheter balloon is inflated above the internal cervical os with 30 to 50 mL of sterile water. This process results in pressure and stretching of the lower uterine segment and the cervix, as well as the release of endogenous prostaglandins. It is especially helpful for patients who cannot receive exogenous prostaglandins for cervical ripening. The balloon will fall out when cervical dilation reaches approximately 3 cm or is removed after 24 hours have elapsed. Simplicity of use, potential for reversibility, reduction in certain adverse effects such as excessive uterine activity, and low cost are advantages to using a mechanical dilator (Leduc et al., 2013). Evidence supports the insertion of a balloon catheter as a cervical ripening method because of its low cost compared with

that of prostaglandins, stability at room temperature, and reduced risk for uterine tachysystole with or without FHR changes (ACOG, 2009/2019; Leduc et al., 2013).

Low-lying placenta is an absolute contraindication to the use of a Foley catheter. Relative contraindications include antepartum hemorrhage, rupture of membranes, and evidence of lower tract genital infection (Leduc et al., 2013).

Hydroscopic dilators (substances that absorb fluid from surrounding tissues and enlarge) also can be used for cervical ripening. Laminaria tents (natural cervical dilators made from desiccated seaweed) and synthetic dilators containing magnesium sulphate (Lamicel) are inserted into the endocervix without rupturing the membranes. As they absorb fluid, they expand and cause cervical dilation and the release of endogenous prostaglandins. These dilators are left in place for 6 to 12 hours before being removed to assess cervical dilation. Fresh dilators are inserted if further cervical dilation is necessary. Synthetic dilators swell faster than natural dilators and become larger with less discomfort. When compared with prostaglandins, these mechanical methods achieved a lower rate of birth within 24 hours but resulted in no change in the Caesarean birth rate. Also, they were less likely to cause uterine tachysystole with or without changes in the FHR (ACOG, 2009/2016; Thorp & Laughon, 2018).

Hydroscopic dilators compare favourably with prostaglandins in terms of their effectiveness in ripening the cervix but are associated with increased discomfort at insertion and during expansion and with a higher incidence of postpartum infections in patients as well as newborns. They are a reliable alternative when prostaglandins are contraindicated or are unavailable. Nursing responsibilities for patients who have dilators inserted include the following:

- Documenting the number of dilators and sponges inserted during the procedure, as well as the number removed
- Assessing for urinary retention, rupture of membranes, uterine tenderness or pain, contractions, vaginal bleeding, infection, and atypical or abnormal FHR

Amniotic membrane stripping or sweeping is a method of inducing labour through the release of prostaglandins and oxytocin. The procedure involves separation of the membrane from the wall of the cervix and lower uterine segment by inserting a finger into the internal cervical os and rotating it 360 degrees. The results of two studies suggested that membrane stripping increased the rate of spontaneous vaginal birth and shortened the induction to birth interval. Neither study reported harmful adverse effects that could be attributed to the procedure. Research has not demonstrated an increase in infections in either patients or newborns associated with membrane stripping. However, because there are limited data available on the risk for infection in patients who are known to be group B streptococci positive, potential risks and benefits of the procedure should be carefully considered before performing membrane stripping on this group of patients (Sheibani & Wing, 2017).

Physical methods such as sexual intercourse (prostaglandins in the semen and stimulation of contractions with orgasm), nipple stimulation (release of endogenous oxytocin from the pituitary gland), and walking (gravity applies pressure to the cervix, which stimulates the secretion of endogenous oxytocin) may be used by patients to "self-induce" labour in an effort to "get it over with." Breast (nipple) stimulation has been shown to initiate or enhance labour, especially the latent phase of labour. Although orgasm does stimulate uterine contractions, it is unclear whether sexual intercourse enhances cervical ripening (Leduc et al., 2013). Ambulation may be an effective measure to augment labour.

Alternative methods. A variety of alternative methods have been used by patients to stimulate cervical ripening and the onset of labour. For example, some patients may take blue cohosh and castor oil for labour-stimulation effects and black cohosh and evening primrose oil to ripen the cervix. Although the effects of these alternative methods are not well researched, nurses must be knowledgeable about these preparations and ask about their use when assessing patients during prenatal visits and on admission during labour. Patients may accidentally take too much of the preparation or use it incorrectly. Also, these preparations may potentiate the effect of pharmacological methods to stimulate cervical ripening and uterine contractions, thereby increasing the potential for tachysystole and precipitous labour and birth.

Acupuncture has been used effectively to induce labour and has been found in several studies to reduce the duration of labour, the use of oxytocin, and the rate of Caesarean birth. Specific points have been identified to stimulate uterine contractions or to facilitate cervical dilation. More than one treatment may be required to establish labour.

Amniotomy. **Amniotomy** (i.e., artificial rupture of membranes [AROM]) can be used to induce labour when the condition of the cervix is favourable (ripe) or to augment labour if progress begins to slow. Labour usually begins within 12 hours of the rupture. Amniotomy can decrease the duration of labour by up to 2 hours, even without oxytocin administration. However, if amniotomy does not stimulate labour, the resulting prolonged rupture may lead to chorioamnionitis. Variable FHR deceleration patterns can occur as a result of cord compression associated with umbilical cord prolapse or decreased amniotic fluid. Once an amniotomy is performed, the patient is committed to giving birth with an unknown outcome for how and when birth will occur. For this reason, amniotomy often is used in combination with oxytocin induction. Evidence from controlled trials clearly demonstrates that amniotomy combined with oxytocin for induction is more effective than either amniotomy or oxytocin alone (Leduc et al., 2013).

Before the procedure, the patient should be told what to expect; they should also be assured that the actual rupture of membranes is painless for both themselves and the fetus, although they may experience some discomfort when the Amnihook is inserted through the vagina and cervix (Box 20.9). The presenting part of the fetus should be engaged and well applied to the cervix to reduce the risk of cord prolapse. The patient should be free of active infection of the genital tract (e.g., herpes) and should be human immunodeficiency virus (HIV) negative or have a viral load low enough that vaginal birth is acceptable. After rupture the amniotic fluid is allowed to drain slowly. The fluid is assessed for colour, odour, amount, and consistency (i.e., for the presence or absence of meconium or blood). The time of rupture and characteristics of the fluid are recorded.

! NURSING ALERT

The FHR is assessed before and immediately after the amniotomy to detect any changes (transient tachycardia is common, but bradycardia and variable decelerations are not), which may indicate cord compression or prolapse.

The patient's temperature should be checked at least every 2 hours after rupture of membranes and more frequently if signs or symptoms of infection are noted. If the temperature is 38°C (100.4°F) or greater, the obstetrical health care provider should be notified. The nurse needs to assess for other signs and symptoms of infection, such as chills in the patient, fetal tachycardia, uterine tenderness on palpation, and foul-smelling vaginal drainage. Comfort measures such as frequently changing the patient's underpads and perineal cleansing need to be implemented.

BOX 20.9 Procedure: Assisting With Amniotomy

Procedure

Explain to the patient what will be done.
Assess fetal heart rate and pattern before procedure begins, to obtain a baseline reading.
Place several underpads under the patient's buttocks to absorb fluid.
Position the patient on a padded bed pan, fracture pan, or rolled-up towel to elevate the hips as needed.
Assist the health care provider who is performing the procedure by providing sterile gloves and lubricant for the vaginal examination.
Unwrap sterile package containing Amnihook or Allis clamp and pass instrument to the primary health care provider, who inserts it alongside the fingers and then hooks and tears the membranes.
Reassess fetal heart rate and pattern.
Assess colour, consistency, amount, and odour of fluid.
Assess the patient's temperature every 2 hours or per protocol.
Evaluate the patient for signs and symptoms of infection.

Documentation

Record the following:

- Indication for amniotomy
- Time of rupture
- Colour, odour, amount, consistency, and clarity of fluid
- Fetal heart rate and pattern before and after procedure
- Labouring patient's status and how well procedure was tolerated

LEGAL TIP

Performing an amniotomy is outside the scope of practice of nurses. A policy that is consistent with professional standards of care and clearly explains the nurse's role in amniotomy should be in place in all labour and birth areas.

Oxytocin. *Oxytocin* is a hormone normally produced by the posterior pituitary gland. It stimulates uterine contractions and aids in milk letdown. A synthetic version of this hormone may be used to either induce labour or augment (speed up) a labour that is progressing slowly because of inadequate uterine contractions.

See Box 20.10 for indications and contraindications for oxytocin induction or augmentation. Although certain maternal and fetal conditions are not contraindications to the use of oxytocin to stimulate labour, they do require special caution during its administration. These conditions include the following:

- Multifetal presentation
- Breech presentation
- Presenting part above the pelvic inlet
- Atypical fetal heart rate and pattern not requiring emergency birth
- Polyhydramnios
- Grand multiparity
- Previous Caesarean birth
- Maternal cardiac disease; hypertension

Oxytocin is the medication most commonly associated with adverse events during childbirth. A standard approach to oxytocin administration should be implemented in each obstetrical unit (Lee et al., 2016).

BOX 20.10 Indications and Contraindications for Use of Oxytocin for Induction or Augmentation of Labour

The indications for oxytocin induction or augmentation of labour may include but are not limited to the following:

- Suspected fetal jeopardy (e.g., intrauterine growth restriction)
- Inadequate uterine contractions; dystocia
- Prelabour rupture of membranes
- Post-term pregnancy
- Chorioamnionitis
- Medical concerns in pregnant patient (e.g., severe Rh isoimmunization, inadequately controlled diabetes, chronic renal disease, or chronic pulmonary disease)
- Gestational hypertension (e.g., pre-eclampsia, eclampsia)
- Fetal death

The management of stimulation of labour is the same, regardless of indication. Because of the potential dangers associated with the injection of oxytocin in the prenatal and perinatal periods, there are contraindications to its use.

Contraindications to oxytocic stimulation of labour include but are not limited to the following:

- Cephalopelvic disproportion, prolapsed cord, transverse lie
- Abnormal fetal heart rate
- Placenta previa or vasa previa
- Prior classic uterine incision or other uterine surgery
- Active genital herpes infection
- Invasive cancer of the cervix
- Previous uterine rupture

SAFETY ALERT

Oxytocin is listed on the Institute for Safe Medication Practices' list of high-alert medications because it has the potential to cause significant harm when used inappropriately (Institute for Safe Medication Practices, 2018).

Oxytocin use can present hazards to the labouring patient and fetus. Hazards in the labouring patient include placental abruption, uterine rupture, unnecessary Caesarean birth because of abnormal fetal heart rate and patterns, postpartum hemorrhage, and infection. When placental perfusion is diminished by contractions that are too frequent or prolonged, the fetus can experience hypoxemia and acidemia, which eventually results in late decelerations and minimal or absent baseline variability. The goal of oxytocin use is to produce contractions of normal intensity, duration, and frequency while using the lowest dose of medication possible (Lee et al., 2016).

The obstetrical health care provider writes the order for the induction or augmentation of labour with oxytocin. The nurse implements the order by initiating the primary IV infusion and administering the oxytocin solution through a secondary line. The nurse's actions related to assessment and care of a patient whose labour is being induced are guided by hospital protocol and professional standards. The ideal dosing regimen of oxytocin is not known, and there are both low-dose and high-dose protocols (see Medication Guide: Oxytocin). EFM is required for oxytocin induction of labour, although once the infusion rate is stable and provided the FHR tracing is normal, it is reasonable to allow periods of up to 30 minutes without EFM for ambulation, personal care, and hydrotherapy (Dore & Ehman, 2020) (Figure 20.4).

MEDICATION GUIDE

Oxytocin

Action

- Oxytocin is a hormone produced in the posterior pituitary gland that stimulates uterine contractions and aids in milk let-down. Syntocinon is a synthetic form of this hormone.

Indications

- Oxytocin is used primarily for labour induction and augmentation. It is also used to control postpartum bleeding.

Dosage

- The IV solution containing oxytocin should be mixed in a standard concentration. Concentrations often used are 10 units in 1 000 mL of fluid, 20 units in 1 000 mL of fluid, or 30 units in 500 mL of fluid.
- Isotonic IV solutions (e.g., 0.9% sodium chloride, lactated Ringer's) are used to avoid electrolyte imbalance.
- Oxytocin is administered intravenously through a secondary line connected to the main line at the proximal port (connection closest to the IV insertion site). Oxytocin is always administered by pump.
- Oxytocin administration is started at a low-dose or high-dose regimen (see below). Dosage is increased per protocol until an adequate contraction pattern is established.
- The goal of oxytocin administration is to produce acceptable uterine contractions as evidenced by a consistent pattern of three to five contractions every 10 minutes.
- Once labour is established, oxytocin is maintained at or decreased to a rate adequate for continued labour progress.

Adverse Effects

- Possible adverse effects in the labouring patient include uterine tachysystole with or without FHR changes, placental abruption, uterine rupture, unnecessary Caesarean birth caused by abnormal fetal heart rate and patterns, postpartum hemorrhage, infection, and death from water intoxication (e.g., severe hyponatremia).
- Possible fetal adverse effects include hypoxemia and acidosis, eventually resulting in abnormal fetal heart rate and patterns.

Nursing Considerations

- Oxytocin is considered a high-alert medication because it has the potential to cause significant harm when used inappropriately.
- Patient and family teaching and support:
  - Reasons for use of oxytocin (e.g., to start or improve labour)
  - Reactions to expect concerning the nature of contractions: the intensity of the contraction increases more rapidly, holds the peak longer, and ends more quickly; contractions will come regularly and more often
- Continue to keep patient and their family informed regarding progress.
- Remember that patients vary greatly in their response to oxytocin; some require only very small amounts of medication to produce adequate contractions, whereas others need larger doses.
- Continue to provide labour support techniques, such as use of the birth ball or a rocking chair.
- Encourage change in position every 20 to 30 minutes; encourage walking or standing, especially after the oxytocin dose is stable.

Assessment

- Assess level of the labouring patient's discomfort and pain and the effectiveness of pain management.
- Fetal status using electronic fetal monitoring: Evaluate tracing every 15 minutes and with every change in dose during the first stage of labour and every 5 minutes during the active pushing phase of the second stage of labour.
- Monitor the contraction pattern and uterine resting tone every 15 minutes and with every change in dose during the first stage of labour and every 5 minutes during the second stage of labour.
- Monitor blood pressure, pulse, and respirations every 30 to 60 minutes and with every change in dose.
- Assess intake and output; limit IV intake to 1 000 mL in 8 hours; urine output should be 120 mL or more every 4 hours.
- Perform vaginal examination as indicated.
- Monitor for adverse effects, including nausea, vomiting, headache, and hypotension.
- Observe emotional responses of labouring patient and their partner.
- The rate of oxytocin infusion should be continually titrated to the lowest dose that achieves acceptable labour progress. Usually the oxytocin dose can be decreased or discontinued after rupture of membranes and in the active phase of first-stage labour.

Reportable Conditions

- Uterine tachysystole (with or without FHR changes)
- Abnormal fetal heart rate and pattern (absent baseline variability and any of the following: [1] recurrent late decelerations, [2] recurrent variable decelerations, [3] bradycardia, or [4] prolonged decelerations)
- Suspected uterine rupture
- Inadequate uterine response at 30 mU/min

Emergency Measures

Discontinue use of oxytocin per hospital protocol and notify primary care provider immediately:

- Turn patient onto lateral position.
- Give IV bolus if patient is hypovolemic or hypotensive.
- If there is evidence of hypoxia or hypovolemia in the patient, administer oxygen by nonrebreather face mask at 8 to 10 units/min or per protocol or primary health care provider's order. Oxygen is reserved for maternal resuscitation in the presence of maternal hypoxia or hypovolemia, NOT for fetal resuscitation.
- Prepare to administer nitroglycerine, if ordered, to decrease uterine activity.
- Continue monitoring fetal heart rate and pattern and uterine activity.

Documentation

- The time the oxytocin infusion is begun, and each time the infusion is increased, decreased, or discontinued
- Assessment data as described above
- Interventions for uterine tachysystole and abnormal fetal heart rate and patterns and the response to the interventions
- Notification of the obstetrical health care provider and that person's response

Low-Dose Protocol

Initial dose: 1–2 mU/min
Increase interval: 30 minutes
Dosage increment: 1–2 mU/min
Usual dose for adequate labour: 8–12 mU/min
Maximum dose before reassessment: 30 mU/min
Benefits: Less risk of tachysystole; overall use of a smaller dose

High-Dose Protocol

Initial dose: 4–6 mU/min
Increase interval: 15–30 minutes
Dosage increment: 4–6 mU/min
Usual dose for adequate labour: 8–12 mU/min
Maximum dose before reassessment: 30 mU/min
Benefits: Reduced length of labour with no appreciable increase in newborn morbidity
Risks: Associated with an increase in uterine tachysystole with associated FHR changes

ALERT: Because mixing methods may vary, *the rate of infusion should always be documented in mU/min* rather than mL/hr.

(2014). Labor and birth. In K. Simpson & P. Creehan (Eds.), *AWHONN's perinatal nursing* (4th ed.). Lippincott. *FHR,* Fetal heart rate; *IV,* intravenous.

Nursing care. An evidence-informed written protocol for the preparation and administration of oxytocin should be established by the obstetrical department (physicians, midwives, nurses) in each institution.

Oxytocin is decreased or discontinued and the obstetrical health care provider notified if tachysystole resulting in an abnormal fetal heart rate or pattern occurs. Other nursing interventions, such as administering 8 to 10 L oxygen by nonrebreather mask, positioning the patient on their side, and administering an IV fluid bolus, are independent nursing interventions and are implemented immediately as necessitated by the clinical picture (see Emergency Measures in Medication Guide). Based on the status of the maternal–fetal unit, the obstetrical health care provider may order the infusion to be restarted once the FHR and uterine activity return to acceptable levels. Depending on the fetal heart rate and pattern assessment and the length of time the infusion was discontinued, the oxytocin may be restarted at half the rate that resulted in tachysystole (e.g., discontinued for 10 to 20 minutes) or at the same rate as the initial rate (e.g., discontinued for more than 30 to 40 minutes) (Simpson & O'Brien-Abel, 2014).

Augmentation of Labour

Augmentation of labour is the stimulation of uterine contractions after labour has started spontaneously but progress has been unsatisfactory. Augmentation is usually implemented for the management of hypotonic uterine dysfunction resulting in a slowing of labour (protracted active phase). Common augmentation methods include oxytocin infusion and amniotomy. Noninvasive methods such as emptying the bladder, ambulation, position changes, relaxation measures, nourishment, hydration, and hydrotherapy can be attempted before invasive interventions are initiated. The procedures and nursing assessments are similar to those used for oxytocin induction of labour (see Medication Guide). See Evolve for Nursing Care Plan on Patient with Hypotonic Uterine Dysfunction.

Some physicians advocate *active management of labour,* that is, augmentation of labour to establish efficient labour with the aggressive use of oxytocin so that the patient gives birth within 12 hours of admission to the labour unit. Advocates of active management believe that intervening early (as soon as a nulliparous labour is not progressing at least 1 cm/hour) with use of higher (pharmacological) oxytocin doses administered at frequent increment intervals shortens labour (Simpson & O'Brien-Abel, 2014).

Additional components of the active management of labour include the following:

- Strict criteria to diagnose that the patient is indeed in active labour with 100% effacement
- Amniotomy within 1 hour of admission of a patient in labour if spontaneous rupture of the membranes has not occurred
- Continuous presence of a nurse who provides one-on-one care for the patient while they are in labour

Many health care providers emphasize using high-dose oxytocin protocols but do not implement all the other components of active management. At least one review of published studies on the effectiveness of active management of labour protocols concluded that the presence of a nurse who provides constant emotional and

physical one-on-one support is the only component associated with shorter labours and lower rates of Caesarean birth (Simpson & O'Brien-Abel, 2014).

Operative Vaginal Births

Forceps-Assisted Birth. A forceps-assisted vaginal birth is one in which an instrument with two curved blades is used to assist in the birth of the fetal head. The cephalic-like curve of the forceps commonly used is similar to the shape of the fetal head, with a pelvic curve to the blades conforming to the curve of the pelvic axis. The blades are joined by a pin, screw, or groove arrangement. These locks prevent the forceps from compressing the fetal skull (Figure 20.5). There are several types of forceps-assisted births, defined primarily by the station and position of the fetal head in relationship to the pelvis of the labouring patient (Table 20.3).

Indications for forceps-assisted birth include a prolonged second stage of labour and the need to shorten the second stage of labour for patient reasons (e.g., exhaustion or cardiopulmonary or cerebrovascular disease) (Hobson et al., 2019; Nielsen et al., 2017). Fetal indications include an abnormal FHR tracing or certain abnormal presentations, arrest of rotation, or extraction of the head in a breech presentation (Hobson et al., 2019).

The use of forceps during childbirth has been decreasing; in 2015–2016, the forceps-assisted birth rate was 3.4% (PHAC, 2020).

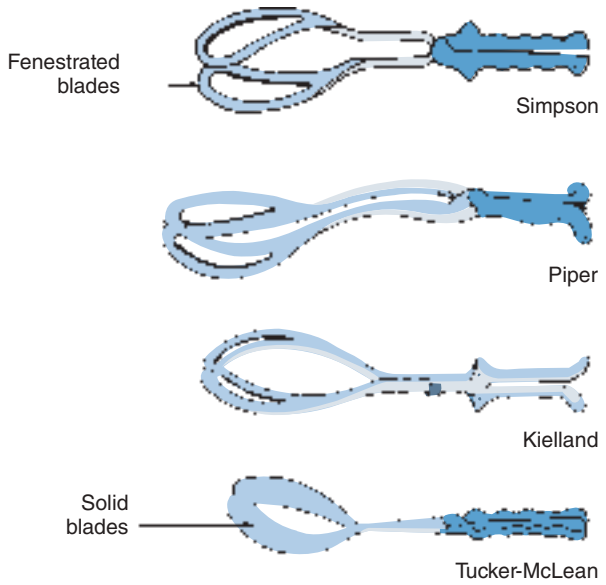

Fig. 20.5 Types of forceps. Piper forceps are used to assist birth of the head in a breech birth.

TABLE 20.3 Definitions for Forceps- and Vacuum-Assisted Births

Outlet	Fetal scalp is visible on the perineum without manually separating the labia
Low	Fetal head is at least at the +2 station
Midpelvis	Fetal head is engaged (no higher than 0 station) but above the +2 station

Source: Hobson, S., Cassell, K., Windrim, R., & Cargill, Y. (2019). SOGC clinical practice guideline: Assisted vaginal birth. *Journal of Obstetrics and Gynaecology Canada, 41*(6), 870–882. https://doi.org/10.1016/j.jogc.2018.10.020.

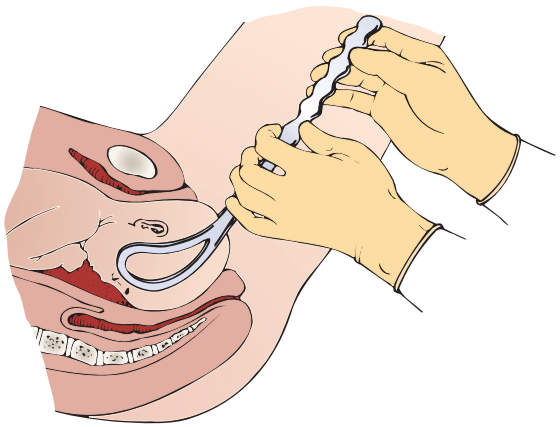

Fig. 20.6 Outlet forceps-assisted extraction of the head.

Certain conditions are required for a forceps-assisted birth to be successful. The patient's cervix must be fully dilated to prevent lacerations and hemorrhage, and the bladder should be empty. The presenting part must be engaged—vertex presentation is desired. Membranes must be ruptured so the position of the fetal head can be determined precisely and the forceps can grasp the head firmly during birth (Figure 20.6). The size of the labouring patient's pelvis must be assessed as adequate for the estimated fetal head circumference and weight.

Management. Both blades are positioned by the physician, and the handles are locked. Traction is usually applied during contractions. The patient may or may not be instructed to push during contractions, depending on physician preference. If a decrease in the FHR occurs, the forceps are removed and reapplied.

! NURSING ALERT

Because compression of the cord between the fetal head and the forceps will cause a decrease in FHR, the FHR is assessed, reported, and recorded before and after application of the forceps.

Nursing care. When a forceps-assisted birth is deemed necessary, the nurse obtains the type of forceps requested by the physician (see Figure 20.5). The nurse can explain to the patient that the forceps blades fit like two tablespoons around an egg, with the blades coming over the baby's ears.

After the birth, the postpartum patient should be assessed for vaginal and cervical lacerations (e.g., bleeding that occurs even with a contracted uterus); urinary retention, which may result from bladder injuries or urethral injuries; and hematoma formation in the pelvic soft tissues, which may result from blood vessel damage. The newborn should be assessed for bruising or abrasions at the site of the blade applications, facial palsy resulting from pressure of the blades on the facial nerve (cranial nerve VII), and subdural hematoma. Newborn and postpartum caregivers should be told that the birth was forceps assisted.

Vacuum-Assisted Birth. Vacuum-assisted birth, or *vacuum extraction*, is a birth method involving the attachment of a vacuum cup to the fetal head, using negative pressure to assist in the birth of the head (Figure 20.7). It is generally not used to assist birth before 34 weeks of gestation. Indications for use are similar to those for outlet forceps. Prerequisites for use include a completely dilated cervix, ruptured membranes, engaged head, vertex presentation, and no suspicion of CPD (Cunningham et al., 2018). The types of vacuum-assisted births are defined the same as for forceps-assisted births—by the station

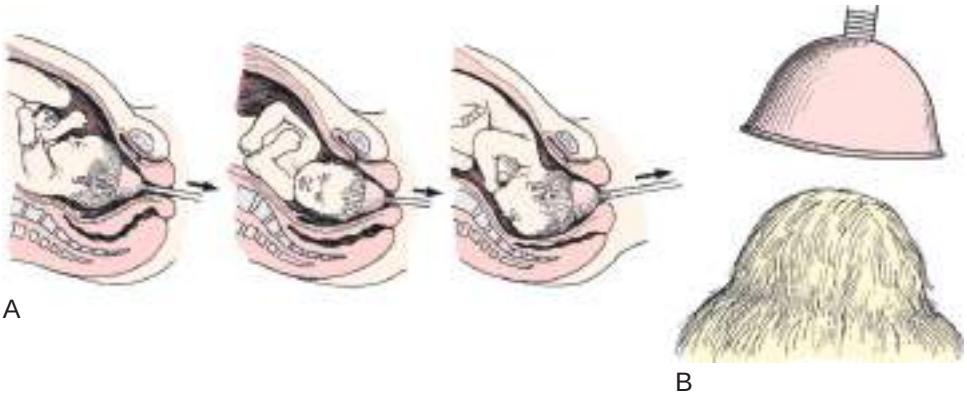

Fig. 20.7 Use of vacuum extraction to rotate fetal head and assist with descent. **A:** *Arrow* indicates direction of traction on the vacuum cup. **B:** Caput succedaneum formed by the vacuum cup.

and position of the fetal head in relation to the maternal pelvis (see Table 20.3). The rate of vacuum-assisted birth in Canada in 2015–2016 was 9.2% (PHAC, 2020). Advantages of vacuum-assisted birth over forceps-assisted birth are the ease with which the vacuum can be placed and the need for less anaesthesia. Also, it is far easier to learn the skills necessary to safely use the vacuum than to gain a similar level of skill with forceps (Thorp & Laughon, 2018).

Management. The vacuum cup is applied to the fetal head by the physician. Basically, two types of vacuum devices are in use. One is a self-contained unit, which allows the physician to both position the cup on the baby's head and generate the desired amount of negative pressure to create a vacuum. With another type of vacuum device, the physician applies the cup to the baby's head, then the nurse connects the suction tubing attached to the cup to wall suction or a separate hand pump and generates the amount of pressure requested by the physician. With both devices, a caput develops inside the cup as the pressure is initiated (see Figure 20.7, *B*). The patient is encouraged to push as traction is applied by the physician. The vacuum cup is released and removed after birth of the head. If vacuum extraction is not successful, a forceps-assisted or Caesarean birth is performed.

Risks to the newborn include **cephalhematoma**, scalp lacerations, and subdural hematoma. Fetal complications can be reduced by adhering strictly to the manufacturer's recommendations for method of application, degree of suction, and duration of application. Complications in the labouring patient are uncommon but can include perineal, vaginal, and cervical lacerations and soft tissue hematomas.

Nursing care. The nurse needs to provide education and support for the patient who has a vacuum-assisted birth. The nurse can prepare the patient for birth and encourage them to remain active in the birth process through the pushing during contractions. The FHR should be assessed frequently during the procedure. After birth, the newborn should be observed for signs of trauma at the application site and for cerebral irritation (e.g., poor sucking or listlessness). Documentation includes the time and number of applications, any "pop-offs," the number of pulls, and the maximum amount of suction used.

Newborn caregivers should be told that the birth was vacuum assisted. After birth, the newborn must be observed for signs of trauma and infection at the application site and for cerebral irritation (e.g., seizures, lethargy, increased irritability or poor feeding) (Simpson & O'Brien-Abel, 2014). The newborn may also be at risk for hyperbilirubinemia and jaundice as bruising resolves. The parents may need to be reassured that the caput succedaneum usually disappears in 3 to 5 days (see Figure 20.7, *B*).

Caesarean Birth

Caesarean birth is the birth of a fetus through a transabdominal incision of the uterus. Whether Caesarean birth is planned (scheduled) or unplanned, the loss of the experience of giving birth to a child in the traditional manner may have a negative effect on a patient's self-esteem. Thus it is important to maintain the focus on the birth of the baby rather than on the operative procedure.

The purpose of Caesarean birth is to preserve the life or health of the labouring patient, the fetus, or both; it may be the best choice when there is evidence of complications in either the labouring patient or fetus. Since the advent of modern surgical methods and care and the use of antibiotics, morbidity and mortality rates have decreased in both the labouring patient and the fetus. In addition, incisions are made into the lower uterine segment rather than into the muscular body of the uterus and thus promote more effective healing. However, despite these advances, Caesarean birth still poses threats to the health of both the labouring patient and the newborn.

The incidence of Caesarean births has increased, from 17.6% in 1993 to 28.8% in 2017–2018 (Canadian Institute for Health Information [CIHI], 2020). Part of the reason for this increase is that a number of common risk factors for Caesarean birth are increasing, such as fetal macrosomia, advanced maternal age, obesity, gestational diabetes, multifetal pregnancy, and labour dystocia in first pregnancies (Thorp & Laughon, 2018). Other factors cited include the increase in primary elective Caesarean births and a decline in the rate of **trial of labour after Caesarean (TOLAC)**. This decline may be the result of perceived risks of TOLAC (e.g., uterine rupture), legal pressures, conservative practice guidelines, and debate over the relative benefits and risks of Caesarean versus vaginal route for births. Although some patients desire elective Caesarean birth, fewer than 10% of all North American patients prefer a Caesarean birth, based solely on their request (Berghella et al., 2017).

Approaches for the management of labour and birth in order to reduce the rate of Caesarean births are presented in Box 20.11. These approaches involve the combined efforts of health care providers and pregnant patients and their families. The labour management approach that most consistently reduces the risk for a Caesarean birth outcome is continuous, early support of the labouring patient that is provided by another person (e.g., doula, relative, friend, nurse, or midwife). When this person is not a member of the labour unit staff and is thus able to spend all of their time providing physical and emotional support, the risk for Caesarean birth is further reduced (Bohren et al., 2017).

BOX 20.11 Recommended Measures to Safely Reduce the Primary Caesarean Birth Rate

- Encourage more expectant management of second-stage labour, considering current definitions of "normal" labour.
- Use standardized fetal heart rate interpretation and management.
- Increase access to nonmedical interventions during labour, such as continuous labour support.
- Offer external cephalic version for breech presentation.
- Offer the option of labour for patients with twin gestations when the first twin is in cephalic presentation.
- Avoid Caesarean birth for suspected fetal macrosomia unless the estimated fetal weight is at least 5 000 g in patients without diabetes and at least 4500 g in patients with diabetes.
- Offer operative (forceps- or vacuum-assisted) vaginal birth, performed by an experienced, well-trained physician.
- Conduct research to provide a better knowledge base to guide decisions regarding Caesarean birth.
- Encourage policy changes that safely lower the rate of primary Caesarean birth.

Data from American College of Obstetricians and Gynecologists & Society for Maternal-Fetal Medicine. (2014). Safe prevention of the primary cesarean delivery. *Obstetrics & Gynecology, 123*, 693–711.

BOX 20.12 Indications for Caesarean Birth

Pregnant Patient

- Specific cardiac disease (e.g., Marfan syndrome, unstable coronary artery disease)
- Specific respiratory disease (e.g., Guillain-Barré syndrome)
- Conditions associated with increased intracranial pressure
- Mechanical obstruction of the lower uterine segment (tumours, fibroids)
- Mechanical vulvar obstruction (e.g., extensive condylomata)
- History of two or more previous Caesarean births
- Elective Caesarean birth (Caesarean on patient request)

Fetal

- Abnormal fetal heart rate or pattern
- Malpresentation (e.g., breech or transverse lie)
- Active herpes lesions in labouring patient
- Maternal human immunodeficiency virus (HIV) with a viral load of more than 1 000 copies/mL
- Congenital anomalies

Labouring Patient–Fetal Conditions

- Dysfunctional labour (e.g., cephalopelvic disproportion, "failure to progress" in labour)
- Placental abruption
- Placenta previa

Data from Berghella, V., Mackeen, A. D., & Jauniaux, E. R. M. (2017). Cesarean delivery. In S. Gabbe, J. Niebyl, J. Simpson, et al. (Eds.), *Obstetrics: Normal and problem pregnancies* (7th ed.). Elsevier.

The type of nursing care given also may influence the rate of Caesarean births. A labour management approach that uses one-to-one support and emphasizes ambulation, position changes in the labouring patient, relaxation measures, oral fluids and nutrition, hydrotherapy, and nonpharmacological pain relief can facilitate the progress of labour and reduce the incidence of dystocia.

Indications. Few absolute indications exist for Caesarean birth. Currently, most are performed for conditions that might pose a threat to both the labouring patient and the fetus if vaginal birth occurred, such as placenta previa or placental abruption (Berghella et al., 2017). Box 20.12 lists common indications for Caesarean birth.

Elective Caesarean birth. Elective Caesarean birth, sometimes referred to as *Caesarean on request* or *Caesarean on demand*, refers to a primary Caesarean birth without medical or obstetrical indication. Reasons given for elective Caesarean birth include fear of the pain of childbirth and the mistaken belief that the surgery will prevent future issues with pelvic support, bladder and bowel incontinence, or sexual dysfunction (Alsayegh et al., 2018). Although some nulliparous patients may fear the pain of labour because of no firsthand experience, multiparous patients may request a Caesarean birth after a previous traumatic vaginal birth. Other pregnant patients desire an elective Caesarean birth because of the convenience of planning a date or having control and choice about when to give birth. At this time, evidence is insufficient to recommend elective Caesarean birth to prevent urinary or fecal incontinence later in life (Berghella et al., 2017; Thorp & Laughon, 2018).

Potential risks of Caesarean birth on request include the following:

- Higher rates of endometritis, blood transfusion, and venous thrombosis
- A longer hospital stay and recovery time for the postpartum patient
- An increased risk for respiratory issues for the baby
- Greater complications in subsequent pregnancies, including uterine rupture and placental implantation difficulties

Caesarean birth on request should not be performed unless a gestational age of 39 weeks has been accurately determined. Also, the procedure is not recommended for patients who desire several additional children, because the risks for placenta previa, placenta accreta, and Caesarean hysterectomy increase with each Caesarean birth (Berghella et al., 2017).

The SOGC does not promote Caesarean on demand and promotes vaginal childbirth but believes that the final decision as to the safest route for childbirth rests with the patient and their health care provider (Alsayegh et al., 2018). It is essential that patients be fully informed about the risks and benefits of Caesarean birth when they consider requesting elective Caesarean birth. Following discussion of the risks and benefits of Caesarean birth versus vaginal birth, if the patient should choose Caesarean birth, the physician may agree and perform the operation no earlier than 39 weeks of gestation (Alsayegh et al., 2018).

Scheduled Caesarean birth. Caesarean birth is scheduled or planned if:

- Labour and vaginal birth are contraindicated (e.g., complete placenta previa, active genital herpes, positive HIV status with a high viral load)
- Birth is necessary but labour is not inducible (e.g., hypertensive states that cause an intrauterine environment that threatens the health of the fetus)
- This course of action has been chosen by the obstetrical health care provider and the patient (e.g., a repeat or elective Caesarean birth).

Patients who are scheduled for a Caesarean birth have time to prepare for it psychologically. However, the psychological responses of these patients may vary. Those having a repeat Caesarean birth can have disturbing memories of the conditions preceding the initial (primary) Caesarean birth and their experiences in the postoperative recovery period. They may be concerned about the added burden of caring for a newborn and perhaps other children while recovering from a surgery. Others may feel glad to have been relieved of the uncertainty about the date and time of birth and to be free from the pain of labour.

Unplanned Caesarean birth. The psychosocial outcomes of unplanned or emergency Caesarean birth are usually more pronounced

and negative in nature than the outcomes associated with a scheduled or planned Caesarean birth. Patients and their families experience abrupt changes in their expectations for birth, postpartum care, and the care of the new baby at home. This may be a traumatic experience for all involved.

The labouring patient may approach the procedure tired and discouraged after a difficult labour. They may worry about their own safety and well-being and that of their fetus. The patient may be dehydrated, with low glycogen reserves. Because preoperative procedures must be done quickly and competently, the time available for explanation of the procedures and operation is often short. Patient and family anxiety levels tend to run high at this time, so much of what is said may be forgotten or misunderstood. The patient may experience feelings of anger or guilt in the postpartum period. Fatigue is often noticeable in these patients, and they need much supportive care.

After surgery, it is important for the nurse to spend time with the patient reviewing the events preceding the operation and the operation itself to ensure that they understand what has happened and that gaps in their recollections are filled. This approach will help create more realistic memories of the childbirth experience and can leave a more positive impression for future pregnancies and labours.

Forced Caesarean birth. Health care providers are ethically obliged to protect the well-being of both the labouring patient and the fetus; a decision for one affects the other. If a patient refuses a Caesarean birth that is recommended because of fetal jeopardy, health care providers must make every effort to find out why they are refusing and provide clear information to ensure that they are making an informed decision. If the patient continues to refuse surgery, the health care provider must decide if it is ethical to get a court order for the surgery; however, every effort should be made to avoid this legal step.

Surgical Techniques. The skin incision used is vertical, extending from near the umbilicus to the mons pubis, or transverse (Pfannenstiel) in the lower abdomen (Figure 20.8). The transverse incision, sometimes referred to as the "bikini" incision, is performed more often. The type of skin incision is generally determined by the urgency of the surgery and the presence of any prior skin incisions (Berghella et al., 2017). The type of skin incision does *not* necessarily indicate the type of uterine incision.

The two main types of uterine incision are the low transverse incision (Figure 20.9, *A*) and the vertical incision, which may be either low or classic (see Figure 20.9, *B* and *C*). Ideally, the vertical incision is contained entirely within the lower uterine segment, but extension into the contractile portion of the uterus (e.g., a classic incision) can occur (Berghella et al., 2017). Indications for a vertical incision include an underdeveloped lower uterine segment, a transverse lie presentation, an anterior placenta previa or accreta, or if uterine leiomyomas (fibroids) obstruct the lower uterine segment (Berghella et al., 2017). Because it is associated with a higher incidence of uterine rupture in subsequent pregnancies than is a lower-segment incision, vaginal birth after a classic uterine incision is contraindicated.

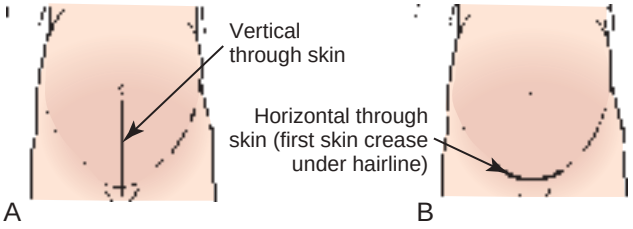

Fig. 20.8 Skin incisions for Caesarean birth. **A:** Vertical. **B:** Horizontal (Pfannenstiel).

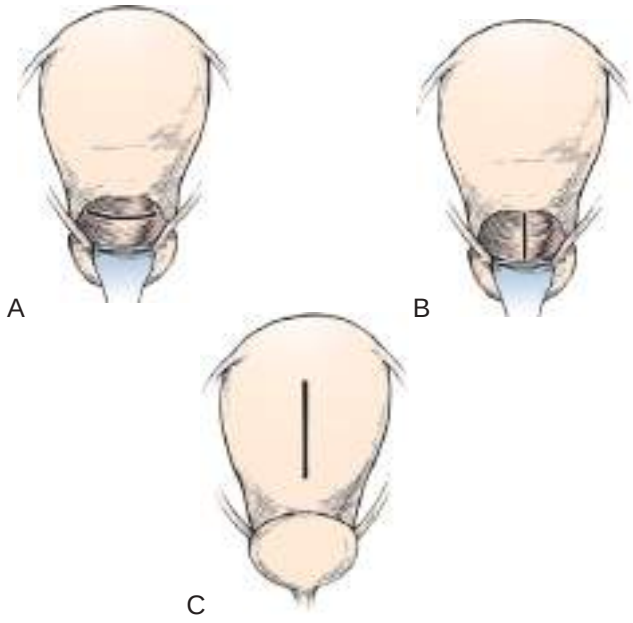

Fig. 20.9 Uterine incisions for Caesarean birth. **A:** Low transverse incision. **B:** Low vertical incision. **C:** Classic incision. (From Gabbe, S. G., Niebyl, J. R., Simpson, J. L., et al. [2017]. *Obstetrics: Normal and problem pregnancies* [7th ed.]. Elsevier.)

The low transverse uterine incision is performed in most Caesarean births (see Figure 20.9, *A*). The transverse incision is preferred over the vertical incision because it does not compromise the upper uterine segment, is easier to perform and repair, and is associated with less blood loss. It also provides for the option of TOLAC in subsequent pregnancies (Berghella et al., 2017).

Complications and Risks. Possible complications related to Caesarean birth include anaesthesia events (difficulty with intubation, medication reactions, aspiration pneumonia), hemorrhage, bowel or bladder injury, amniotic fluid embolism, and air embolism. Possible postpartum complications include atelectasis; endometritis; urinary tract infection; abdominal wound hematoma formation, dehiscence, infection, or necrotizing fasciitis; thromboembolic disease; and bowel dysfunction (Thorp & Laughon, 2018). In addition to these risks, the patient will also have a longer recovery period and additional time in the hospital.

Caesarean birth is associated with uncommon but significant dangers to the newborn. The fetus may be born prematurely if the gestational age has not been accurately determined (iatrogenic prematurity). Fetal asphyxia can occur if the uterus and placenta are poorly perfused as a result of hypotension in the labouring patient caused by regional anaesthesia (epidural or spinal) or positioning. Fetal injuries (e.g., injuries caused by scalpel lacerations) can also occur during the surgery. The newborn is more likely to require resuscitation efforts and develop respiratory complications (Thorp & Laughon, 2018).

Anaesthesia. Spinal, epidural, and general anaesthetics are used for Caesarean births. Regional blocks (epidural and spinal) are used most often because of their safety, and most patients want to be awake for and aware of the birth experience. However, the choice of anaesthetic depends on several factors. The patient's medical history or present condition, such as a spinal injury, hemorrhage, or coagulopathy, may rule out the use of regional anaesthesia. In the case of an emergency and the patient's or newborn's life being at risk, general anaesthesia will most likely be used unless an epidural is already in place. The patient is

also a factor. The person may not know all the options or may have fears about "a needle in the back" or of being awake and feeling pain. They need to be fully informed about the risks and benefits of the different types of anaesthesia so that they can participate in the decision whenever there is a choice to be made. See Chapter 18 for further discussion.

Prenatal Preparation. A discussion of Caesarean birth should be included in all childbirth preparation classes. No patient can be guaranteed a vaginal birth, even if they are in good health and no indication of danger to the fetus exists before the onset of labour. Therefore, every pregnant patient needs to be aware of and prepared for the possibility of having a Caesarean birth.

Childbirth educators should emphasize the similarities and differences between a Caesarean and a vaginal birth. Most hospitals permit partners and family members to share in these births as they do in vaginal births. Patients who have undergone Caesarean birth agree that the continued presence and support of their partners helped them respond more positively to the entire experience. In addition, hospitals are moving toward practices in the operating room, such as skin-to-skin, that help normalize the birth process for the patient and the baby.

Along with preparing pregnant patients for the possibility of Caesarean birth, more importantly, childbirth educators should empower clients to believe in their ability to give birth vaginally and to seek care measures during labour that will enhance the progress of their labour and reduce their risk for Caesarean birth.

Nursing Care

Preoperative care. The preparation of the patient for a Caesarean birth is the same as that for other elective or emergency surgery. The obstetrical health care provider discusses with the patient and their family the need for the Caesarean birth. The anaesthesiologist assesses the patient's cardiopulmonary system and describes the options for anaesthesia. Patients who are scheduled for an elective Caesarean are often told to remain NPO (nothing by mouth) for at least 8 hours before the surgery. Informed consent is obtained for the procedure.

Blood and urine tests are usually done within a week before a planned Caesarean birth or on admission to the hospital. Laboratory tests, most commonly ordered to establish baseline data, include a complete blood cell count, blood type and Rh status, and possibly a urinalysis. Vital signs, blood pressure, and fetal heart rate and pattern continue to be assessed per hospital routine until the operation begins. IV fluids are started to maintain hydration and to provide an open line for the administration of medications and for blood, if needed. Other physical preoperative preparation usually includes inserting a retention (Foley) catheter to keep the bladder empty (this should be done after administration of anaesthetic, if possible) and administering prescribed preoperative medications. In the rare instance that an abdominal-mons shave or a clipping of pubic hair is ordered by the obstetrical health care provider, this is performed in the operating room just before making the incision because shaving can result in injury of the integument, thereby increasing the risk for infection. Often TED hose and SCD boots will be placed on the patient's legs to prevent blood clot formation, especially if it is determined that there is increased risk for development of thrombophlebitis. An antacid is often administered orally to neutralize gastric secretions in case of aspiration. Removal of contact lenses, dentures, nail polish, and jewellery may be optional, depending on hospital policies and type of anaesthesia used. If the patient wears glasses and is going to be awake, the nurse should make sure that their glasses accompany them to the operating room so they can see the newborn.

During preoperative preparation, the support person is encouraged to remain with the patient as much as possible to provide continuing emotional support (if this is culturally acceptable to the patient and support person). The nurse needs to provide essential information about the preoperative procedures during this time. Although nursing actions may have to be carried out quickly if a Caesarean birth is unplanned, verbal communication, particularly explanations, is important. Silence and lack of information can be frightening to the patient and their support person. The nurse's use of touch (if culturally appropriate) can communicate feelings of care and concern for the patient. The nurse can assess the patient's and partner's perceptions about Caesarean birth. As the patient expresses their feelings, the nurse may identify possible self-concept concerns that may need to be addressed during the postpartum period. If there is time before the birth, the nurse can teach the patient about postoperative expectations and pain relief, turning, coughing, and deep-breathing measures.

Intraoperative care. Family-centred care is the goal for the patient who is undergoing Caesarean birth and for their family. Some options that can be offered to improve the Caesarean birth experience include playing music chosen by the parents, softening the overhead lighting, using a surgical drape with a window if desired by the patient, and limiting extraneous conversation in the operating room. Implementing skin-to-skin care and breastfeeding in the operating room for any newborn who is healthy are other interventions that are often desired by patients and their families. Even seemingly "small" interventions, such as inserting the IV line into the patient's nondominant arm or hand, can enhance the birth experience (Schorn et al., 2015).

Caesarean births occur in operating rooms in the surgical suite or in the labour and birth unit. Once the patient has been taken to the operating room, the care becomes the responsibility of the obstetrical team, surgeon, anaesthesiologist, and nursing staff (Figure 20.10). If possible, the partner or another person, dressed appropriately for the operating room, accompanies the patient to the surgical unit and remains close to them so that continued support and comfort can be provided. In an unplanned Caesarean birth, the nurse who cared for the patient during labour should be part of the interprofessional care team in the operating room, if possible.

The nurse who is circulating can assist with positioning the patient on the surgical table. Positioning is important so that the uterus is displaced laterally, to prevent compressing the inferior vena cava, which causes decreased placental perfusion. This is usually accomplished by placing a wedge under the hip. The patient's legs should be secured to the table to ensure proper positioning during the surgery. A Foley catheter is inserted into the bladder at this time if one is not already in place.

If the patient has general anaesthesia, the partner may not be permitted in the operating room. If the partner or another person is not allowed or chooses not to be present, the nurse can stay in communication with them and give progress reports whenever possible. If the patient is awake during the birth, the nurse or anaesthetist can tell the patient what is happening and provide support. The patient may be anxious about the sensations they are experiencing, such as the coldness of solutions used to prepare the abdomen and pressure or pulling during the actual birth of the infant. They may also be apprehensive because of the bright lights or the presence of unfamiliar equipment and masked and gowned personnel in the room. Explanations by the nurse can help decrease the patient's anxiety.

Care of the newborn usually is delegated to a nurse or other care provider skilled in newborn resuscitation. If risk factors are present, a pediatrician may also be present. An infant warmer with resuscitation equipment is readied before surgery. Those responsible for care are expert not only in resuscitative techniques but also in the ability to detect normal and abnormal newborn responses. After birth, if the

Note small amount of bleeding. **B:** The newborn's birth through the uterine incision is nearly complete. **C:** A quick assessment is performed; note significant moulding of head resulting from cephalopelvic disproportion. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

newborn's condition permits and the mother is awake, the baby may be placed skin-to-skin on the birthing parent or partner or can be given to the partner to hold (Figure 20.11). The newborn whose condition is compromised is transported after initial stabilization to the nursery for observation and the implementation of appropriate interventions. Usually the partner may accompany the newborn; if not, personnel should keep the family informed of the newborn's progress, and parent–infant contacts are initiated as soon as possible.

Fig. 20.11 **A:** Parents and their newborn. While the physician manually removes the placenta; suctions the remaining amniotic fluid and blood from the uterine cavity; and closes the uterine incision, peritoneum, muscle layer, fatty tissue, and, finally, the skin while the new family shares some private time. **B:** Parents become better acquainted with their newborn while mother rests after surgery. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

LEGAL TIP: Disclosure of Patient Information

Some parents want the privilege of informing family and friends of the gender of the newborn (if it was not known before the birth) or other information about the birth. Before responding to requests for such information from people waiting outside the birthing area, the nurse should check to see if the parents have given consent for such information to be released and to whom.

Immediate postoperative care. Once surgery is completed, the patient is transferred to a postanaesthesia recovery area. Patients who undergo a Caesarean birth have both postoperative and postpartum needs that must be addressed. They are surgical patients, as well as new parents. Nursing assessments in this immediate postbirth period follow agency protocol and include degree of recovery from the effects of anaesthesia, postoperative and postbirth status, and degree of pain. If general anaesthesia was administered, it is essential that a patent airway be maintained and that the patient be positioned to prevent possible aspiration until they are fully alert and responsive

(see Chapter 18, General Anaesthesia). Vital signs should be taken every 15 minutes for 1 to 2 hours or until stable. The condition of the incisional dressing, the fundus, and the amount of lochia need to be assessed, as well as IV intake and urine output through the Foley catheter. Oxytocin is usually added to at least the first litre of the IV infusion to ensure that the fundus remains firmly contracted, thereby reducing blood loss unless the medication carbetocin has been administered in the operating room. The patient should be helped to turn and do coughing, deep-breathing, and leg exercises. Medications for pain relief should be administered before postoperative pain becomes severe.

Routine postpartum care is organized to facilitate parent–infant interaction as soon as possible and to answer the family's questions. When appropriate, the nurse should assess the new parent's readiness to see the baby, as well as their response to the anaesthesia and to the event that may have necessitated general anaesthesia (e.g., emergency Caesarean birth when vaginal birth was anticipated). If the baby is present, the parents should be given some time alone with the baby to facilitate bonding and attachment. Newborns should be placed skin-to-skin with a parent as soon as possible, and breastfeeding can be initiated when the postpartum patient feels like trying to breastfeed, preferably within the first 30 to 60 minutes after birth. The patient is usually transferred to the postpartum unit after 1 to 2 hours or once their condition is stable and the effects of anaesthesia have decreased (i.e., patient is alert, oriented, and able to feel and move extremities).

Postpartum care. The attitude of the nurse and other health team members can influence the patient's perception of themselves after a Caesarean birth. The caregivers should stress that the patient is a new parent first and a surgical patient second. This attitude helps the patient perceive themselves as having the same concerns and needs as those of other new parents while at the same time requiring supportive postoperative care.

The patient's physiological concerns for the first few days may be dominated by pain at the incision site and pain resulting from intestinal gas, thus the need for pain relief. For the first 24 hours after surgery, pain relief can be provided by epidural opioids, patient-controlled analgesia (PCA), or IV or intramuscular injections. The most commonly used analgesics include opioids (e.g., hydromorphone or morphine sulphate) and NSAIDs (e.g., naproxen). If opioids are used, an antiemetic (e.g., dimenhydrinate [Gravol], promethazine [Phenergan], ondansetron [Zofran]) is often ordered to be administered either as needed by the patient or around the clock as long as the opioid is used. Palpation of the fundus with the possibility of massage should be performed after an analgesic is given to decrease pain. By 24 hours after surgery, patients are generally given oral analgesics. Other comfort measures such as position changes, splinting the incision with pillows, and relaxation and breathing techniques may be implemented.

Patients are often the best judge of what their bodies need and can tolerate, including the postoperative ingestion of foods and fluids. Because most patients have an epidural or spinal anaesthetic for surgery, most health care providers allow the early introduction of solid food if desired and tolerated. Some health care providers may order clear fluids until bowel sounds return, but research does not support this practice for gynecological surgery (Charoenkwan & Matovinovic, 2014). IV fluids are usually continued until the patient is tolerating fluids orally. Patients should be taught methods to help limit gas formation and thereby minimize the severity of gas pains (see Patient Teaching box: Postpartum Pain Relief After Caesarean Birth).

PATIENT TEACHING

Postpartum Pain Relief After Caesarean Birth

Incisional Pain

- Splint incision with a pillow when moving or coughing.
- Use relaxation techniques such as listening to music, deep breathing, and dimming lights.

Intestinal Gas

- Get out of bed as quickly as possible and walk as often as you can.
- Do not eat or drink gas-forming foods, carbonated beverages, or whole milk.
- Do not use straws for drinking fluids.
- Take antiflatulence medication if prescribed.
- Lie on your left side to expel gas.
- Rock in a rocking chair.

Nurses must be alert to the patient's physiological needs, managing care to ensure adequate rest and pain relief. Couplet care for a Caesarean birth patient can be modified according to their physiological limitations as a surgical patient.

Daily care includes perineal care and routine hygienic care, including showering after the dressing has been removed (if showering is acceptable according to the patient's cultural beliefs and practices). The indwelling (Foley) catheter is also usually removed on the first postpartum day (usually within 8 to 12 hours). The patient is encouraged to be out of bed and ambulating several times each day as soon as possible. Use of TED hose or SCD boots should continue as long as the patient remains in bed. They may be removed when they begin ambulating. The nurse assesses the patient's vital signs, incision, fundus, and lochia according to hospital policies, procedures, or protocols. Breath sounds, bowel sounds, circulatory status of lower extremities, and urinary and bowel elimination also are assessed. It is also important to note parental emotional status and progress of attachment to their baby.

SAFETY ALERT

The patient should be taught to seek assistance initially when getting out of bed, especially when an IV line and catheter are still in place. Thereafter, when rising from a supine position, they should sit on the side of the bed first to determine if dizziness will occur, then stand at the bedside, and finally ambulate.

During the postpartum period, the nurse can provide care that meets the psychological and learning needs of patients who have had Caesarean births. The nurse should explain postpartum procedures to help the patient participate in the recovery from surgery. Also, the nurse can help the patient plan care and visits from family and friends that allow for adequate rest periods. Information and assistance with newborn care can facilitate adjustment to the role as a parent. The patient needs to be supported as they breastfeed the baby, receiving individualized assistance to comfortably hold and position the baby at the breast. The side-lying position or football hold and the use of pillows to support the newborn can enhance comfort and facilitate successful breastfeeding (see Chapter 27). The partner and other family members can be included in teaching sessions about newborn care and the postpartum patient's recovery.

SAFETY ALERT

When holding the baby or breastfeeding, a patient may become drowsy and even fall asleep because of the sedation that occurs with the use of analgesics. It is important that someone be with them during these times.

The couple also should be encouraged to express their feelings about the birth experience. Some parents are angry, frustrated, or disappointed that a vaginal birth was not possible. Some patients may express feelings of low self-esteem or a negative self-image. Others express relief and gratitude that the baby is healthy and safely born. It may be helpful for them to have the nurse who was present during the birth visit help fill in "gaps" about the experience.

Discharge after Caesarean birth is usually by the second or third postoperative day. The patient's predominant needs at home are for rest and sleep; relief of pain and discomfort; and assistance with household chores, newborn care and feeding, and self-care. The nurse must provide discharge teaching in the limited time the patient is in the hospital, while also ensuring that they are comfortable and able to rest. The nurse should assess the patient's information needs and coordinate the health care team's efforts to meet them.

Discharge teaching and planning should include information about the following:

- Nutrition
- Measures to relieve pain and discomfort
- Exercise and specific activity restrictions
- Time management that includes periods of uninterrupted rest and sleep
- Hygiene, breast, and incision care
- Timing for resumption of sexual activity and contraception
- Signs of complications (see Patient Teaching box: Signs of Postoperative Complications After Discharge Following Caesarean Birth)
- Newborn care

The patient's family and friends should be educated about their needs during the recovery process, and their assistance should be coordinated before discharge. Referrals to community agencies may be indicated to further promote the recovery process. A postdischarge program of telephone follow-up and home visits can facilitate the patient's full recovery after Caesarean birth.

PATIENT TEACHING

Signs of Postoperative Complications After Discharge Following Caesarean Birth

Report the following signs to your health care provider:

- Temperature exceeding 38°C (100.4°F)
- Urination; painful urination, urgency, cloudy urine
- Lochia: A heavier than normal menstrual period, clots, odour
- Caesarean incision: Redness, swelling, bruising, foul-smelling discharge or bleeding, wound separation
- Severe, increasing abdominal pain

Trial of Labour After Caesarean (TOLAC)

A patient who has had a previous low-segment Caesarean birth may be a candidate for a TOLAC. Indications for primary Caesarean birth such as dystocia, breech presentation, or abnormal FHR pattern often are nonrecurring. Therefore, a patient who has had a Caesarean birth with a low transverse uterine incision and subsequently becomes pregnant may not have any contraindications to labour and vaginal birth in that pregnancy and may be offered a TOLAC. Box 20.13 lists contraindications suggested by the SOGC for a TOLAC. The major risk associated with TOLAC is uterine rupture, although the absolute risk for this is low (Dy et al., 2019). Other risks include operative injury, blood transfusion, hysterectomy, endometritis, and patient death (Dy et al., 2019; Thorp & Laughon, 2018) (see Clinical Reasoning Case Study: Trial of Labour After Caesarean [TOLAC]).

BOX 20.13 Contraindications for a Trial of Labour After Caesarean (TOLAC)

- Previous or suspected classical uterine incision
- Previous inverted T or low vertical uterine incision
- Previous uterine rupture
- Previous major uterine surgery
- Patient requests repeat Caesarean birth
- Inability to perform an emergency Caesarean birth if necessary

Data from Dy, J., DeMeester, S., Lipworth, H., & Barrett, J. (2019). SOGC clinical practice guideline: No. 382—Trial of labour after Caesarean. *Journal of Obstetrics and Gynaecology Canada, 41*(7), 992–1011. https://doi.org/10.1016/j.jogc.2018.11.008.

CLINICAL REASONING CASE STUDY

Trial of Labour After Caesarean (TOLAC)

Heather, a 28-year-old G2 T1 P0 A0 L1, had a Caesarean birth in her previous pregnancy because of breech position of the fetus. During her routine prenatal visit at 32 weeks of gestation, Heather tells the nurse that she really wants to have a vaginal birth this time. Heather asks, "What do you think? Can I try for a TOLAC?"

Questions

1. Evidence—Is there sufficient evidence to advise Heather about the safety and feasibility of a TOLAC?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Risks that Heather faces if she chooses a TOLAC
   b. Criteria that must be met for Heather to attempt a TOLAC
   c. Labour management practices that facilitate a successful TOLAC
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Heather's care.

The overall vaginal birth after Caesarean (VBAC) success rate is approximately 60 to 80%. The strongest predictors for a successful VBAC are a prior vaginal birth and spontaneous (rather than induced or augmented) labour (Dy et al., 2019). Patients whose first Caesarean birth was performed because of a nonrecurring indication (e.g., breech presentation) also are likely to have a successful VBAC (Dy et al., 2019). Patients with the following characteristics are less likely to have a successful VBAC (Dy et al., 2019):

- Recurrent indication (e.g., labour dystocia) for initial Caesarean birth
- Increased age in labouring person
- Non-White race or ethnicity
- Gestational age greater than 40 weeks
- Obesity in labouring person
- Pre-eclampsia
- Short interpregnancy interval (less than 18-month interval)
- Induction and/or augmentation of labour
- Increased newborn birth weight

Patients are the primary decision makers with regard to choice of birth method. During the antepartum period, the patient should be given information about TOLAC and encouraged to choose it as an alternative to a repeat Caesarean, as long as no contraindications exist.

VBAC support groups (see Additional Resources at end of the chapter) and prenatal classes can help prepare the patient psychologically for labour and vaginal birth. Patients need to believe not only that their efforts during a TOLAC will be successful but also that they are fully capable of doing what is necessary to give birth vaginally. They must be given the opportunity to discuss their previous labour experience, including feelings of failure and loss of control, and to express any concern they may have about how they will manage during their upcoming labour and birth. Not everyone is enthusiastic about TOLAC and VBAC. After being fully informed about the benefits and risks, more than 25% of potential candidates choose to have a repeat Caesarean birth instead (Thorp & Laughon, 2018).

There is conflicting evidence that administering oxytocin to induce or augment labour increases the risk of uterine rupture. If oxytocin is used for the TOLAC, caution and close monitoring of the labouring patient are urged. However, use of prostaglandins to ripen the cervix or induce labour is not recommended because they have been associated with an increased risk for uterine rupture (Dy et al., 2019).

If a patient chooses TOLAC, attention should be given to their psychological as well as physical needs. Anxiety increases the release of catecholamines and can inhibit the release of oxytocin, delaying the progress of labour and possibly leading to a repeat Caesarean birth. To alleviate anxiety, the nurse can encourage the patient to use breathing and relaxation techniques and change position to promote labour progress. The patient's partner can be encouraged to provide comfort measures and emotional support. Collaboration among the labouring patient, their partner, the nurse, and other health care providers often results in a successful VBAC. If a TOLAC does not proceed to vaginal birth, the patient will need support and encouragement to express their feelings about having another Caesarean birth. It is important that this outcome not be labelled a "failed" VBAC.

The nurse needs to assess the patient's vital signs and the fetus' heart rate and pattern and should be alert for signs of potential complications. If complications develop, the nurse is responsible for initiating appropriate actions, including notifying the obstetrical health care provider, and for evaluating and documenting the patient's and fetal responses to the interventions. Supporting and encouraging the patient and their partner and providing information on progress can reduce stress, enhance the labour process, and facilitate a successful outcome.

Many patients who are appropriate candidates for TOLAC lack access to health care providers and health care facilities that are able and willing to offer this option. Because resources for immediate Caesarean birth may not be available in all birthing facilities, the best alternative in some situations may be to refer interested patients to other facilities that have the obstetrical, anaesthetic, pediatric, and surgical staff necessary to offer TOLAC (Dy et al., 2019).

OBSTETRICAL EMERGENCIES

Meconium-Stained Amniotic Fluid

Meconium-stained amniotic fluid indicates that the fetus has passed meconium (first stool) before birth. Meconium-stained amniotic fluid is green. The consistency of the amniotic fluid is often described as either thin (light) or thick (heavy), depending on the amount of meconium present. Three possible reasons for the passage of meconium are as follows:

- It is a normal physiological function that occurs with maturity (meconium passage being infrequent before weeks 23 or 24, with an increased incidence after 38 weeks) or with a breech presentation.
- It is the result of hypoxia-induced peristalsis and sphincter relaxation.
- It may be a sequel to umbilical cord compression–induced vagal stimulation in mature fetuses.

The major risk associated with meconium-stained amniotic fluid is the development of **meconium aspiration syndrome (MAS)** in the newborn. MAS causes a severe form of aspiration pneumonia that occurs most often in term or post-term infants who have passed meconium in utero (see Chapter 28, Meconium Aspiration Syndrome). MAS most likely results from a long-standing intrauterine process rather than from aspiration immediately after birth as respirations are initiated (Rozance & Rosenberg, 2017).

Collaborative Care. The presence of an interprofessional team skilled in newborn resuscitation is required at the birth of any infant with meconium-stained amniotic fluid. To address occurrence of meconium-stained amniotic fluid, the Canadian Paediatric Society along with the American Academy of Pediatrics (AAP) and the American Heart Association (AHA) Neonatal Resuscitation Program no longer recommend routine suctioning of the newborn's mouth and nose followed by endotracheal suctioning after birth. Instead, management of a newborn with meconium-stained amniotic fluid is based only on assessment of the baby's condition at birth. No clinical studies warrant basing tracheal suctioning guidelines simply on meconium consistency (AAP & AHA, 2016). See the Emergency box: Immediate Management of the Newborn With Meconium-Stained Amniotic Fluid for specific interventions.

EMERGENCY

Immediate Management of the Newborn With Meconium-Stained Amniotic Fluid

Before Birth

- Assess the amniotic fluid for the presence of meconium after rupture of membranes.
- If the amniotic fluid is meconium stained, gather equipment and supplies that might be necessary for neonatal resuscitation.
- Have at least one person capable of performing endotracheal intubation on the baby present at the birth.

Immediately After Birth

- Assess whether the baby appears term, has good muscle tone, and is breathing or crying.
- If the baby meets these three criteria, the baby should remain skin-to-skin with the parent and routine care should be provided.
- If the baby does not meet any of these three criteria, the baby should be moved to a warmer for further assessment. If secretions are present, clear the airway with a bulb syringe. Do not vigorously suction the baby because this may cause bradycardia or apnea.

Data from American Academy of Pediatrics (AAP) and American Heart Association (AHA). (2016). *Textbook of neonatal resuscitation* (7th ed.). AAP.

SAFETY ALERT

Every birth should be attended by at least one person whose only responsibility is the baby and who is capable of initiating resuscitation. Either that person or someone else who is immediately available should have the skills required to perform a complete resuscitation.

Shoulder Dystocia

Shoulder dystocia is an uncommon obstetrical emergency that increases the risk for morbidity and mortality in the fetus, newborn, or labouring patient during the attempt to accomplish birth vaginally. Shoulder dystocia is a condition in which the head is born but the anterior shoulder cannot pass under the pubic arch. It is difficult to estimate the incidence of shoulder dystocia because of a lack of consensus related to the definition; however, 1% has been identified as a useful average (Cunningham et al., 2018). The incidence of shoulder dystocia has increased in recent years, perhaps because of larger birth weights or simply because more attention is now paid to documenting the condition (Cunningham et al., 2018).

Fetopelvic disproportion caused by excessive fetal size (greater than 4 000 g) or pelvic abnormalities in the labouring patient may be a cause of shoulder dystocia, although up to half of all cases of shoulder dystocia occur with smaller fetuses (Lanni et al., 2017; Thorp & Laughon, 2018). Other risk factors for shoulder dystocia include diabetes during pregnancy (risk for macrosomia), a prolonged second stage of labour, and a history of shoulder dystocia with a previous birth. In half of all cases of shoulder dystocia, however, no risk factors are identified (Thorp & Laughon, 2018). Shoulder dystocia cannot be accurately predicted or prevented (Cunningham et al., 2018). Retraction of the fetal head against the perineum immediately after its emergence (turtle sign), however, is an early warning that birth of the shoulders may be difficult (Thorp & Laughon, 2018).

Fetal injuries are usually caused either by asphyxia related to the delay in completing the birth or by trauma from the manoeuvres used to accomplish the birth. Complications related to trauma include brachial plexus and phrenic nerve injuries and fracture of the humerus or clavicle. The most serious complication is brachial plexus injury (Erb palsy), which occurs in 10 to 20% of infants born following shoulder dystocia (Thorp & Laughon, 2018). Evidence now exists that brachial plexus injuries may result from intrauterine forces during the second stage of labour rather than from the manoeuvres used to accomplish birth (Lanni et al., 2017). If brachial plexus injuries are recognized early and treated properly, 80 to 90% heal completely. Therefore, permanent neurological injury is rare. The major complications in postpartum patients associated with shoulder dystocia are postpartum hemorrhage and rectal injuries (Lanni et al., 2017).

Collaborative Care. Many manoeuvres, such as suprapubic pressure and position changes in the labouring patient, have been suggested and tried to free the anterior shoulder. The McRoberts manoeuvre and suprapubic pressure are usually the first-line interventions for shoulder dystocia, because they are noninvasive and easily learned and they can be performed quickly. The specific interventions used are less important than is being prepared at every vaginal birth to manage shoulder dystocia using a planned sequence of interventions if the need arises (Lanni et al., 2017).

In the McRoberts manoeuvre (Figure 20.12), the patient's legs are hyperflexed on the abdomen. This manoeuvre causes the sacrum to straighten, and the symphysis pubis rotates toward the patient's head; the angle of pelvic inclination is decreased, freeing the shoulder. Suprapubic pressure can then be applied over the anterior shoulder (Figure 20.13) in an attempt to dislodge the shoulder. Use of the McRoberts manoeuvre and suprapubic pressure may relieve more than one half of all cases of shoulder dystocia. Fundal pressure as a method of relieving shoulder dystocia should be avoided because it will only further impact the anterior shoulder behind the symphysis pubis (Lanni et al., 2017). The Gaskin manoeuvre (having the patient move to a hands-and-knees position) has also been highly effective in resolving cases of shoulder dystocia. However, the Gaskin manoeuvre may be difficult to accomplish if the patient has significant loss of motor function caused by regional anaesthesia.

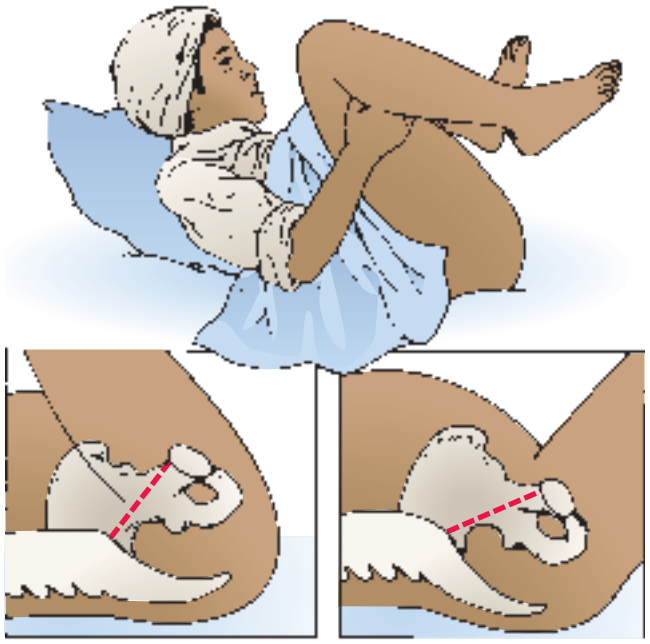

Fig. 20.12 McRoberts manoeuvre. (From Gabbe, S. G., Niebyl, J. R., Simpson, J. L., et al. [2017]. *Obstetrics: Normal and problem pregnancies* [7th ed.]. Elsevier.)

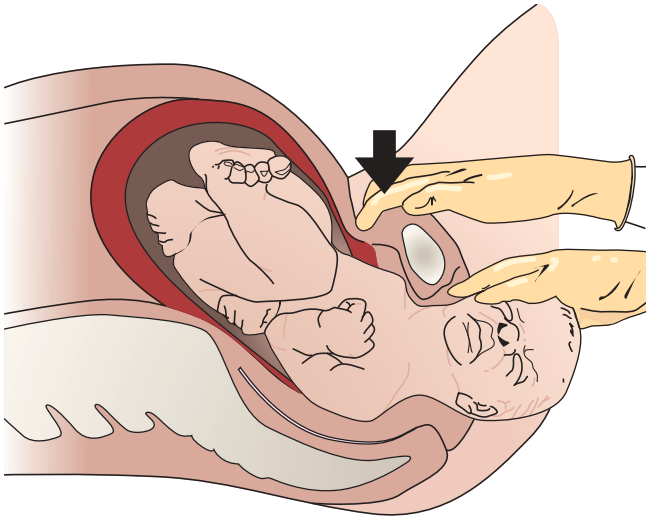

Fig. 20.13 Application of suprapubic pressure. (From Gabbe, S. G., Niebyl, J. R., Simpson, J. L., et al. [2017]. *Obstetrics: Normal and problem pregnancies* [7th ed.]. Elsevier.)

When shoulder dystocia is diagnosed, the nurse should stay calm and immediately call for additional assistance. The nurse can then help the patient assume the position(s) that may facilitate birth of the shoulders, assist the obstetrical health care provider with these manoeuvres, and monitor the fetal response. The nurse should also provide encouragement and support to reduce anxiety and fear.

Newborn assessment should include examination for fracture of the clavicle or humerus, brachial plexus injuries, and asphyxia. Postpartum patient assessment should focus on early detection of hemorrhage and trauma to the soft tissue of the birth canal.

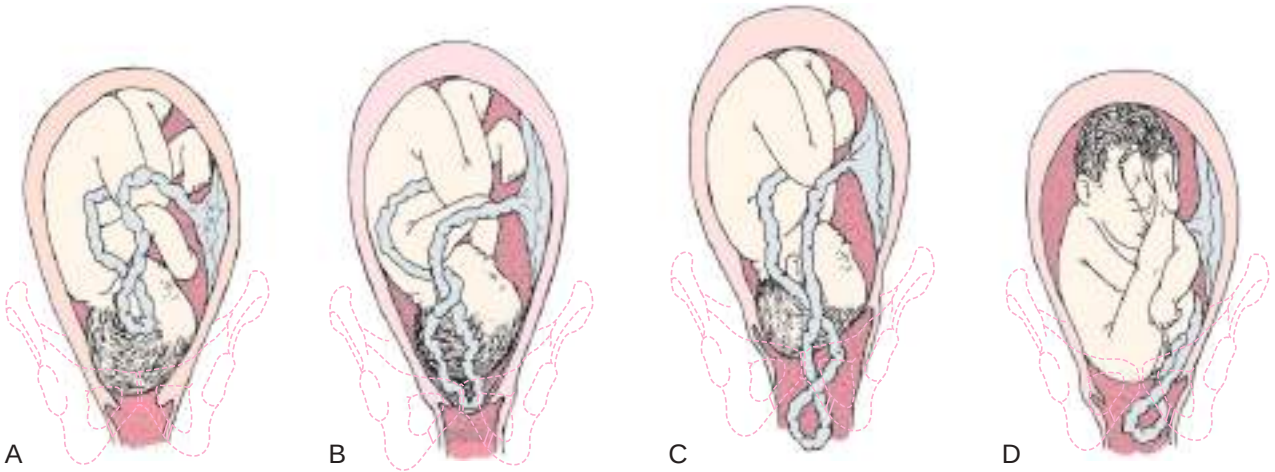

Fig. 20.14 Prolapse of umbilical cord. Note pressure of presenting part on umbilical cord, which endangers fetal circulation. **A:** Occult (hidden) prolapse of cord. **B:** Complete prolapse of cord. Note that membranes are intact. **C:** Cord presenting in front of fetal head may be seen in vagina. **D:** Frank breech presentation with prolapsed cord.

Prolapsed Umbilical Cord

Prolapse of the umbilical cord occurs when the cord lies below the presenting part of the fetus. Umbilical cord prolapse may be occult (hidden, not visible) at any time during labour, regardless of whether or not membranes are ruptured (Figure 20.14, *A* and *B*). It is most common to see frank (visible) prolapse directly after rupture of membranes, when gravity washes the cord in front of the presenting part (see Figure 20.14, *C* and *D*). Contributing factors are a long cord (longer than 100 cm), malpresentation (breech or transverse lie), or unengaged presenting part.

If the presenting part does not fit snugly into the lower uterine segment, as in polyhydramnios, when the membranes rupture, a sudden gush of amniotic fluid may cause the cord to be displaced downward. Similarly, the cord may prolapse during amniotomy if the presenting part is high. A small or preterm fetus may not fit snugly into the lower uterine segment; as a result, cord prolapse is more likely to occur.

Collaborative Care. Prompt recognition of a prolapsed cord is important because fetal hypoxia resulting from prolonged cord compression (i.e., occlusion of blood flow to and from the fetus for more than 5 minutes) can occur and potentially lead to fetal hypoxia, newborn asphyxia, neurological brain injury, or death of the fetus. Pressure on the cord may be relieved by the examiner putting a sterile gloved hand into the vagina and holding the presenting part off of the umbilical cord (Figure 20.15, *A* and *B*). The patient should be assisted into a position such as lateral recumbent (see Figure 20.15, *C*), Trendelenburg, or knee–chest (see Figure 20.15, *D*) position, in which gravity keeps the presenting part off the cord. If the cervix is fully dilated, a forceps- or vacuum-assisted birth can be performed for the fetus in a cephalic presentation; otherwise, emergent Caesarean surgery is likely to be performed. Abnormal fetal heart rate and pattern (e.g., bradycardia, absent or minimal variability, and variable or prolonged decelerations), inadequate uterine relaxation, and bleeding also can occur as a result of a prolapsed umbilical cord. Indications for immediate interventions are presented in the Emergency box: Prolapsed Umbilical Cord. Ongoing assessment of the patient and the fetus is critical to determine the effectiveness of each action taken. The patient and the family are often aware of the seriousness of the situation; therefore, the nurse must provide support by giving explanations for the interventions being implemented and their effect on the status of the fetus.

EMERGENCY

Prolapsed Umbilical Cord

Signs

- Variable or prolonged deceleration during uterine contraction
- Patient reports feeling the cord after membranes rupture
- Cord is seen or felt in or protruding from the vagina

Interventions

- Call for assistance. Do not leave the patient alone.
- Have someone notify the obstetrical health care provider immediately.
- Glove the examining hand quickly and insert two fingers into the vagina to the cervix. With one finger on either side of the cord or both fingers to one side, exert upward pressure against the presenting part to relieve compression of the cord (see Figure 20.15, *A* and *B*). Do not move your hand. Another person may place a rolled towel under the patient's right or left hip.
- Place patient into the extreme Trendelenburg or a lateral recumbent position (see Figure 20.15, *C*), or a knee–chest position (see Figure 20.15, *D*).
- If the cord is protruding from the vagina, wrap it loosely in a sterile towel saturated with warm, sterile, normal saline solution. Do not attempt to replace the cord into the cervix.
- Administer oxygen to the patient by mask at 8 to 10 L/min until birth is accomplished.
- Start intravenous fluids or increase existing drip rate.
- Continue to monitor fetal heart rate continuously.
- Explain to the patient and support person what is happening and the management plan.
- Prepare for immediate vaginal birth if the cervix is fully dilated or for Caesarean birth if it is not.

Rupture of the Uterus

Uterine rupture is defined as the symptomatic disruption and separation of the layers of the uterus or previous scar. Uterine rupture can result in the ejection of fetal parts or the entire fetus into the peritoneal cavity. It is a rare but very serious obstetrical injury that occurs in 1 in 2 000 births (Francois & Foley, 2017). During labour and birth, the major risk factor for uterine rupture is a scarred uterus as a result of previous Caesarean birth or other uterine surgery. Rupture usually

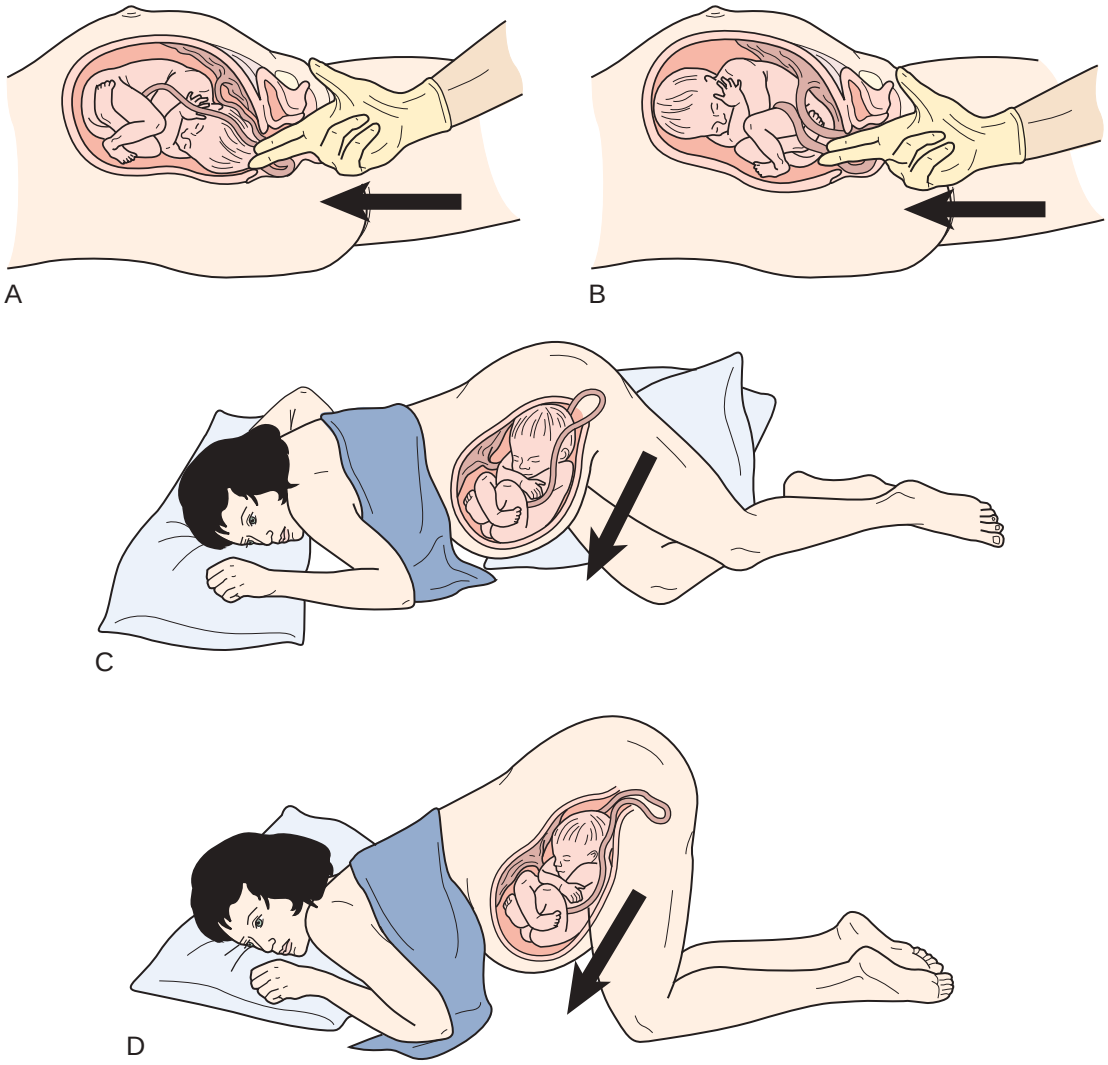

Fig. 20.15 *Arrows* indicate direction of pressure against presenting part to relieve compression of prolapsed umbilical cord. Pressure exerted by examiner's fingers in **A:** vertex presentation and **B:** breech presentation. **C:** Gravity relieves pressure when woman is in a lateral position with hips elevated as high as possible with pillows. **D:** Knee–chest position.

occurs during a TOLAC; symptomatic rupture is rarely observed in planned, repeat Caesarean births. The likelihood of uterine rupture varies, depending on the type and location of the previous uterine incision. Uterine rupture occurs most often with a previous classic incision. Other factors that increase the risk for uterine rupture include multiple prior Caesarean births, no previous vaginal births, induced or augmented labour, term gestation, thin uterine scar identified by ultrasound, multifetal gestation, fetal macrosomia, post–Caesarean birth infection, and short interpregnancy interval (Francois & Foley, 2017; Landon & Grobman, 2017).

Uterine dehiscence, sometimes called *incomplete uterine rupture,* is separation of a prior scar. It may go unnoticed unless the patient undergoes a subsequent Caesarean birth or other uterine surgery. The potential for maternal or fetal complications as a result of uterine dehiscence is negligible because separation of a prior scar does not result in hemorrhage (Landon & Grobman, 2017).

Signs and symptoms vary with the extent of the uterine rupture. The most common finding is an abnormal FHR tracing, particularly prolonged decelerations or bradycardia sometimes preceded by variable or late decelerations. A loss of fetal station may also occur. The patient may experience vaginal bleeding, constant abdominal pain, uterine tenderness, a change in uterine shape, blood in the urine, and cessation of contractions (Francois & Foley, 2017; Landon & Grobman, 2017). The patient may also exhibit signs of hypovolemic shock caused by hemorrhage (i.e., hypotension, tachypnea, pallor, and cool, clammy skin). If the placenta separates, the FHR will be absent. Fetal parts may be palpable through the abdomen.

Collaborative Care. Prevention is the best treatment. Patients at risk for uterine rupture should be assessed closely during labour. Labouring patients who are induced with oxytocin or prostaglandin (especially if the previous birth was Caesarean) should be monitored for signs of uterine tachysystole with or without FHR changes because this can precipitate uterine rupture. If tachysystole occurs, the oxytocin infusion is discontinued or decreased, and a tocolytic medication may be given to decrease the intensity of uterine contractions. After giving birth, patients should be assessed for excessive bleeding, especially if the fundus is firm and signs of hemorrhagic shock are present.

If rupture occurs, the type of medical management depends on its severity. A small rupture may be managed with a laparotomy and birth of the newborn, repair of the laceration, and blood transfusions, if needed. Hysterectomy and blood replacement are the usual treatments for a complete rupture.

The nurse's role may include starting IV fluids, transfusing blood products, administering oxygen, and assisting with preparation for immediate surgery. Supporting the patient's family and providing information about the treatment are important during this emergency. The associated fetal mortality rate is high (approximately 50 to 75%). Maternal morbidity and mortality can also be substantial (Cunningham et al., 2018). Providing information about spiritual support services or suggesting that the family contact their own support system may be warranted.

Amniotic Fluid Embolism

Amniotic fluid embolism (AFE), also known as **anaphylactoid syndrome of pregnancy**, is a rare but devastating complication of pregnancy characterized by the sudden, acute onset of hypoxia, hypotension, cardiovascular collapse, and coagulopathy. The incidence is estimated at 1.7 to 7.7 in 100 000 births. The true incidence is unknown because of the difficulty in confirming the diagnosis and inconsistent reporting of nonfatal cases (Drummond & Yeomans, 2019).

AFE occurs during labour, during birth, or within 30 minutes after birth. This combination of sudden respiratory and cardiovascular collapse, along with coagulopathy, is similar to that observed in patients with anaphylactic or septic shock. In both conditions, a foreign substance is introduced into the circulation, resulting in disseminated intravascular coagulation, hypotension, and hypoxia (Drummond & Yeomans, 2019).

In AFE, the foreign substance that initiates the condition is presumed to be present in amniotic fluid that is introduced into the circulation of the labouring patient. However, the exact factor that initiates AFE has not been identified. In the past, particles of fetal debris (e.g., vernix, hair, skin cells, or meconium) found in amniotic fluid were thought to be responsible for initiating the syndrome; however, fetal debris can be found in the pulmonary circulation of most normal labouring patients. Also, fetal debris is identified in only 78% of patients diagnosed with AFE. Therefore, AFE is diagnosed clinically (Drummond & Yeomans, 2019). Although AFE is rare, the mortality rate is 61% or higher (Drummond & Yeomans, 2019). Outcome for newborns in cases of AFE is poor. The newborn survival rate is between 20 and 60%. However, only half of these fetuses survive neurologically intact (Drummond & Yeomans, 2019).

Risk factors for AFE include advanced age, non-White race, placenta previa, pre-eclampsia, and forceps-assisted or Caesarean birth. Other factors commonly associated with the development of AFE are rapid labour and meconium staining (Cunningham et al., 2018). Previously it was thought that the hypertonic uterine contractions that often accompany AFE actually caused the event. Instead, it appears that the physiological response to AFE produces the hypertonic contractions (Drummond & Yeomans, 2019).

Collaborative Care. The immediate interventions for AFE are summarized in the Emergency box: Amniotic Fluid Embolism (Anaphylactoid Syndrome of Pregnancy). Care must be instituted immediately. Cardiopulmonary resuscitation is often necessary. If cardiopulmonary arrest occurs, for optimal fetal survival, a perimortem Caesarean birth should be accomplished within 5 minutes (Drummond & Yeomans, 2019). The nurse's immediate responsibility is to assist with the resuscitation efforts.

EMERGENCY

Amniotic Fluid Embolism (Anaphylactoid Syndrome of Pregnancy)

Signs

- Respiratory distress
  - Restlessness
  - Dyspnea
  - Cyanosis
  - Pulmonary edema
  - Respiratory arrest
- Circulatory collapse
  - Hypotension
  - Tachycardia
  - Shock
  - Cardiac arrest
- Hemorrhage
  - Coagulation failure: bleeding from incisions, venipuncture sites, trauma (lacerations); petechiae, ecchymoses, purpura
  - Uterine atony

Interventions

Oxygenate.
- Administer oxygen by nonrebreather face mask (10 L/min) or resuscitation bag delivering 100% oxygen.
- Prepare for intubation and mechanical ventilation.
- Initiate or assist with cardiopulmonary resuscitation. Tilt pregnant patient 30 degrees to side to displace uterus.

Maintain cardiac output and replace fluid losses.
- Position patient on their side.
- Administer IV fluids.
- Administer blood: packed cells, fresh frozen plasma.
- Insert in-dwelling catheter and measure hourly urine output.

Correct coagulation failure.

Monitor fetal and maternal status.

Prepare for emergency birth once patient's condition has stabilized.

Provide emotional support to the patient, partner, and family.

Additional interventions will likely include replacing blood and clotting factors and maintaining adequate hydration and blood pressure. The patient is usually placed on mechanical ventilation. Invasive hemodynamic monitoring may also be required (Drummond & Yeomans, 2019).

Support of the patient's partner and family is needed; they will be anxious and distressed. Brief explanations of what is happening are important during the emergency and can be reinforced after the immediate crisis is over. If the patient dies and the infant survives, grieving, anger, and blame may interfere with parent–infant attachment. When both the parent and infant die, it is important that the family has the opportunity to spend time with them. Emotional support and involvement of the perinatal loss support team or other resource for grief counselling, including the spiritual care team, are needed (see Box 24.7). Referral to grief and loss support groups is appropriate. The nursing staff also may need help in coping with emotions that result from a patient's death.

KEY POINTS

- *Preterm labour* is defined as uterine contractions leading to cervical change occurring between 20 and 37 completed weeks of pregnancy; *preterm birth* is any birth that occurs before the completion of 37 weeks of pregnancy.

- The cause of preterm labour is unknown and is assumed to be multifactorial.
- Bed rest, a commonly prescribed intervention for preterm labour, has many deleterious adverse effects and has never been shown to decrease preterm birth rates.
- Preterm birth that occurs in a tertiary care centre leads to better outcomes for the labouring patient and the newborn.
- Vigilance for signs of infection is a major part of the care for patients with PPROM.
- Dystocia results from differences in the normal relationships among any of the five factors affecting labour.
- Dystocia due to uterine contractions occurs as a result of hypertonic uterine dysfunction, hypotonic uterine dysfunction, or inadequate voluntary expulsive forces.
- The functional relationships among the uterine contractions, the fetus, and the pelvis of the labouring patient are altered by changing positions of the labouring patient.
- Uterine contractility is increased by oxytocin and prostaglandin and decreased by tocolytic medications.
- Cervical ripening using chemical or mechanical measures can increase the success of labour induction.
- Expectant parents benefit from learning about operative obstetrics (e.g., forceps- or vacuum-assisted birth, Caesarean birth) during the prenatal period.
- The basic purpose of Caesarean birth is to preserve the life and health of the labouring patient and the fetus.
- Unless contraindicated, a vaginal birth may be possible after a previous Caesarean birth.
- Labour management that emphasizes one-to-one support of the labouring patient by another person (doula, nurse, or midwife) can reduce the rate of Caesarean births and increase the rate of trial of labour after Caesarean (TOLAC).
- Obstetrical emergencies (e.g., shoulder dystocia, prolapsed cord, rupture of the uterus, and amniotic fluid embolism) occur rarely but require immediate intervention.
- The perinatal loss support team or other resource for grief counselling, including the spiritual care team, can provide support for families experiencing death of the perinatal patient, the infant, or both.

Physiological Changes in the Postpartum Patient

Lisa Keenan-Lindsay

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the anatomical and physiological changes that occur during the postpartum period.
2. Apply assessment techniques for uterine involution and lochial flow.
3. List expected values for vital signs and blood pressure, deviations from normal findings, and probable causes of the deviations.

The postpartum period is the interval between the birth of the newborn and the return of the reproductive organs to their normal nonpregnant state. This period is sometimes referred to as the **puerperium**, or **fourth trimester** of pregnancy, and is considered to last 6 to 12 weeks. The physiological changes that occur during the reversal of the processes of pregnancy are distinctive, but they are normal. To provide care during the recovery period that is beneficial to the postpartum patient, their newborn, and their family, the nurse needs to synthesize knowledge of anatomy and physiology of the postpartum patient during the recovery period, the newborn's physical and behavioural characteristics, newborn care activities, and the family's response to the birth of the newborn. This chapter focuses on anatomical and physiological changes that occur in the postpartum patient during the postpartum period.

REPRODUCTIVE SYSTEM AND ASSOCIATED STRUCTURES

Uterus

Involution Process. The return of the uterus to a nonpregnant state following birth is called **involution**. This process begins immediately after expulsion of the **placenta** with contraction of the uterine smooth muscle.

During the first 12 hours postpartum, the **fundus** of the uterus is located approximately at the level of the umbilicus. At this time, the uterus weighs approximately 1 000 g (Blackburn, 2018). By 24 hours after birth, the uterus is about the same size as it was at 20 weeks of gestation. Involution progresses rapidly during the next few days. The fundus descends 1 to 2 cm every 24 hours (Figure 21.1). By the sixth postpartum day, the fundus is normally located halfway between the umbilicus and the symphysis pubis. The uterus should not be palpable abdominally after 2 weeks. The uterus, which at full term weighs approximately 11 times its prepregnancy weight, involutes to approximately 500 g by 1 week after birth and to 350 g by 2 weeks after birth. The size of the uterus gradually decreases over the next month so that by 6 weeks the uterus has nearly returned to its nonpregnant location and size (Blackburn, 2018).

Increased estrogen and progesterone levels are responsible for stimulating the massive growth of the uterus during pregnancy. Prenatal uterine growth results from both *hyperplasia*, an increase in the number of muscle cells, and *hypertrophy*, an enlargement of the existing cells. After birth, the decrease in these hormones causes *autolysis*, the self-destruction of excess hypertrophied tissue. The additional cells laid down during pregnancy remain and account for the slight increase in uterine size after each pregnancy.

Subinvolution is the failure of the uterus to return to a nonpregnant state. The most common causes of subinvolution are retained placental fragments and infection (see Chapter 24).

Contractions. Postpartum hemostasis is achieved primarily by compression of intramyometrial blood vessels as the uterine muscle contracts rather than by platelet aggregation and clot formation. The hormone **oxytocin**, released from the pituitary gland, strengthens and coordinates these uterine contractions, which compress blood vessels and promote hemostasis. During the first 1 to 2 postpartum hours, uterine contractions may decrease in intensity and become uncoordinated. Because it is vital that the uterus remain firm and well contracted, exogenous oxytocin is usually administered intravenously or intramuscularly

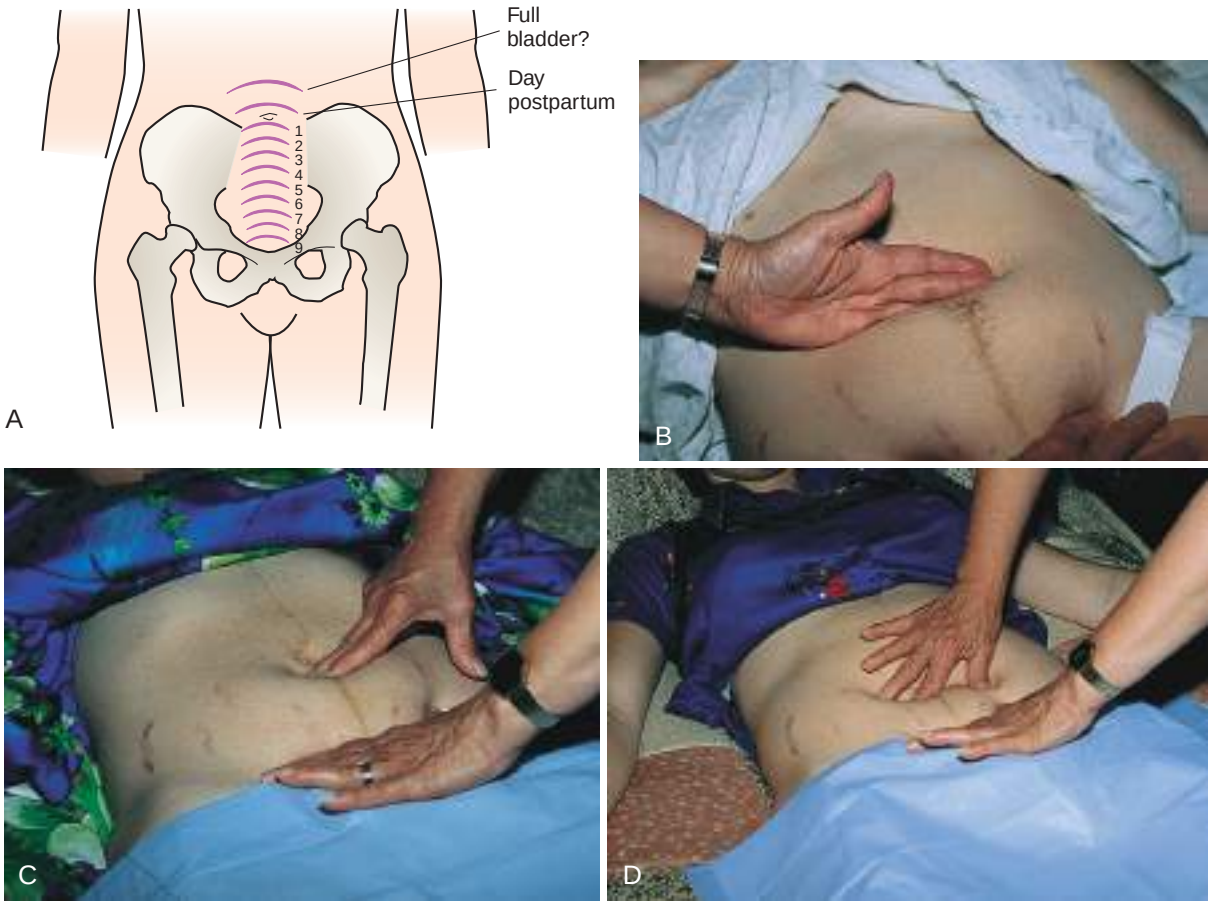

Fig. 21.1 Assessment of involution of uterus after childbirth. **A:** Normal progress, days 1 through 9. **B:** Size and position of uterus 12 hours after childbirth. **C:** Two days after childbirth. **D:** Four days after childbirth. (*B* through *D*, courtesy Marjorie Pyle, RNC, Lifecircle.)

immediately after expulsion of the placenta. Patients who are at risk of increased bleeding may have an intravenous infusion of oxytocin for the first several hours after birth (e.g., long labour, grand multiparity). The uterus is very sensitive to oxytocin during the first week or so after birth. Breastfeeding immediately after birth and in the early days postpartum increases the release of oxytocin, which decreases blood loss and reduces the risk for postpartum hemorrhage.

Afterpains. In first-time mothers uterine tone is good, the fundus generally remains firm, and the patient usually perceives only mild uterine cramping. Periodic relaxation and vigorous contractions are more common in subsequent pregnancies and may cause uncomfortable cramping called **afterpains** (afterbirth pains), which typically resolve in 3 to 7 days. Afterpains are more noticeable after births in which the uterus was overdistended (e.g., large baby, multifetal gestation, polyhydramnios). Breastfeeding and exogenous oxytocic medication usually intensify these afterpains because both stimulate uterine contractions.

Placental Site. Immediately after the placenta and membranes are expelled, vascular constriction and thromboses reduce the placental site to an irregular nodular and elevated area. Upward growth of the endometrium causes sloughing of necrotic tissue and prevents the scar formation characteristic of normal wound healing. This unique healing process enables the endometrium to resume its usual cycle of changes and permit implantation and placentation in future pregnancies. Endometrial regeneration is completed by postpartum day 16, except at the placental site. Regeneration at the placental site usually is not complete until 6 weeks after birth (Blackburn, 2018).

Lochia. Postbirth uterine discharge, commonly called **lochia**, initially is bright red (lochia rubra) and may contain small clots. For the first 2 hours after birth, the amount of uterine discharge should be about that of a heavy menstrual period. After that time, the lochia flow should steadily decrease.

Lochia rubra consists mainly of blood and decidual and trophoblastic debris. The flow pales, becoming pink or brown (lochia serosa) after 3 to 4 days. Lochia serosa consists of old blood, serum, leukocytes, and tissue debris. **Lochia serosa** is a pinkish-brown discharge lasting approximately 2 to 4 weeks (Blackburn, 2018). **Lochia alba** is whitish-yellow in colour because it contains primarily leukocytes and decidual cells; it may continue for another few weeks, although not all patients experience lochia alba. Overall lochia duration may last 4 to 6 weeks postpartum (Blackburn, 2018).

If the patient receives an oxytocic medication, regardless of the route of administration, the flow of lochia is often scant until the effects of the medication wear off. The amount of lochia is usually less after a Caesarean birth because the surgeon suctions the blood and fluids from the uterus or wipes the uterine lining before closing the incision. Flow of lochia usually increases with ambulation. Lochia tends to pool in the vagina when the patient is lying in bed; the patient then may experience a gush of blood when they stand. This gush should not be confused with hemorrhage.

Persistence of lochia rubra early in the postpartum period suggests continued bleeding as a result of retained fragments of the placenta or membranes. It is not uncommon for patients to experience a sudden, but brief, increase in bleeding 7 to 14 days after birth when sloughing of eschar over the placental site occurs. If this increase in bleeding does not subside within 1 to 2 hours, the patient needs to be evaluated for possible retained placental fragments (Isley & Katz, 2017).

About 10 to 15% of patients still have normal lochia serosa discharge at their 6-week postpartum examination (Isley & Katz, 2017). However, in some patients, the continued flow of lochia serosa or lochia alba by 3 to 4 weeks after birth can indicate endometritis, particularly if the patient has fever, pain, or abdominal tenderness. Lochia should smell like normal menstrual flow; an offensive odour usually indicates infection.

Not all postpartal vaginal bleeding is lochia; vaginal bleeding after birth may be caused by unrepaired vaginal or cervical lacerations. Box 21.1 lists factors used to distinguish between lochial and nonlochial bleeding.

Cervix

The cervix is soft immediately after birth. The ectocervix (portion of the cervix that protrudes into the vagina) appears bruised and has some small lacerations—optimal conditions for the development of infection. The cervical os, which dilated to 10 cm during labour, closes gradually. The cervix up to the lower uterine segment remains edematous, thin, and fragile for several days after birth. By the second or third postpartum day, the cervix is dilated 2 to 3 cm, and by 1 week after birth, it is approximately 1 cm dilated (Blackburn, 2018). The external cervical os never regains its prepregnancy appearance; it is no longer shaped like a circle but appears as a jagged slit that is often described as a "fish mouth" (see Figure 10.2, *B*). **Lactation** delays the production of cervical and other estrogen-influenced mucus and mucosal characteristics.

Vagina and Perineum

Postpartum estrogen deprivation is responsible for the thinness of the vaginal mucosa and the absence of **rugae**. The greatly distended, smooth-walled vagina gradually decreases in size and regains tone, although it never completely returns to its prepregnancy state. Rugae reappear within 3 weeks, but they are never as prominent as they are in the nulliparous person. Most rugae are permanently flattened. The mucosa remains atrophic in the lactating patient, at least until menstruation resumes. Thickening of the vaginal mucosa occurs with the return of ovarian function. Estrogen deficiency is responsible for a decreased amount of vaginal lubrication; vaginal dryness is more prevalent among breastfeeding patients. Localized dryness and coital discomfort (**dyspareunia**) may persist until ovarian function returns and menstruation resumes. The use of a water-soluble lubricant to reduce discomfort during sexual intercourse is usually recommended.

Immediately after vaginal birth, the introitus is erythematous and edematous, especially in the area of the **episiotomy** or laceration repair. Within 2 weeks, it is barely distinguishable from that of a nulliparous patient if lacerations and an episiotomy have been carefully repaired, hematomas are prevented or treated early, and the patient practises good hygiene.

Most episiotomy or laceration repairs are visible only if the patient is lying on their side with their upper buttock raised or if they are placed in the lithotomy position. A good light source is essential for visualization of some repairs. Healing of an episiotomy or laceration is the same as that of any surgical incision. Signs of infection (pain, redness, warmth, swelling, or discharge) or loss of approximation (separation of the edges of the incision) may occur. Initial healing occurs within 2 to 3 weeks, but 4 to 6 months can be required for the repair to heal completely (Blackburn, 2018). If forceps were used for the birth, the patient may have experienced vaginal or cervical lacerations; hematomas of the pelvic soft tissues can also occur with forceps-assisted birth (see Chapter 20).

Hemorrhoids (anal varicosities) are commonly seen (see Figure 10.15). Internal hemorrhoids may evert while the patient is pushing during birth. Patients often experience associated symptoms such as itching, discomfort, and bright red bleeding upon defecation. Hemorrhoids usually decrease in size within 6 weeks of childbirth.

Pelvic Muscular Support. The supporting structure of the uterus and vagina can be injured during childbirth and can contribute to later gynecological problems. Supportive tissues of the pelvic floor that are torn or stretched during childbirth may require up to 6 months to regain tone. **Kegel exercises**, which help strengthen perineal muscles and encourage healing, are recommended after childbirth (see Patient Teaching box: Kegel Exercise in Chapter 5). Later in life, patients can experience *pelvic relaxation*—the lengthening and weakening of the fascial supports of pelvic structures. These structures include the uterus, upper posterior vaginal wall, urethra, bladder, and rectum. Although relaxation can occur in any patient, it is commonly a direct but delayed complication of childbirth.

Abdomen

When the postpartum patient stands during the first days after birth, their abdomen protrudes and gives them a still-pregnant appearance. During the first 2 weeks after birth, the abdominal wall is relaxed. It takes about 6 weeks for the abdominal wall to return almost to its prepregnancy state (Figure 21.2). The skin regains most of its previous elasticity, but some striae may persist. The return of muscle tone depends on previous tone, proper exercise, and the amount of adipose tissue. Occasionally, with or without overdistension because of a large fetus or multiple fetuses, the abdominal wall muscles separate, a condition termed **diastasis recti** abdominis (see Figure 10.14, *B*). Persistence of this separation may be disturbing to the patient, but surgical correction rarely is necessary. With time, the separation becomes less apparent.

BOX 21.1 Lochial and Nonlochial Bleeding

Lochial Bleeding

- Lochia usually trickles from the vaginal opening. The steady flow is greater as the uterus contracts.
- A gush of lochia may result as the uterus is massaged. If it is dark in colour, it has been pooled in the relaxed vagina, and the amount soon lessens to a trickle of bright red lochia (in the early puerperium).

Nonlochial Bleeding

- If the bloody discharge spurts from the vagina, and the uterus is firmly contracted, there may be cervical or vaginal tears in addition to the normal lochia.
- If the amount of bleeding continues to be excessive and bright red, a tear may be the source.

ENDOCRINE SYSTEM

Placental Hormones

Significant hormonal changes occur during the postpartum period. Expulsion of the placenta results in dramatic decreases of the hormones produced by that organ. Estrogen and progesterone levels drop

Fig. 21.2 Abdominal wall 7 weeks after Caesarean birth is almost back to prepregnancy appearance. Note that the linea nigra is still visible. (Azoreg. This file is licensed under the Creative Commons Attribution-Share Alike 3.0 Unported license, https://creativecommons.org/licenses/by-sa/3.0/deed.en.)

markedly after expulsion of the placenta and reach their lowest levels 1 week after birth. Decreased estrogen levels are associated with diuresis of excess extracellular fluid accumulated during pregnancy. In nonlactating patients, estrogen levels begin to increase by 2 weeks after birth and by postpartum day 17 are higher than in patients who breastfeed (Isley & Katz, 2017).

Human chorionic gonadotropin (hCG) disappears fairly quickly from the circulation of the postpartum patient. However, because removing hCG from the extravascular and intracellular spaces takes additional time, the hormone can be detected in the maternal system for 3 to 4 weeks after birth (Blackburn, 2018).

Metabolic Changes

Decreases in human placental lactogen, estrogens, cortisol, and the placental enzyme insulinase reverse the diabetogenic effects of pregnancy, resulting in significantly lower blood glucose levels in the immediate puerperium. Patients with type 1 diabetes will likely require much less insulin for several days after birth, especially if they are breastfeeding. Because these normal hormonal changes make the puerperium a transitional period for carbohydrate metabolism, it is more difficult to interpret results of glucose tolerance tests at this time.

Thyroid volume gradually returns to normal by 3 months after birth. Levels of thyroxine and triiodothyronine decrease to prepregnant levels within 4 weeks. There is an increased risk for transient autoimmune thyroiditis in the postpartum period (Isley & Katz, 2017).

The basal metabolic rate remains elevated for the first 1 to 2 weeks after birth (James, 2014). It gradually returns to prepregnancy levels.

Pituitary Hormones and Ovarian Function

Prolactin levels in blood rise progressively throughout pregnancy. After birth, as levels of estrogen and progesterone decrease, prolactin levels increase more. In patients who breastfeed, prolactin levels are highest during the first month after birth and remain elevated above nonpregnant levels as long as the patient is breastfeeding. Serum prolactin levels are influenced by the frequency of breastfeeding, the duration of each feeding, and the degree to which supplementary feedings are used. Individual differences in the strength of an infant's sucking stimulus probably also affect prolactin levels. In nonlactating patients, prolactin levels decline after birth and reach the prepregnant range by the third postpartum week (Isley & Katz, 2017).

Lactating and nonlactating patients differ considerably in the timing of their first ovulation and when menstruation resumes. Ovulation occurs as early as 27 days after birth in nonlactating patients, with a mean time of about 7 to 9 weeks. About 70% of nonbreastfeeding patients resume menstruating by 12 weeks after birth. The mean time to ovulation in patients who breastfeed is about 6 months (Isley & Katz, 2017). The persistence of elevated serum prolactin levels in breastfeeding patients appears to be responsible for suppressing ovulation. In someone who is lactating, both the resumption of ovulation and the return of menses are determined in large part by breastfeeding patterns. For example, ovulation is delayed longer in patients who breastfeed exclusively than in patients who breastfeed and offer supplemental infant formula to their infants. Because of the uncertainty about the return of ovulation and menstruation, the patient who is not exclusively breastfeeding needs to consider contraceptive options early in the postpartum period. The first menstrual flow after childbirth is usually heavier than normal. Within three or four cycles the amount of menstrual flow returns to the person's prepregnancy volume.

URINARY SYSTEM

The hormonal changes of pregnancy (i.e., high steroid levels) contribute to an increase in renal function; diminishing steroid levels after childbirth may partly explain the reduced renal function that occurs during the puerperium. Kidney function returns to normal within 1 month after birth. About 6 weeks are required for the pregnancy-induced hypotonia and dilation of the ureters and renal pelves to return to the nonpregnant state. In a small percentage of patients, dilation of the urinary tract may persist for 3 months or longer, increasing the chances of developing a urinary tract infection (Isley & Katz, 2017).

Urine Components

The renal **glycosuria** induced by pregnancy disappears by 1 week postpartum, but lactosuria may occur in lactating patients. The blood urea nitrogen increases during the puerperium as autolysis of the involuting uterus occurs. Plasma creatinine levels return to normal by 6 weeks postpartum. Pregnancy-associated proteinuria resolves by 6 weeks after birth (Blackburn, 2018). Ketonuria may occur in patients with an uncomplicated birth or after a prolonged labour with dehydration.

Fluid Loss

Within 12 hours of birth, patients begin to lose excess tissue fluid accumulated during pregnancy. Postpartal diuresis, caused by decreased estrogen levels, removal of increased venous pressure in the lower extremities, and loss of the remaining pregnancy-induced increase in blood volume, also aids the body in ridding itself of excess fluid. Urine output of 3 000 mL or more each day during the first 2 to 3 days is common. Profuse diaphoresis often occurs, especially at night, for the first 2 to 3 days after birth. Fluid loss through perspiration and increased urinary output accounts for a weight loss of 2 to 3 kg during the early puerperium (Cunningham et al., 2018). Fluid loss through perspiration and increased urinary output accounts for a weight loss of approximately 2.25 kg during the puerperium.

Urethra and Bladder

Birth-induced trauma, increased bladder capacity following childbirth, and the effects of conduction anaesthesia (epidural or spinal) combine to cause a decreased urge to void. In addition, pelvic soreness caused by the forces of labour, vaginal lacerations, or the episiotomy reduces or alters the voiding reflex. Decreased voiding combined with postpartal diuresis may result in bladder distension.

Immediately after birth, excessive bleeding can occur if the bladder becomes distended because it pushes the uterus up and to the side and prevents it from contracting firmly. Later in the puerperium, overdistension can make the bladder more susceptible to infection and impede the resumption of normal voiding (Cunningham et al., 2018). With adequate emptying of the bladder, bladder tone is usually restored by 5 to 7 days after childbirth.

Some patients experience *stress incontinence* during the postpartum period. This is more likely to occur after vaginal than Caesarean birth. Stress incontinence can be related to tissue trauma to the pelvic floor occurring with maternal expulsive efforts and increased size of the newborn. Coached pushing versus uncoached (non-Valsalva) pushing can increase the risk for damage to the pelvic floor and subsequent stress incontinence (James, 2014).

GASTROINTESTINAL SYSTEM

Most new mothers are very hungry shortly after birth and usually can tolerate a regular diet. Requests for extra portions of food and frequent snacks are not uncommon.

A spontaneous bowel evacuation may not occur for 2 to 3 days after childbirth. This delay can be explained by decreased muscle tone in the intestines during labour and the immediate puerperium, prelabour diarrhea, and lack of food or dehydration during labour. The postpartum patient often anticipates discomfort during the bowel movement because of perineal tenderness as a result of episiotomy, lacerations, or hemorrhoids and may resist the urge to defecate. Patients need to be encouraged to increase fluid and fibre intake to prevent constipation and discomfort. Regular bowel habits should be reestablished when bowel tone returns. Occasionally stool softeners may be required.

Operative vaginal birth (forceps or vacuum use) and anal sphincter lacerations are associated with an increased risk of postpartum anal incontinence. Patients with this problem are more often incontinent of flatus than of stool. If anal incontinence lasts more than 6 months, studies should be conducted to determine the specific cause and appropriate treatment (Isley & Katz, 2017).

Patients who have had a Caesarean birth may have abdominal pain due to a buildup of flatus. Patients need to be encouraged to move as much as possible to enhance movement of the intestinal system.

BREASTS

Promptly after birth there is a decrease in the concentrations of hormones (i.e., estrogen, progesterone, hCG, prolactin, cortisol, and insulin) that stimulated breast development during pregnancy. The time it takes for these hormones to return to prepregnancy levels is determined in part by whether the mother breastfeeds their infant.

Breastfeeding Mothers

During the first 24 hours after birth, there is little, if any, change in the breast tissue. **Colostrum**, or early milk, a clear, yellow fluid, may be expressed from the breasts. The breasts initially feel soft and then gradually become fuller and heavier as the colostrum transitions to milk by about 72 to 96 hours after birth; this is often referred to as the "milk coming in" or lactogenesis II. The breasts may feel warm, firm, and somewhat tender. Bluish-white milk with a skim-milk appearance (true milk) can be expressed from the nipples. As milk glands and milk ducts fill with milk, breast tissue may feel somewhat nodular or lumpy. Unlike the lumps associated with fibrocystic breast disease or cancer (which can be palpated consistently in the same location), the nodularity associated with milk production tends to shift in position. Some patients experience **engorgement** at this time due to an increase in blood and lymphatic fluid as milk production increases. Engorged breasts are hard and uncomfortable; the fullness of the nipple tissue can make it difficult for the newborn to latch on and feed. With frequent breastfeeding and proper care, engorgement is a temporary condition that typically lasts only 24 to 48 hours (see Chapter 27).

Nonbreastfeeding Mothers

The breasts generally feel nodular in contrast to the granular feel of breasts in nonpregnant patients. The nodularity is bilateral and diffuse. Prolactin levels drop rapidly. Colostrum is present for the first few days after childbirth. Palpation of the breast on the second or third day as milk production begins may indicate tissue tenderness in some patients. On the third or fourth postpartum day engorgement may occur. The breasts are distended (swollen), firm, tender, and warm to the touch. Breast distension is caused primarily by the temporary congestion of veins and lymphatics rather than by an accumulation of milk. Milk is present but should not be expressed. Axillary breast tissue (the tail of Spence) and any accessory breast or nipple tissue along the milk line can be involved. Engorgement resolves spontaneously, and discomfort decreases usually within 24 to 36 hours. A well-fitted supportive bra, ice packs, fresh cabbage leaves, or mild analgesics may be used to relieve discomfort. Nipple stimulation should be avoided. If suckling is never begun (or is discontinued), lactation ceases within a few days to a week.

CARDIOVASCULAR SYSTEM

Blood Volume

Changes in blood volume after birth depend on several factors, such as blood loss during childbirth and the amount of extravascular water (physiological edema) mobilized and excreted.

Pregnancy-induced hypervolemia (an increase in blood volume of 40 to 45% over prepregnancy values near term) allows most patients to tolerate considerable blood loss during childbirth. The average blood loss for a vaginal birth of a single fetus ranges from 300 mL to 500 mL (10% of blood volume). The typical blood loss for patients who give birth by Caesarean is 500 mL to 1 000 mL (15 to 30% of blood volume). During the first few days after birth, the plasma volume decreases further as a result of diuresis (Blackburn, 2018).

The patient's response to blood loss during the early puerperium differs from that in a nonpregnant patient. Three postpartum physiological changes protect the patient by increasing the circulating blood volume: (1) elimination of uteroplacental circulation reduces the size of the maternal vascular bed by 10 to 15%; (2) loss of placental endocrine function removes the stimulus for vasodilation; and (3) mobilization of extravascular water stored during pregnancy occurs. By the third postpartum day, the plasma volume has been replenished as extravascular fluid returns to the intravascular space (Isley & Katz, 2017) (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Postpartum Blood Loss and Fatigue

You are caring for four patients on the postpartum unit, two of whom had vaginal births and two of whom had Caesarean births. Each of the patients has stated they are feeling tired and has expressed concern about the amount of blood they lost during birth. Before providing patient education related to fatigue after birth and blood loss, you review the patient records with attention to estimated blood loss, hemoglobin and hematocrit values, intake and output, and nursing notes.

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about the relation between tiredness (fatigue) after birth and blood loss? What other information would be important to know about each patient?
2. Assumptions—What assumptions can be made about the following factors?
   a. Comparison of amount of blood loss between patients who give birth vaginally and by Caesarean
   b. Postpartum norms for hematocrit and hemoglobin for patients who give birth vaginally and by Caesarean
   c. Causes of fatigue after birth
   d. Interventions to alleviate fatigue and replace blood lost at birth
3. What implications and priorities for nursing care can be drawn at this time?

Cardiac Output

Pulse rate, stroke volume, and cardiac output increase throughout pregnancy. Dramatic changes in maternal hemodynamic status occur with birth of the newborn and delivery of the placenta. The immediate blood loss reduces plasma volume without reducing cardiac output. This is due to the compensatory influx of nearly 500 mL of blood into the maternal system from the uteroplacental bed, a rapid decrease in uterine blood flow, and mobilization of extracellular fluid. Typically, cardiac output is increased immediately after birth by 60 to 80% over prelabour values; it returns to prelabour values within 1 hour. Stroke volume, cardiac output, end-diastolic volume, and systemic vascular resistance remain elevated over nonpregnant values for 12 weeks after birth and may not stabilize until 24 weeks after birth (Blackburn, 2018).

Vital Signs. Few alterations in vital signs are seen under normal circumstances. Heart rate and blood pressure return to nonpregnant levels within a few days (Isley & Katz, 2017) (Table 21.1). Respiratory function rapidly returns to nonpregnant levels after birth. After the uterus is emptied, the diaphragm descends, the normal cardiac axis is restored, and the point of maximal impulse and the electrocardiogram are normalized.

As many as 50% of patients experience shivering episodes during the first few minutes up to the first hour after birth. The exact cause is unknown, and usually no treatment is needed; if the shivering is related to the effects of anaesthesia, pharmacological treatment may be needed (Berens, 2021).

Blood Components.

Hematocrit and hemoglobin. In patients with an average blood loss during birth, the hematocrit level drops moderately for 3 to 4 days, then begins to increase, and reaches nonpregnant levels by 8 weeks postpartum (Isley & Katz, 2017). A postpartum hematocrit can be lower than normal if the blood loss was increased or if the hypervolemia of pregnancy was less than normal.

TABLE 21.1 Vital Signs After Childbirth

Normal Findings	Deviations From Normal Findings and Probable Causes
Temperature	
During the first 24 hours temperature may increase to 38°C as a result of dehydrating effects of labour. After 24 hours the patient should be afebrile.	A diagnosis of puerperal sepsis is suggested if an increase in maternal temperature to 38°C is noted after the first 24 hours after childbirth and recurs or persists for 2 days. Other possibilities are mastitis, endometritis, urinary tract infections, and other systemic infections.
Pulse	
Pulse, along with stroke volume and cardiac output, remains elevated for the first hour or so after childbirth. It gradually decreases over the first 48 hours postpartum. Puerperal bradycardia (40–50 beats/min) is common.	A rapid pulse rate or one that is increasing may indicate hypovolemia as a result of hemorrhage or an increased temperature.
Respirations	
The respiratory rate, which was unchanged or slightly increased during pregnancy, should be within the patient's normal prepregnancy range soon after birth.	Hypoventilation (respiratory depression) may occur after an unusually high subarachnoid (spinal) block or epidural opioid after a Caesarean birth.
Blood Pressure	
Blood pressure shows a transient increase of approximately 5% over the first few days after birth, returning to prepregnancy levels over weeks or months. Orthostatic hypotension, as indicated by feelings of faintness or dizziness immediately after standing up, can develop in the first 48 hours as a result of the splanchnic engorgement that may occur after birth.	A low or decreasing blood pressure may indicate the existence of hypovolemia secondary to hemorrhage; however, it is a late sign, and other symptoms of hemorrhage are usually seen first. An increased reading may result from excessive use of vasopressor or oxytocic medications. Because gestational hypertension can persist into or occur first in the postpartum period, routine evaluation of blood pressure is needed. If a patient states they have a headache, hypertension must be ruled out as a cause before analgesics are administered.

White blood cell count. Normal leukocytosis of pregnancy ranges from 5 to 15 $\times$ 10^9/L. During and after labour the white blood cell may rise to 30 $\times$ 10^9/L. Leukocytosis, coupled with the increase in erythrocyte sedimentation rate that normally occurs, can obscure the diagnosis of acute infections at this time (Antony et al., 2017).

Coagulation factors. Clotting factors and fibrinogen are normally increased during pregnancy and remain elevated in the immediate puerperium. When combined with vessel damage and immobility, this hypercoagulable state causes an increased risk of thromboembolism,

especially after a Caesarean birth. Patients need to be encouraged to move around as soon as possible after birth to prevent thromboembolism, and some patients may require anticoagulants. Fibrinolytic activity also increases during the first few days after childbirth (Isley & Katz, 2017). Factors I, II, VIII, IX, and X decrease to nonpregnant levels within a few days. Fibrin split products, probably released from the placental site, can also be found in maternal blood.

Varicosities

Varicosities (varices) of the legs and around the anus (hemorrhoids) are common during pregnancy (Figure 21.3). All varices, even the less common vulvar varices, regress (empty) rapidly immediately after childbirth. Total or nearly total regression of varicosities is expected after childbirth.

RESPIRATORY SYSTEM

When birth occurs, there is an immediate decrease in intra-abdominal pressure, which allows for greater excursion of the diaphragm. With decreased pressure on the diaphragm and reduced pulmonary blood flow, chest wall compliance increases. Rib cage elasticity can take months to return to a prepregnancy state. The costal angle that was increased during pregnancy may not completely return to the prepregnancy level. The decline in progesterone that occurs with loss of the placenta causes $Paco_2$ levels to rise (Blackburn, 2018).

NEUROLOGICAL SYSTEM

Neurological changes during the puerperium are those that result from a reversal of maternal adaptations to pregnancy and those resulting from trauma during labour and childbirth.

Pregnancy-induced neurological discomforts disappear after birth. Elimination of physiological edema through the diuresis that follows childbirth relieves carpal tunnel syndrome by easing compression of the median nerve. The periodic numbness and tingling of fingers usually disappear after the birth, unless lifting and carrying the baby aggravates the condition.

Headaches are not uncommon in the first few weeks postpartum. The most common form of headache occurs in breastfeeding patients and are those caused by muscular contraction or tension and migraines without aura. Tension headaches are characterized by a persistent bandlike or viselike pain extending from the base of the neck to the forehead (Blackburn 2018). Headaches do require careful assessment as they may be due to postpartum-onset pre-eclampsia, or leakage of cerebrospinal fluid into the extradural space during placement of the needle for administration of epidural or spinal anaesthesia (see Chapter 18, Postdural puncture headache [PDPH]).

Fig. 21.3 Varicosities in legs. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

MUSCULOSKELETAL SYSTEM

Adaptations of the mother's musculoskeletal system that occur during pregnancy are reversed in the puerperium. These adaptations include the relaxation and subsequent hypermobility of the joints and the change in the mother's centre of gravity in response to the enlarging uterus. The joints are completely stabilized by 6 to 8 weeks after birth. Although all other joints return to their normal prepregnancy state, those in the parous patient's feet do not. The new mother may notice a permanent increase in shoe size. Back pain usually resolves in a few weeks or months following birth.

INTEGUMENTARY SYSTEM

Melasma (chloasma or "mask of pregnancy") usually disappears in the postpartum period but can persist in about 30% of patients (Wang & Kroumpouzos, 2017). Hyperpigmentation of the areolae and linea nigra may not regress completely after childbirth. Some patients will have permanent darker pigmentation of those areas. **Striae gravidarum** (stretch marks) (Figure 10.12) on the breasts, abdomen, and thighs may fade but usually do not disappear.

Vascular abnormalities such as spider angiomas (nevi), palmar erythema, and epulis generally regress in response to the rapid decline in estrogen after the end of pregnancy. For some patients, spider nevi persist indefinitely.

Hair growth slows during the postpartum period. Some patients may experience hair loss because the amount of hair lost is temporarily more than the amount regrown. The abundance of fine hair seen during pregnancy usually disappears after giving birth; however, any coarse or bristly hair that appears during pregnancy usually remains. Fingernails return to their prepregnancy consistency and strength.

IMMUNE SYSTEM

In the postpartum period, the patient's immune system, which was mildly suppressed during pregnancy, gradually returns to its prepregnant state, although the exact timeline is unclear (Blackburn, 2018). This rebound of the immune system can trigger flare-ups of autoimmune conditions such as multiple sclerosis or lupus erythematosus (Isley & Katz, 2017).

KEY POINTS

- The uterus involutes rapidly after birth and returns to the true pelvis within 2 weeks and resumes normal size and position by 6 weeks.
- The rapid decrease in estrogen and progesterone levels after expulsion of the placenta is responsible for triggering many of the anatomical and physiological changes in the puerperium.

- Assessment of lochia and fundal height is essential to monitor the progress of normal involution and to identify potential problems.
- The return of ovulation and menses is determined in part by whether the patient breastfeeds their infant.
- Marked diuresis, decreased bladder sensitivity, and overdistension of the bladder can lead to problems with urinary elimination.
- Pregnancy-induced hypervolemia, combined with several postpartum physiological changes, allows the patient to tolerate considerable blood loss at birth.
- Few alterations in vital signs are seen after birth under normal circumstances.
- Hypercoagulability, vessel damage, and immobility predispose the patient to thromboembolism.

Nursing Care of the Family During the Postpartum Period

Keri-Ann Berga

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe components of a systematic postpartum assessment.
2. Recognize signs of potential complications in the postpartum patient.
3. Identify criteria for postpartum discharge.
4. Develop a plan to provide care for a postpartum patient.
5. Explain the influence of cultural beliefs and practices on postpartum care.
6. Identify psychosocial needs of the patient in the early postpartum period.
7. Prepare a plan for teaching for a new postpartum parent's self-management.
8. Describe the nurse's role in these postpartum follow-up strategies: home visits, telephone follow-up, warm lines and help lines, support groups, and referrals to community resources.

At no other time is family-centred maternity and newborn care more important than in the postpartum period. Nursing care is provided in the context of the family unit and focuses on assessment and support of the postpartum patient's physiological and emotional adaptation after birth. During the early postpartum period, components of nursing care include assisting the new parent with rest and recovery from the process of labour and birth, assessing their physiological and psychological adaptation after birth, preventing complications, educating them about self-care and newborn care, and supporting the postpartum parent and partner during the initial transition to parenthood. In addition, the nurse considers the needs of other family members and includes strategies when providing nursing care to help the family adjust to the new baby.

The approach to the care of patients after birth is wellness oriented. In Canada most patients remain hospitalized no more than 1 or 2 days after vaginal birth and 2 to 4 days for a Caesarean birth. Because so much important information needs to be shared with these patients in a very short time, their care and follow-up in the community must be thoughtfully planned and provided. This chapter discusses nursing care of the childbearing person and their family in the postpartum period, extending into the fourth trimester.

TRANSFER FROM THE RECOVERY AREA

After the initial recovery period of about 1 to 2 hours has been completed (see Chapter 17: The Fourth Stage of Labour), the patient may be transferred to a postpartum room in the same or another nursing unit. In facilities with labour, birth, recovery, and postpartum (LBRP) rooms, the patient labours, gives birth, recovers, and spends the postpartum period in the same room, and the nurse who provides care during the recovery period may continue to care for the patient in the same space. In some settings patients who have received general or regional anaesthesia must be cleared for transfer from the recovery area by a member of the anaesthesia care team. In other settings a nurse makes this determination.

In preparing the transfer report, the nurse caring for the patient during the recovery period uses information from the records of admission, birth record, and recovery. Information communicated to the postpartum nurse includes obstetrical history; age; anaesthetic used; any medications given; duration of labour and time of rupture of membranes; whether labour was induced or augmented; type of birth and repair; blood type and Rh status; group B streptococcus status; status of rubella immunity; hepatitis serology test results; intravenous infusion of any fluids; physiological status since birth; description of fundus, lochia, bladder, and perineum; sex and weight of infant; time of birth; name of the care provider for both newborn and postpartum patient; chosen method of feeding; any abnormalities noted; and assessment of initial parent–infant interactions. In addition, specific information should be provided regarding the infant's Apgar scores (see Chapter 26), voiding, and stooling and whether the infant has been fed since birth. Nursing interventions that have been completed (e.g., eye prophylaxis and vitamin K injection) also must be recorded. Table 22.1 gives examples for documenting this information before the transfer of the patient from the recovery area.

TABLE 22.1 Recovery Nurse's Report

Item	Example of Documentation of Mother	Example of Documentation of Newborn
Type of labour and birth; unusual observations, if any, of the placenta	Spontaneous or assisted (forceps, vacuum extraction) vaginal birth; vertex presentation; time of ROM	Spontaneous or assisted (forceps) vaginal birth; vertex presentation; time of ROM
GTPAL, age	G1 T0 P0 A0 L0, age 22 yr; 39 wk of gestation	G1 T0 P0 A0 L0, age 22 yr; 39 wk of gestation
Anaesthesia and analgesia used	None; epidural, spinal, local	None; epidural, spinal, local
Condition of perineum	Episiotomy; lacerations; repaired; intact	
Events since birth	Vital signs, BP, fundus, lochia, intake and output, medications (dosage, time of administration, and results); length of time newborn was skin-to-skin and with whom; response to newborn; observation of family interactions, including siblings, if present	Vital signs, blood glucose level (if assessed), nursed at breast for _____ min Voided × 1; meconium stool × 1 Eye prophylaxis given Vitamin K injection given Skin-to-skin for _____ min Held by siblings who are happy (or have other response to newborn)
Condition and sex of newborn; other information	Time of birth; weight; whether breastfeeding or bottle-feeding; sex of the baby	Time of birth; Apgar at 1 and 5 min; sex; weight; name of health care provider; breastfeeding or bottle-feeding
Relevant information from prenatal record	Need for rubella vaccination; presence of infections; hepatitis B status; HIV status; blood type; Rh status; GBS status and treatment if positive	Unremarkable pregnancy; mother's hepatitis B status and GBS status; whether mother received adequate antibiotic prophylaxis for GBS
Miscellaneous information: IV drip	If IV drip is infusing, rate of infusion, medications added (e.g., oxytocin), whether to keep open or discontinue after completion of bag that is hung	Whether mother received magnesium sulphate; time of last systemic analgesia; IV solution and rate
Social factors	If patient is releasing baby for adoption, whether they want to see baby, breastfeed, or allow visitors, or other preferences they may have	Baby up for adoption

BP, Blood pressure; *GBS,* group B streptococcus; *HIV,* human immunodeficiency virus; *IV,* intravenous; *ROM,* rupture of membranes.

In recent years, many inpatient nursing units, including perinatal care areas, have used a bedside report. Bedside reporting is increasingly being used instead of the traditional report given at the nurses' station. Bedside reporting has been shown to improve patient safety and patient satisfaction. Patients feel more involved in their plan of care, which increases their satisfaction. Additionally, completing the report at the bedside has enabled many nurses to both visualize and communicate with the patient at the time of report, which improves patient safety (Agency for Healthcare Research and Quality [AHRQ], 2013/2017).

PLANNING FOR DISCHARGE

From their initial contact with the labouring patient, nurses prepare the new parent for the time when they will return home. Planning for discharge begins with the first interaction between the nurse, the childbearing person, and their family and continues until they leave the hospital or birthing facility.

The length of stay after giving birth depends on many factors, including the physical condition of the mother and the newborn, emotional status of the mother, social support at home, and patient education needs for self-care and newborn care. Those who give birth in birthing centres and in the hospital may be discharged within a few hours, after the mother's and newborn's conditions are stable, although most mothers and newborns with no complications are discharged from the hospital within 24 to 36 hours after vaginal birth.

Before discharge the nurse needs to ensure that the health of the mother and newborn is stable and that the new parent is able and confident to provide care for their newborn; there should be adequate support systems in place and access to follow-up care. It is essential that the nurse consider the individual needs of the patient and their newborn and provide care that is coordinated to meet these needs. Timely physiological interventions and treatment can help prevent morbidity and hospital readmission. Hospital-based maternity nurses continue to play invaluable roles as caregivers, teachers, and advocates for parents, newborns, and families in developing and implementing effective home-care strategies. With predetermined criteria for identifying low risk in mothers and newborns (Box 22.1), the length of hospitalization can be based on medical need for care in an acute care setting or in consideration of ongoing care needed in the home. Postpartum order sets and maternal teaching checklists (Figure 22.1) can be used to accomplish patient care tasks and educational outcomes. Nurses must also provide discharge teaching related to the newborn.

With coordination, clinical care and education can be planned and provided throughout the pregnancy, during the hospital stay, and in the home after discharge to promote and support the family's continued well-being. To optimize the health of mothers and infants, postpartum care should be an ongoing process, rather than a single encounter, with services and supports tailored to each individual's needs (McKinney et al., 2018). In addition, education programs should include information for both at-risk and healthy postpartum patients, because complications may not be clearly identified or apparent before a patient's discharge after birth (Suplee et al., 2017). Community-based postpartum care programs are also key to reducing readmission of newborns. Mothers should be contacted and, if needed, seen by a skilled caregiver within 24 to 48 hours after discharge to ensure that newborn health issues are identified (e.g., jaundice, dehydration).

BOX 22.1 Criteria for Discharge

Mother

Perineum is healing with appropriate care provided.
There are no intrapartum or postpartum complications that require ongoing treatment or observation.
The mother is mobile with adequate pain control.
Bladder and bowel functions are adequate (although patient will probably not have had a bowel movement).
The mother has received Rh immune globulin, if appropriate.
The mother has demonstrated ability to feed the infant—i.e., the infant has demonstrated adequate latch.
Contraception advice has been provided.
The care provider for ongoing care has been identified and notified of discharge.
The community liaison nurse is aware of discharge and has access to the patient's contact information for postdischarge follow-up (if appropriate).
Appointments are made for follow-up and the mother understands the necessity for and timing of newborn health checks.
If the home environment is not adequate, community resources are in place to support the new mother and newborn.
The mother is aware of community resources and how and when to access these resources.
The mother has received rubella immunization if not immune.

Infant

The newborn is a full-term (37 to 42 weeks) with weight appropriate for gestational age.
There is normal cardiorespiratory adaptation to extrauterine life.
Temperature, respirations, and heart rate are within normal limits and stable.
At least two successful feedings have been completed (normal sucking and swallowing).
Urination and stooling have occurred at least once.
There is no evidence of significant jaundice in the first 24 hours after the birth.
There is no evidence of sepsis.
There is no evidence of bleeding from circumcision for ≥2 hours (if procedure is performed prior to discharge).
Metabolic screening tests have been performed according to provincial policies; tests should be repeated at the follow-up visit if done before the infant is 24 hours old.
Newborn hearing screening test is completed before discharge; if not, alternative arrangements have been made for testing.
The mother is able to provide newborn care and recognizes signs of illness or concerns related to their newborn.
Arrangements have been made for assessment and evaluation of the newborn within 48 hours of discharge, i.e., with a community health nurse, physician, or midwife.
Initial hepatitis B vaccine has been given or scheduled for the first follow-up visit if required by provincial guidelines.
Postpartum follow-up screening has been completed, based on jurisdiction. Some provinces offer telephone calls, clinic or home visits, depending on risk factors.

LEGAL TIP: Early Discharge

Regardless of whether or not the postpartum patient and their family have chosen early discharge, the nurse and the primary health care provider are responsible for ensuring that they are not discharged before their condition has stabilized within normal limits.

NURSING CARE

The nursing plan of care includes both the postpartum person and their newborn. It is also family centred, considering the needs and concerns of the family and focusing on family unity (Waller-Wise, 2012). In most hospitals in Canada, combined care (also called *single-room maternity care*) is practised. Nurses in these settings have been educated in both mother and newborn care and function as primary nurses for the mother and newborn.

Ongoing Physical Assessment

Ongoing assessments are performed throughout hospitalization. In addition to vital signs, physical assessment of the postpartum patient focuses on evaluation of the breasts, uterine fundus, lochia, perineum, bladder and bowel function, vital signs, and legs, using the acronym BUBBLLEE. See Table 22.2 for normal findings.

B = Breasts (firmness) and nipples
U = Uterine fundus (location; consistency)
B = Bladder function (amount; frequency)
B = Bowel function (passing gas or bowel movements)
L = Lochia (amount; colour)
L = Legs (peripheral edema)
E = Episiotomy/Laceration or Caesarean birth incision (perineum: discomfort; condition of repair, if done)
E = Emotional status (mood, fatigue)

Routine Laboratory Tests. Several laboratory tests may be performed in the immediate postpartum period. Hemoglobin and hematocrit values may be evaluated on the first postpartum day to assess blood loss during birth, especially after Caesarean birth, although it is important to remember that hematocrit can be lower than normal if the blood loss was increased or if the hypervolemia of pregnancy was less than normal. In addition, if the patient's rubella and Rh status are unknown, tests to determine their status and need for possible treatment should be performed at this time.

Nursing Interventions

Based on the available data (e.g., medical record) and assessment findings, the nurse plans with the patient which nursing measures are appropriate and which are to be given priority. The nursing plan of care includes periodic assessments to detect deviations from normal physical changes, measures to relieve discomfort or pain, safety measures to prevent injury or infection, and teaching and counselling measures designed to promote the postpartum patient's feelings of competence in self-care and newborn care. The partner as well as other family members who are present can be included in the teaching. The nurse needs to evaluate continuously and be ready to change the plan, if indicated. Almost all hospitals use standardized care plans or care maps as a base. Nurses individualize care of the postpartum patient and newborn according to their specific needs (see Nursing Care Plan: Postpartum Care—Vaginal Birth, available on Evolve). Signs of potential complications that may be identified during the assessment process are listed in Table 22.2.

Nurses assume many roles while implementing the plan of care. They provide direct physical care, teach mother and baby care, and provide anticipatory guidance and counselling. Perhaps most important of all, they nurture the postpartum patient by providing encouragement and support as they begin to assume the many tasks of motherhood. Nurses who take the time to "mother the mother" do much to increase feelings of self-confidence in new mothers. Nurses need to be careful to

TABLE 22.2 Postpartum Assessment and Signs of Potential Complications

Assessment	Normal Findings	Signs of Potential Complications
Blood pressure (BP)	Consistent with BP baseline during pregnancy; can have orthostatic hypotension for 48 hours	Hypertension: anxiety, pre-eclampsia, essential hypertension Hypotension: hemorrhage
Temperature	36.2°–38° C (97.2°–100.4° F)	>38° C (100.4° F) after 24 hours: infection
Pulse	60–100 beats/min	Tachycardia: pain, fever, dehydration, hemorrhage
Respirations	12–24 breaths/min	Bradypnea: effects of opioid medications Tachypnea: anxiety; may be sign of respiratory disease
Breath sounds	Clear to auscultation	Crackles: possible fluid overload
Breasts	Days 1–2: soft	Firmness, heat, pain: engorgement
	Days 2–3: filling Days 3–5: full, soften with breastfeeding (milk is "in")	Redness of breast tissue, heat, pain, fever, body aches: mastitis
Nipples	Skin intact; no soreness reported	Redness, bruising, cracks, fissures, abrasions, blisters: usually associated with latching difficulties
Uterus (fundus)	Firm, midline; first 24 hours at level of umbilicus; involutes ≈1–2 cm/day	Soft, boggy, higher than expected level: uterine atony Lateral deviation: distended bladder
Bladder	Able to void spontaneously by 8 hours; no distension; able to empty completely; no dysuria	Overdistended bladder possibly causing uterine atony, excessive lochia
	Diuresis begins ≈12 hours after birth; can void 3 000 mL/day	Dysuria, frequency, urgency: infection
Bowels and abdomen	Passing flatus soon after vaginal birth Bowel movement by day 2 or 3 after birth Abdomen soft, active bowel sounds in all quadrants (assessed if Caesarean birth)	No bowel movement by day 3 or 4: constipation; diarrhea
Lochia	Birth to 3-4 days: rubra (dark red) Day 4–to 2–4 weeks: serosa (brownish red or pink) After 10–14 days: alba (yellowish white) Amount: scant to moderate Few clots Fleshy odour	Large amount of lochia: uterine atony, vaginal or cervical laceration Foul odour: infection
Swelling (legs)	Peripheral edema possibly present	Redness, tenderness, pain, venous thromboembolism (VTE)
Perineum/Incision	Minimal edema	Pronounced edema, bruising, hematoma
	Laceration or episiotomy: edges approximated	Redness, warmth, drainage: infection
	Caesarean: incision dressing clean and dry; suture line intact	Abdominal incision—redness, edema, warmth, drainage: infection
Rectal area	No hemorrhoids; if hemorrhoids are present, soft and pink	Discoloured hemorrhoidal tissue, severe pain: thrombosed hemorrhoid
Emotional status/ Energy level	Able to care for self and newborn; able to sleep Excited, happy, interested or involved in newborn care Sad and tearful on day 3–14: postpartum blues	Lethargy, extreme fatigue, difficulty sleeping: postpartum depression Sad, tearful, disinterested in newborn care: postpartum mood disorder

include the patient's partner and other primary support persons in education and counselling. The childbearing person and their family need to be oriented to their surroundings. Familiarity with the postpartum unit, routines, resources, and personnel reduces one potential source of anxiety—the unknown. The mother can be reassured through knowing whom and how they can call for assistance and what they can expect in the way of supplies and services. If the mother's usual daily routine before admission differs from the routine of the facility, the nurse should work with them to develop a mutually acceptable routine. The nurse must also confirm the patient's identity by checking their wristband. At the same time, the newborn's identification number is matched with the corresponding band on the mother's wrist and, in some instances, the partner's wrist. The nurse should determine how the mother wishes to be addressed and note their preference in the health care record.

Promoting Safety. While newborn abduction from hospitals in Canada is rare, hospital staff should be alert and prepared for such an event. The mother should be taught to check the identity of any person who comes to remove the baby from their room; for instance, hospital personnel wear picture identification badges. On some units all staff members wear matching scrubs or special badges. Other units use closed-circuit television, computer monitoring systems, or fingerprint identification pads. Many hospitals have systems to prevent newborn abduction that involve attaching a security tag to the newborn's ankle. This will cause an alarm to sound or doors to lock when the newborn is close to a unit exit. Patients and nurses must work together to ensure the safety of newborns in the hospital environment.

SAFETY ALERT

Nurses play a critical role in educating parents about measures to prevent newborn abduction. Parents should be instructed how to identify legitimate hospital personnel, to never leave the newborn in the hospital room without direct supervision, and to request a second staff member to verify the identity of any questionable person who wants to take the baby from the mother's room. Parents should be instructed to use caution when posting photos of the new baby on the Internet and publishing public notices about the birth.

Preventing Excessive Bleeding. The most frequent cause of excessive bleeding after childbirth is uterine **atony** (i.e., failure of the uterine muscle to contract firmly). The two most important interventions for preventing excessive bleeding are maintaining good uterine tone and preventing bladder distension. If uterine atony occurs, the relaxed uterus distends with blood and clots, blood vessels in the placental site are not clamped off, and excessive bleeding results. Although the cause of uterine atony is not always clear, it often results from retained placental fragments.

Excessive blood loss after childbirth can also be caused by vaginal or vulvar hematomas or by unrepaired lacerations of the vagina or cervix. These potential sources might be suspected if excessive vaginal bleeding occurs in the presence of a firmly contracted uterine fundus. See discussion of postpartum hemorrhage (PPH) in Chapter 24 for more information on reasons for excessive bleeding.

! NURSING ALERT

A perineal pad saturated in 15 minutes or less or pooling of blood under the buttocks is an indication of excessive blood loss requiring immediate assessment, intervention, and notification of the primary health care provider.

Accurate visual estimation of blood loss is an important nursing responsibility. Blood loss is usually described subjectively as scant, light, moderate, or heavy (profuse). Figure 22.2 shows examples of perineal pad saturation corresponding to each of these descriptions.

Although postpartal blood loss may be estimated by observing the amount of staining on a perineal pad, it is difficult to judge the amount of lochial flow based only on observation of perineal pads. Quantification of blood loss by weighing clots and items saturated with blood (1 g equals 1 mL) is recommended as the most accurate way to objectively determine blood loss.

Any estimation of lochial flow is inaccurate and incomplete without consideration of the time factor. The patient who saturates a perineal pad in 1 hour or less is bleeding much more heavily than someone who saturates a perineal pad in 8 hours. When assessing blood loss, the nurse needs to ask the patient how long it has been since they changed their perineal pad.

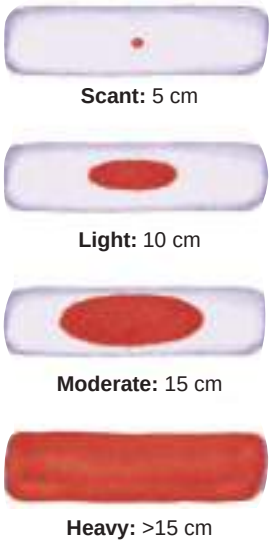

Fig. 22.2 Blood loss after birth is assessed by the extent of perineal pad saturation as (from top to bottom) scant, light, moderate, or heavy (one pad saturated within 2 hours). (From Leifer, G. [2015]. *Introduction to maternity and pediatric nursing* [7th ed.]. Saunders.)

Nurses in general tend to overestimate rather than underestimate blood loss. Also, different brands of perineal pads vary in their saturation volume and soaking appearance. For example, blood placed on some brands tends to soak down into the pad, whereas on other brands it tends to spread outward. Nurses should determine saturation volume and soaking appearance for the perineal pad brands used in their institution to improve accuracy of blood loss estimation.

! NURSING ALERT

The nurse should always check under the mother's buttocks. Although the amount on the perineal pad may be slight, blood may flow between the buttocks onto the linens under the patient. When this happens, excessive bleeding goes undetected.

When excessive bleeding occurs, vital signs need to be monitored closely. Blood pressure is not a reliable indicator of impending shock from early hemorrhage because compensatory mechanisms prevent a significant drop in blood pressure until the person has lost 30 to 40% of their blood volume. Respirations, pulse, skin condition, urinary output, and level of consciousness are more sensitive means of identifying hypovolemic shock. The frequent physical assessments performed during the fourth stage of labour (see Box 17.17) are designed to provide prompt identification of excessive bleeding (see Emergency box: Hypovolemic Shock).

EMERGENCY

Hypovolemic Shock

Signs and Symptoms

Persistent significant bleeding: Perineal pad is soaked within 15 minutes; initially it may not be accompanied by a change in the patient's vital signs, colour or behaviour.
Patient states that they feel weak, light-headed, "funny," or "nauseated" or "see stars."
Patient does not want to hold their baby.
Patient appears anxious or exhibits air hunger.
Skin colour turns ashen or greyish.
Skin feels cool and clammy.
Pulse rate increases.
Blood pressure declines.

Interventions

Notify primary health care provider.
If uterus is atonic, massage gently and expel clots to cause uterus to contract.
Administer uterotonic medications (e.g., oxytocin, prostaglandins) as ordered to increase uterine tone.
Give oxygen by nonrebreather face mask or nasal prongs at 8 to 10 L/min.
Tilt patient to their side or elevate the right hip; elevate the legs to at least a 30-degree angle.
Provide additional or maintain existing IV infusion of lactated Ringer's solution or normal saline solution to restore circulatory volume (the patient should have two patent IV lines: insert second IV infusion using 16- to 18-gauge IV catheter).
Administer blood or blood products as ordered.
Monitor vital signs.
Insert an in-dwelling urinary catheter to monitor perfusion of kidneys.
Administer emergency medications as ordered.
Prepare for possible surgery or other emergency treatments or procedures.
Record incident, medical and nursing interventions instituted, and person's response to interventions.

IV, Intravenous.

Maintaining uterine tone. A major intervention to restore good uterine tone is stimulation, by gently massaging the fundus until firm (Figure 22.3). Fundal massage can cause a temporary increase in the amount of vaginal bleeding seen as pooled blood leaves the uterus. Clots can be expelled. The uterus may remain boggy even after massage and expulsion of clots.

Fundal massage can be a very uncomfortable procedure. Communicating the causes and dangers of uterine atony and the purpose of fundal massage to the patient can help facilitate understanding for the reasons for the procedure and may help the patient tolerate it better, based on its importance. Teaching the patient to massage their own fundus enables the patient to maintain some control and can decrease their anxiety.

When uterine atony and excessive bleeding occur, additional interventions likely to be used are administration of intravenous fluids and uterotonic medications (medications that stimulate contraction of the uterine smooth muscle). See the Medication Guide: Uterotonic Medications Used to Manage Postpartum Hemorrhage, in Chapter 24 for information about common uterotonic medications.

Preventing bladder distension. Uterine atony and excessive bleeding after birth can be the result of bladder distension. A full bladder causes the uterus to be displaced above the umbilicus and well to one side of the midline in the abdomen. It also prevents the uterus from contracting normally.

Postpartum patients can be at risk of bladder distension resulting from urinary retention, based on intrapartum factors. These risk factors include epidural anaesthesia, extensive vaginal or perineal lacerations, episiotomy, instrument-assisted birth, or prolonged labour. Patients who have had in-dwelling catheters can experience some difficulty as they initially attempt to void after the catheter is removed. Nurses aware of these risk factors can be proactive in preventing complications.

Nursing interventions focus on helping the patient empty their bladder spontaneously as soon as possible. The first priority is to assist the patient to the bathroom or onto a bedpan if they are unable to ambulate. Having the patient listen to running water, placing the patient's hands in warm water, or pouring water from a squeeze bottle over the perineum may stimulate voiding. Assisting the patient into the shower or sitz bath and encouraging the patient to void can be effective. Administering analgesics, if ordered, may be indicated because some people anticipate pain and thus fear voiding. If these measures are unsuccessful, a sterile catheter can be inserted to drain the urine.

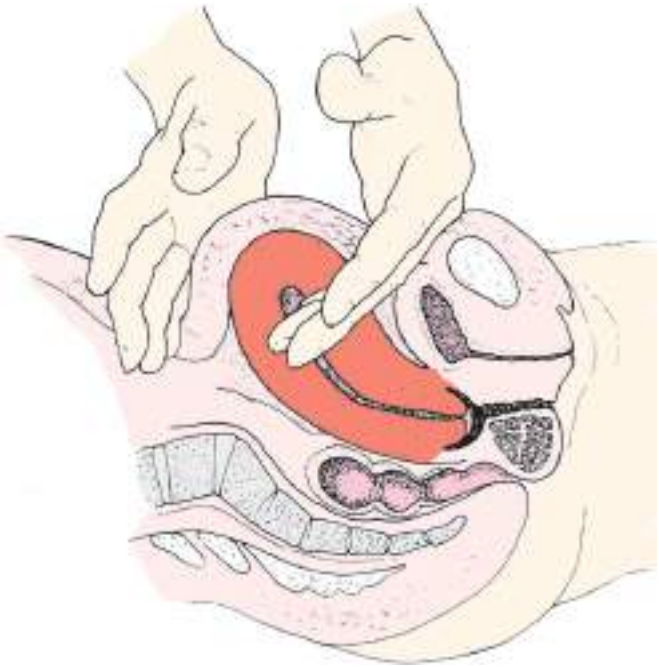

Fig. 22.3 Palpating and massaging fundus of uterus. Note that upper hand is cupped over fundus; lower hand dips in above symphysis pubis and supports uterus while it is massaged gently.

Preventing Infection. Nurses in the postpartum setting are acutely aware of the importance of preventing infection in their patients. One important means of preventing infection is maintaining a clean environment. Bed linens should be changed as needed. Disposable pads should be changed frequently. Patients should wear shoes when walking about to avoid picking up bacteria from the floor and contaminating the linens when they return to bed. Personnel must be conscientious about their hand hygiene to prevent cross-infection. Routine precautions must be practised. Staff members with colds, coughs, or skin infections (e.g., a cold sore on the lips [herpes simplex virus type I]) must follow hospital protocol when in contact with postpartum patients. In many hospitals, staff with open herpetic lesions, strep throat, conjunctivitis, upper respiratory infections, or diarrhea are encouraged to avoid contact with mothers and newborns by staying home until the condition is no longer contagious. Visitors with signs of illness should not be permitted to enter the postpartum unit.

Perineal lacerations and episiotomies can increase the risk of infection through interruption in skin integrity. Proper perineal care helps prevent infection in the genitourinary area and aids the healing process. Nurses should teach the patient to wipe from front to back (urethra to anus) after voiding or defecating in order to prevent infection. In many hospitals, a squeeze bottle (peri-bottle) filled with warm water is used after each voiding to cleanse the perineal area. The postpartum patient should change their perineal pad from front to back each time they void or defecate and wash their hands thoroughly before and after doing so (Box 22.2).

Promoting Comfort. Most patients experience some degree of discomfort during the postpartum period. Common causes of discomfort include **afterpains**, perineal laceration or episiotomy, hemorrhoids, sore nipples, and breast engorgement. The patient's description of the type and severity of pain is the best guide in choosing an appropriate intervention. To confirm the location and extent of discomfort, the nurse needs to inspect and palpate areas of pain, as appropriate, for redness, swelling, discharge, and heat and observe for body tension, guarded movements, and facial tension. Blood pressure, pulse, and respirations may be elevated in response to acute pain. Diaphoresis may accompany severe pain. A lack of objective signs does not necessarily mean there is no pain because there may also be a cultural component to the expression of pain. Nursing interventions are intended to eliminate the pain sensation entirely or reduce it to a tolerable level that allows the postpartum patient to care for themselves and their baby. Nurses may use both nonpharmacological and pharmacological interventions to promote comfort. Pain relief is generally enhanced by using more than one method or route.

SAFETY ALERT

If a postpartum patient states they have extreme perineal pain, especially after having received pain medication, the first action by the nurse should be to assess the perineum. There may be a hematoma or perineal infection that is causing the pain. Although rare, an inordinate degree of pain can be a sign of serious complications including perineal cellulitis, necrotizing fasciitis, or angioedema (Isley & Katz, 2017).

BOX 22.2 Interventions for Episiotomy, Lacerations, and Hemorrhoids

Explain both the procedure and rationale before implementation.

Cleansing

Teach the patient to do the following:

- Wash hands before and after cleansing perineum and changing pads.
- Wash perineum with mild soap and warm water at least once daily.
- Cleanse from symphysis pubis to anal area.
- Apply peripad from front to back, protecting inner surface of pad from contamination.
- Wrap soiled pad and place in covered waste container.
- Change pad with each void or defecation or at least four times per day.
- Assess amount and character of lochia with each pad change.

Ice Pack (for First 24 Hours)

Apply a covered ice pack to perineum from front to back:

- During first 2 hours to decrease edema formation and to increase comfort
- After the first 2 hours following the birth to provide anaesthetic effect

Squeeze Bottle (Peri-Bottle)

Demonstrate use and assist patient.
Fill bottle with tap water warmed to approximately 38°C (comfortably warm on the wrist).
Instruct patient to position nozzle between their legs so that squirts of water reach perineum as they sit on toilet seat. Explain that it will take the whole bottle of water to cleanse the perineum.
Teach patient to blot dry with toilet paper or clean wipes.
Remind patient to avoid contamination from anal area.
Apply clean pad.

Peri-bottle. (Courtesy Lunapads.)

Sitz Bath: Disposable

Encourage patient to use at least twice a day for 20 minutes, if required.
Place call bell within easy reach.
Clamp tubing and fill bag with warm water.
Raise toilet seat and place bath in bowl with overflow opening directed toward back of toilet.
Place container above toilet bowl.
Attach tube into groove at front of bath.
Loosen tube clamp to regulate rate of flow; fill bath to about one-half full.
Teach patient to sit on sitz bath by first tightening gluteal muscles and keeping them tightened and then relaxing them after they are on the sitz bath.
Place dry towels within reach.
Ensure privacy.
Check patient in 15 minutes.

Sitz bath (Leifer, G. [2015]. *Introduction to maternity and pediatric nursing* [7th ed.]. Saunders.)

Topical Applications

Apply anaesthetic cream or spray: use sparingly three to four times per day, if required.
Offer witch hazel pads (Tucks) for after voiding or defecating; patient pats perineum dry from front to back and then applies witch hazel pads.
Apply hemorrhoidal cream as ordered to anal area after cleansing.

Nonpharmacological interventions. A variety of nonpharmacological measures are used to reduce postpartum discomfort. These include distraction, imagery, therapeutic touch, relaxation, acupressure, aromatherapy, hydrotherapy, massage therapy, and music therapy. Many of these measures are similar to those used during labour, discussed in Chapter 18.

For patients who are experiencing discomfort associated with uterine contractions, applying warmth (e.g., heating pad) or lying prone may be helpful. Interaction with the newborn may also provide distraction and decrease this discomfort. Because afterpains are more severe during and after breastfeeding, interventions are planned to provide the most timely and effective relief. Administering pain medication about 30 minutes before breastfeeding can help minimize afterpains that are caused by breastfeeding.

A simple intervention that can decrease the discomfort associated with an episiotomy or perineal lacerations is to encourage the patient

to lie on their side whenever possible. Other interventions include application of an ice pack (for first 24 hours); topical medication (if ordered); heat (usually after 24 hours); cleansing with a squeeze bottle; and a cleansing shower, tub bath, or sitz bath. Many of these interventions, especially ice packs, sitz baths, and topical applications (e.g., witch hazel pads), are also effective for hemorrhoids (see Box 22.2).

Sore nipples in breastfeeding mothers are most likely related to ineffective latch technique. Assessment of and assistance with feeding are most important in helping the mother establish an effective technique. To ease discomfort associated with sore nipples, the mother may apply expressed colostrum or breastmilk, topical preparations such as purified lanolin, or hydrogel pads (see Chapter 27).

Breast engorgement can occur whether the postpartum patient is breastfeeding or formula-feeding. The discomfort associated with engorged breasts may be reduced by applying ice packs or cabbage leaves (or both) (see further discussion below) to the breasts and wearing a well-fitted support bra. Anti-inflammatory medications can also help relieve some of the discomfort. Decisions about specific interventions for engorgement are based on whether the person chooses breastfeeding, chestfeeding, or bottle-feeding (Wolfe-Roubatis & Spatz, 2015).

Pharmacological interventions. Pharmacological interventions are commonly used to relieve or reduce postpartum discomfort. Most health care providers routinely order a variety of analgesics to be administered as needed, including both **opioid** and nonopioid (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs]) medications. NSAIDs commonly used are ibuprofen or naproxen. These medications provide better relief from uterine cramping and perineal pain than acetaminophen. Ibuprofen is preferred for breastfeeding patients because it has a low milk/maternal plasma drug concentration ratio and a short-half life (Isley & Katz, 2017). In some hospitals, NSAIDs are administered on a scheduled basis, especially if the patient had perineal repair. Topical application of antiseptic or anaesthetic ointments or spray can be used for perineal pain. Patient-controlled analgesia (PCA) pumps and epidural analgesia are commonly used to provide pain relief after Caesarean birth.

! NURSING ALERT

The nurse should monitor all patients receiving opioids carefully because respiratory depression and decreased intestinal motility are adverse effects.

Most patients want to participate in decisions about using analgesia. If an analgesic is to be given, the nurse must, in conjunction with the mother, make a clinical judgement of the type, dosage, and frequency from the medications ordered. Patients and their support people should be informed of the prescribed analgesic and its common adverse effects; this teaching should be documented. Many hospitals offer self-medication packages for postpartum patients. These packages have the medications that a patient might require in the immediate postpartum period. Clear instructions are given regarding the medications and how to take them when necessary, while also remembering to document the date, time, and dose each time they take the medication.

If acceptable pain relief has not been obtained within 1 hour and there has been no change in the initial assessment, the nurse should contact the primary care provider for additional pain-relief orders or further directions. Unrelieved pain results in fatigue, anxiety, and a worsening perception of the pain. It can also indicate the presence of a previously unidentified or untreated condition.

Breastfeeding mothers often have concerns about the effects of an analgesic on the newborn. Although nearly all medications present in maternal circulation are also found in breast milk, many analgesics commonly used during the postpartum period are considered relatively safe for breastfeeding patients and their newborns. Nonopioid analgesics are preferred for pain management in postpartum breastfeeding women because they do not alter maternal or newborn alertness (Lawrence & Lawrence, 2016). Timing of medication administration can be adjusted to minimize newborn exposure. A mother may be given pain medication immediately after breastfeeding so that the interval between medication administration and the next nursing period is as long as possible, although some patients may require medication prior to breastfeeding if they are having significant afterpains. The decision to administer medications of any type to a breastfeeding mother must always be made by carefully weighing the patient's need against actual or potential risks to the newborn. Resources are readily accessible for nurses and health care providers to examine the safety of medications for breastfeeding mothers (see Additional Resources at the end of the chapter).

Promoting Rest. Fatigue is common in the early postpartum period and involves both physiological and psychological components. Sleep loss, feeling stressed, and physical exhaustion have been reported as the top three conditions patients experience within the first 2 months after birth (Declercq et al., 2014). The early postpartum period is the time that new parents experience the greatest disruption to their lives as they try to adjust to the nearly constant demands of a newborn (Aber et al., 2013). Other factors can contribute to physical fatigue or exhaustion, such as long labour or Caesarean birth, hospital routines that interrupt periods of sleep and rest, and physical discomfort. Fatigue can also be associated with anemia, infection, or thyroid dysfunction. The excitement and exhilaration experienced after the birth of the newborn makes resting difficult. Physical discomfort can interfere with sleep. Well-intentioned visitors may interrupt periods of rest in the hospital and at home.

Postpartum fatigue. *Postpartum fatigue (PPF)* is more than just feeling tired; it is a complex phenomenon affected by a combination of physiological, psychological, and situational variables (Volrathongchai et al., 2013). Disrupted sleep and fatigue in the postpartum patient may contribute to the development of a perinatal mood disorder (PMD) (Bhati & Richards, 2015; Okun, 2015; Park et al., 2013). Symptoms of PPF and depressive symptoms are interrelated. Depressive symptoms can affect fatigue, whereas fatigue can lead to depressive symptoms.

Fatigue is likely to worsen over the first 6 weeks after birth, often because of situational factors. After discharge from the hospital, fatigue increases as the patient provides care and feeding for the newborn in combination with other family and household responsibilities, such as caring for other children, preparing meals, and doing laundry. Many patients have partners, family members, or friends to provide much-needed assistance, whereas others may be without any help at all. The nurse needs to inquire about resources available to the patient after discharge and help them to plan accordingly.

Interventions are planned to meet the patient's individual needs for sleep and rest while they are in the hospital. Back rubs and other comfort measures may be necessary. For instance, the side-lying position for breastfeeding helps minimize fatigue in nursing mothers. Support and encouragement of mothering behaviours can help reduce anxiety. Hospital and nursing routines can be adjusted to meet the needs of individual mothers. In addition, the nurse can help the family limit visitors and provide a comfortable chair or bed for the partner or other family member staying with the new mother.

Because PPF can be very debilitating, follow-up after hospital discharge is important. Screening for PPF can be done at the routine 6-week postpartum visit with the health care provider. Nurses in the pediatric care provider's office or clinic should also be alert for signs

of PPF, as they often see the mother before the mother sees an obstetrical care provider.

Physiological factors contributing to PPF are amenable to intervention and may be identified even before birth. People with sleeping disorders during pregnancy, anemia, infection or inflammation, or thyroid dysfunction can be identified as having increased risk for PPF. Other physical conditions and psychological or situational factors that might contribute to PPF should be identified during the prenatal period. The medical records of patients with known risk factors should be flagged to alert hospital staff to their special needs (see Clinical Reasoning Case Study).

CLINICAL REASONING CASE STUDY

Fatigue and Rest After Childbirth

Patricia gave birth to her third baby; she has two children at home, ages 3 years and 18 months. Her partner travels frequently with his job. She is breastfeeding the baby without difficulty but is concerned about how she will care for all three of her children, stating, "I remember how tired I was after my last baby. I'm not sure I can manage with three children since my partner is gone so much. Do you have any suggestions to help me?"

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about whether support would be helpful for Patricia?
2. Assumptions—What assumptions can be made about the following factors?
   a. The relation between breastfeeding and fatigue
   b. Support in the postpartum period
   c. The role of sleep and rest in relation to fatigue and depression
   d. Spacing of pregnancies and fatigue
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of health care providers who might be involved in Patricia's care.

Promoting Ambulation. Early ambulation promotes the return of strength. Free movement should be encouraged once anaesthesia wears off, unless an opioid analgesic has been administered. After the initial recovery period is over, the mother should be encouraged to ambulate frequently.

In the early postpartum period some patients can feel light-headed or dizzy upon standing. The rapid decrease in intra-abdominal pressure after birth results in a dilation of blood vessels supplying the intestines (splanchnic engorgement) and causes blood to pool in the viscera. This condition contributes to the development of orthostatic hypotension and can occur when the patient who has recently given birth sits or stands, first ambulates, or takes a warm shower or sitz bath. The nurse must consider the baseline blood pressure; amount of blood loss; and type, amount, and timing of analgesic or anaesthetic medications administered when assisting a patient to ambulate.

Patients who have had epidural or spinal anaesthesia may have slow return of sensory and motor function in their lower extremities, increasing the risk of falls with early ambulation. Careful assessment by the postpartum nurse can prevent falls. Factors that the nurse should consider are the time lapse since the medication was given; the patient's ability to bend both knees, place both feet flat on the bed, and lift buttocks off the bed without assistance; medications since birth; vital signs; and estimated blood loss with birth. Before allowing the patient to ambulate the nurse should assess the patient's ability to stand unassisted beside the bed: they should simultaneously bend both knees slightly and then stand with knees locked. If the patient is unable to balance themselves they should be eased back into bed safely (Lockwood & Anderson, 2013).

NURSING ALERT

To promote patient safety and prevent injury, it is important to have hospital personnel present at least the first time the patient gets out of bed after birth because the patient can feel weak, dizzy, faint, or light-headed. The patient should be instructed to call for assistance before getting out of bed the first time and any time thereafter if they feel dizzy or weak. The partner or family members who are present should be instructed to call for help as well.

Early ambulation is also successful in reducing the incidence of venous thromboembolism (VTE). Blood is hypercoagulable in the postpartum period, especially during the first 48 hours after birth (Isley & Katz, 2017). Patients who must remain in bed after giving birth are at increased risk for this complication. For patients who are immobilized, antiembolic stockings (TED hose) or sequential compression device (SCD) boots may be ordered prophylactically, especially after Caesarean birth. If a patient remains in bed longer than 8 hours (e.g., for postpartum magnesium sulphate therapy for pre-eclampsia), exercise to promote circulation in the legs is indicated, using the following routine:

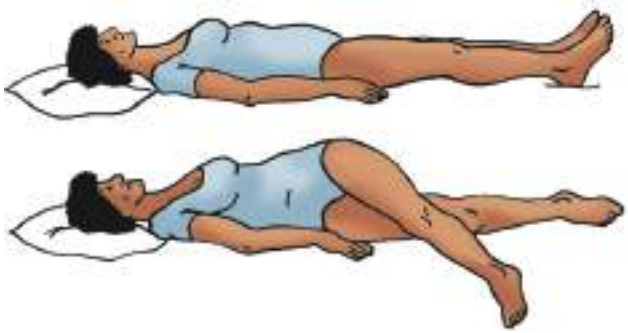
- Alternate flexion and extension of feet.
- Rotate ankles in circular motion.
- Alternate flexion and extension of legs.
- Press back of knee to bed surface; relax.

If the patient is susceptible to VTE, they should be encouraged to walk about actively and discouraged from sitting immobile in a chair. Patients with increased risk for thromboembolism include those with morbid obesity (body mass index [BMI] >40), and those who had an unexpected Caesarean birth, are over 35 years of age, and had VTE during pregnancy. These patients should be offered low-molecular-weight heparin during the postpartum period. The length of time required for the prophylaxis ranges from 10 days to 6 weeks and depends on the number of risk factors (Royal College of Obstetricians and Gynaecologists [RCOG], 2015). In addition, it is important to note that the higher-molecular-weight anticoagulants, or warfarin, are considered safe for breastfeeding mothers. The dose is based on maternal weight (RCOG, 2015). (See further discussion in Chapter 24).

Patients with varicosities are advised to wear support hose. If a thrombus is suspected, as evidenced by warmth, redness, or tenderness in the suspected leg, the primary health care provider should be notified immediately; meanwhile the patient should be confined to bed with the affected limb elevated on pillows.

Promoting Exercise. Some people who have just given birth are interested in regaining their nonpregnant figures and previous level of exercising. Postpartum exercise can usually begin soon after birth, although the patient should be encouraged to start with simple exercises and gradually progress to more strenuous ones. Figure 22.4 illustrates a number of exercises appropriate for the new mother. Abdominal exercises are postponed until about 4 weeks after Caesarean birth. It often takes several months for the body to return to prepregnancy weight and shape, and nurses should provide new mothers with realistic information regarding this.

Promoting Nutrition. During the hospital stay, most postpartum patients have a good appetite and eat well; nutritious snacks are usually welcomed. Patients may request that family members bring to the hospital favourite or culturally appropriate foods. Cultural dietary preferences must be respected. An example is that some Asian mothers may only eat hot

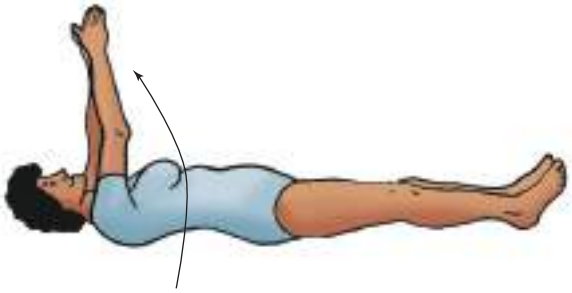


Abdominal Breathing. Lie on back with knees bent. Inhale deeply through nose. Keep ribs stationary and allow abdomen to expand upward. Exhale slowly but forcefully while contracting the abdominal muscles; hold for 3 to 5 seconds while exhaling. Relax.

Reach for the Knees. Lie on back with knees bent. While inhaling, deeply lower chin onto chest. While exhaling, raise head and shoulders slowly and smoothly and reach for knees with arms outstretched. The body should rise only as far as the back will naturally bend while waist remains on floor or bed (about 6 to 8 inches). Slowly and smoothly lower head and shoulders back to starting position. Relax.

Double Knee Roll. Lie on back with knees bent. Keeping shoulders flat and feet stationary, slowly and smoothly roll knees over to the left to touch floor or bed. Maintaining a smooth motion, roll knees back over to the right until they touch floor or bed. Return to starting position and relax.

Leg Roll. Lie on back with legs straight. Keeping shoulders flat and legs straight, slowly and smoothly lift left leg and roll it over to touch the right side of floor or bed and return to starting position. Repeat, rolling right leg over to touch left side of floor or bed. Relax.



Combined Abdominal Breathing and Supine Pelvic Tilt (Pelvic Rock). Lie on back with knees bent. While inhaling deeply, roll pelvis back by flattening lower back on floor or bed. Exhale slowly but forcefully while contracting abdominal muscles and tightening buttocks. Hold for 3 to 5 seconds while exhaling. Relax.

Buttocks Lift. Lie on back with arms at sides, knees bent, and feet flat. Slowly raise buttocks and arch back. Return slowly to starting position.

Single Knee Roll. Lie on back with right leg straight and left leg bent at the knee. Keeping shoulders flat, slowly and smoothly roll left knee over to the right to touch floor or bed and then back to starting position. Reverse position of legs. Roll right knee over to the left to touch floor or bed and return to starting position. Relax.

Arm Raises. Lie on back with arms extended at 90-degree angle from body. Raise arms so they are perpendicular and hands touch. Lower slowly.

Fig. 22.4 Postpartum exercise should begin as soon as possible. The patient should start with simple exercises and gradually progress to more strenuous ones.

food after birth and will avoid anything cold. This interest in food presents an ideal opportunity for nutrition counselling on dietary needs after pregnancy, such as for breastfeeding, preventing constipation and anemia, promoting weight loss, and promoting healing and well-being. Prenatal vitamins and iron supplements should be continued until 6 weeks after birth, and some patients may require supplements for the entire time they breastfeed.

The recommended caloric intake for the moderately active, non-lactating postpartum female is 1 800 to 2 200 kcal/day. According to the Government of Canada (2010), the estimated energy requirement for a breastfeeding person is an extra 350 to 400 kcal/day, which is usually an extra snack or a small meal. Higher-than-normal caloric intake is recommended for patients who are underweight or who exercise vigorously and those who are breastfeeding more than one newborn.

Promoting Bladder Function. The postpartum patient should void spontaneously within 6 to 8 hours after giving birth. The first several voidings should be measured to document adequate emptying of the bladder. A volume of at least 150 mL is expected for each voiding. Some patients experience difficulty in emptying the bladder, possibly as a result of diminished bladder tone, edema from trauma, use of epidural or spinal anaesthetic, or fear of discomfort. Nursing interventions for inability to void and bladder distension are discussed in the Preventing Bladder Distention section earlier in the chapter.

Urinary incontinence is not uncommon, especially if there was significant perineal trauma with birth. Pelvic floor muscle training, also known as **Kegel exercises**, helps to strengthen muscle tone, particularly after vaginal birth. Kegel exercises help in regaining the muscle tone often lost as pelvic tissues are stretched and torn during pregnancy and birth. Patients who maintain muscle strength may benefit years later by maintaining urinary continence.

It is essential that patients learn to perform Kegel exercises correctly (see Patient Teaching box: Kegel Exercise, in Chapter 5). Some people perform them incorrectly and can increase their risk of incontinence, which can occur when inadvertently bearing down on the pelvic floor muscles, thrusting the perineum outward. The technique can be assessed during the pelvic examination at the patient's checkup by inserting two fingers intravaginally and checking whether the pelvic floor muscles correctly contract and relax.

Promoting Bowel Function. After birth, patients can be at risk for constipation related to the adverse effects of medications (e.g., opioid analgesics, iron supplements, magnesium sulphate), dehydration, immobility, perineal lacerations or episiotomy, or hemorrhoids. Some patients fear discomfort with straining to have a bowel movement.

Nursing interventions to promote normal bowel elimination include educating the patient about measures to avoid constipation. These interventions include ambulating and increasing the intake of fluids and fibre. Alerting the postpartum patient to adverse effects of medications such as opioid analgesics (decreased gastrointestinal tract motility) may encourage them to implement measures to reduce the risk of constipation. It is normal to not have a bowel movement for 2 to 3 days after birth, so many new mothers may be home before having a bowel movement. Occasionally, stool softeners or laxatives may be necessary during the early postpartum period, especially if the patient has extensive perineal repairs.

Some mothers experience gas pains; this is more common following Caesarean birth. Ambulation or rocking in a rocking chair may stimulate passage of flatus and relieve discomfort. Anti-gas medications may be ordered. Patients who have had a Caesarean birth should avoid drinking carbonated beverages and the use of straws, as well as eating foods that tend to produce gas (e.g., legumes, beans, broccoli), as this promotes gas formation.

NURSING ALERT

Rectal suppositories and enemas should not be administered to patients with third- or fourth-degree perineal lacerations. These measures to treat constipation can be very uncomfortable and can cause hemorrhage or damage to the suture line.

Promoting Breastfeeding. The ideal time to initiate breastfeeding is as soon as possible after birth (Breastfeeding Committee for Canada [BCC], 2021). The Baby-Friendly Initiative (BFI) recommends placing the newborn in uninterrupted skin-to-skin contact for at least 1 to 2 hours after birth (BCC, 2021). At this time, the newborn is in an alert state and ready to nurse. Breastfeeding promotes contraction and involution of the uterus and thus can help decrease the risk of PPH. With the first feeding, the nurse can assess the appearance of the breasts and nipples, assess the patient's basic understanding of breastfeeding technique, and provide assistance and basic instructions to facilitate breastfeeding as well as provide information about responsive, cue-based feeding (see Community Focus box: Breastfeeding Support). Optimal positioning and latching will help the baby to suck effectively. It is recommended that positioning and latching be assessed before discharge from the hospital and when any breastfeeding issues occur (BFI Strategy for Ontario and Toronto Public Health, 2019). Maternal confidence, also referred to as *breastfeeding self-efficacy*, is highly correlated with positive breastfeeding outcomes, including initiation, duration, and exclusivity (McQueen et al., 2011). Patients will need continuous support throughout their hospitalization and prompt follow-up after discharge to ensure successful breastfeeding. (See Chapter 27 for further information on assisting the breastfeeding patient.)

COMMUNITY FOCUS

Breastfeeding Support

Studies have shown that people breastfeed longer if they have support in their breastfeeding efforts. Both nurses and International Board Certified Lactation Consultants (IBCLCs) can provide such support after childbirth. Some hospitals and birthing centres offer IBCLC support during the inpatient stay after birth. Often IBCLCs are nurses or have other allied health backgrounds. IBCLCs are an important part of the health care team and remain a significant means for reaching population-level breastfeeding goals (Chetwynd et al., 2019). It is recommended that families have a plan for support after discharge, including a follow-up visit with their primary health care provider, as well as for support with breastfeeding. In discharge planning, nurses should refer breastfeeding mothers to community groups for support. It is vital that nurses facilitate a seamless transition between the services provided by the hospital, community health services, and peer support programs. Social support interventions that include peer support have been shown to be successful in increasing the duration of exclusive breastfeeding and satisfaction with breastfeeding. Community health nurses can facilitate breastfeeding efforts through organizing or facilitating support groups. Mothers experienced in breastfeeding can also facilitate these efforts as an evidence-informed peer support intervention.

Identify sources of breastfeeding support in your community. Are these resources free of charge and available in various parts of the community? What form does the support take? Are there group classes? Individual consultation? Who provides the consultation? Make a list of the resources you identified and share the list with your clinical group.

Suppression of Lactation. Suppression of lactation is necessary when the person has decided not to breastfeed or in the case of newborn death. Wearing a well-fitted support bra continuously for at least the first 72 hours after giving birth aids in this process. These patients should avoid breast stimulation, including running warm water over the breasts, newborn suckling, or expressing milk. Some nonbreastfeeding mothers experience severe breast engorgement (swelling of breast tissue caused by increased blood and lymph supply to the breasts as the body produces milk, which occurs at about 72 to 96 hours after birth). If breast engorgement occurs, it usually can be managed satisfactorily with nonpharmacological interventions.

Periodic application of ice packs to the breasts can help decrease the discomfort associated with engorgement. The patient should use a 15-minutes-on, 45-minutes-off schedule (to prevent the rebound swelling that can occur if ice is used continuously). Although there is lack of scientific evidence to support effectiveness, cabbage leaves are often recommended to help relieve engorgement; formula-feeding mothers may be told to place fresh green cabbage leaves over their breasts and to replace the leaves when they are wilted. A mild analgesic or anti-inflammatory medication can reduce discomfort associated with engorgement. Medications that were once prescribed for lactation suppression (e.g., estrogen, estrogen and testosterone, and bromocriptine) are no longer used.

Health Promotion for Future Pregnancies

Rubella vaccination. For postpartum patients who have not had rubella or for those who are serologically not immune (titre of 1:8 or enzyme immunoassay level less than 0.8), a subcutaneous injection of rubella vaccine is recommended in the immediate postpartum period to prevent the possibility of contracting rubella in future pregnancies; this is given as the measles, mumps, rubella (MMR) vaccine. Seroconversion occurs in approximately 90% of people vaccinated after birth. The live attenuated rubella virus is not communicable; therefore, breastfeeding mothers can be vaccinated (Government of Canada, 2019). However, because the virus is shed in urine and other body fluids, the vaccine should not be given if the mother or other household members are immunocompromised. A transient arthralgia or rash is common after administration of the rubella vaccine. Canadian guidelines recommend immunizing new mothers immediately postpartum, and they should delay pregnancy for at least 4 weeks following MMR vaccination (Government of Canada, 2019).

LEGAL TIP: Rubella Vaccination

Informed consent for rubella vaccination in the postpartum period includes information about possible adverse effects and the risk of teratogenic effects. Patients and their families need to understand that they must practise contraception for 1 month after being vaccinated to avoid pregnancy, given the theoretical risk of disease transmission to the fetus. There is no evidence demonstrating a teratogenic risk from the vaccine. Termination of pregnancy should not be recommended following inadvertent immunization with either of these vaccines on the basis of fetal risks following maternal immunization.

Prevention of Rh isoimmunization. Injection of Rh **immune globulin** (a solution of gamma-globulin that contains Rh antibodies) within 72 hours after birth prevents sensitization in the Rh-negative woman who has had a fetomaternal transfusion of Rh-positive fetal red blood cells (RBCs) (see Medication Guide: Rh Immune Globulin). Rh immune globulin promotes lysis of fetal Rh-positive blood cells before the mother forms their own antibodies against them. Administration of Rh immune globulin is intended to prevent complications in future pregnancies should the Rh-negative patient have an Rh-positive fetus.

MEDICATION GUIDE

Rh Immune Globulin

Action

Suppression of immune response in nonsensitized people with Rh-negative blood who receive Rh-positive blood cells because of fetomaternal hemorrhage, transfusion, or accident

Indications

Routine antepartum prevention at 26 to 28 weeks of gestation in people with Rh-negative blood; suppress antibody formation after birth, miscarriage, pregnancy termination, abdominal trauma, ectopic pregnancy, amniocentesis, version, or chorionic villus sampling

Dosage/Route

Standard dose: 1 vial (300 mcg) IM in deltoid or ventrogluteal muscle
Microdose: 1 vial (50 mcg) IM in deltoid or ventrogluteal muscle
Rh_o(D) immune globulin can be given IM or IV

Adverse Effects

- Myalgia, lethargy, localized tenderness and stiffness at injection site, mild and transient fever, malaise, headache; rarely nausea, vomiting, hypotension, tachycardia, and allergic response can occur

Nursing Considerations

- Give standard dose to the mother at 28 weeks of gestation as prophylaxis or after an incident or exposure risk that occurs after 28 weeks of gestation (e.g., amniocentesis, second-trimester miscarriage or abortion, after external version)
- Give standard dose within 72 hours after birth if the baby is Rh positive.
- Give microdose for first-trimester miscarriage or abortion, ectopic pregnancy, or chorionic villus sampling.
- Verify that the woman is Rh negative and has not been sensitized; if postpartum that Coombs' test is negative; and that baby is Rh positive. Provide a thorough explanation to the patient and support person(s) about the procedure, including the purpose, possible adverse effects, and the effect on future pregnancies. Have patient sign a consent form if required by the agency. Verify correct dosage and confirm the lot number and patient's identity before giving the injection (verify with another nurse or by other procedure per agency policy); document administration per agency policy. Observe patient for at least 20 minutes after administration for allergic response.
- Document lot number and expiration date in the patient record.
- The medication is made from human plasma (a consideration if the patient is a Jehovah's Witness). Patients receiving this medication must be informed about the risks and benefits, and the nurse needs to document this discussion and the patient's understanding before administering the medication. The risk of transmitting infectious agents, including viruses, cannot be completely eliminated.

IM, Intramuscularly; *IV,* intravenously.

NURSING ALERT

After birth, Rh immune globulin is administered to all Rh-negative, antibody (Coombs' test)–negative patients who give birth to Rh-positive newborns. Rh immune globulin is administered to the mother intramuscularly or intravenously. It should never be given to an newborn.

The administration of 300 mcg of Rh immune globulin is usually sufficient to prevent maternal sensitization. However, if a large

fetomaternal transfusion is suspected, the dosage needed should be determined by performing a Kleihauer-Betke test, which detects the amount of fetal blood in the maternal circulation. If more than 15 mL of fetal blood is present in maternal circulation, the dosage of Rh immune globulin must be increased.

Because Rh immune globulin is considered a blood product, precautions similar to those used for transfusing blood are necessary when it is given. The identification number on the patient's hospital wristband should correspond to the identification number found on the laboratory slip. The nurse must also check to see that the lot number of the laboratory slip corresponds to the lot number on the vial. Finally, the expiration date on the vial should be checked to ensure that it is a usable product.

SAFETY ALERT

Rh immune globulin suppresses the immune response. Therefore, the patient who receives both Rh immune globulin and a live virus immunization such as rubella must be tested in 3 months to see if they have developed rubella immunity. If not, they will need another dose of the vaccine.

Psychosocial Assessment and Care

Meeting the psychosocial needs of new parents involves assessing their reactions to the birth experience, their feelings about themselves, and their interactions with the new baby (Figure 22.5) and other family members. Specific interventions are then planned in order to increase the parents' knowledge and self-confidence as they assume the care and responsibility of the new baby and integrate this new member into their existing family structure in a way that meets their cultural expectations.

Taking time to assess maternal emotional needs and concerns before discharge can promote better psychological health and adjustment to parenting. Ongoing support for patients during the postpartum period is also needed. Issues such as fatigue that often appear during the hospital stay tend to continue after discharge and can intensify. Postpartum support is especially beneficial to at-risk populations, such as low-income primiparas, people who lack adequate support because of isolation (e.g., physical or language), those at risk for family dysfunction and child abuse, and those at risk for PMD (see Chapter 24).

Sometimes the findings of the psychosocial assessment indicate serious actual or potential difficulties that must be addressed. Box 22.3 identifies psychosocial characteristics and behaviours that may warrant ongoing evaluation after hospital discharge. Patients exhibiting these needs should be referred to appropriate community resources for assessment and management.

Fig. 22.5 Parents getting acquainted with their newborn. (iStock.com/FatCamera)

BOX 22.3 Signs of Potential Psychosocial Complications

The following signs in the mother can suggest potentially serious complications and should be reported to the health care provider or clinic (these may be noticed by the partner or other family members):

- Unable or unwilling to discuss labour and birth experience
- Refers to self as ugly and useless
- Excessively preoccupied with self (body image)
- Markedly depressed
- Lacks a support system
- Partner or other family members react negatively to baby
- Refuses to interact with or care for baby (e.g., does not name baby, does not want to hold or feed baby, is upset by vomiting and wet or dirty diapers) (cultural appropriateness of actions must be considered)
- Expresses disappointment over baby's sex
- Sees baby as messy or unattractive
- Baby reminds mother of family member or friend they do not like
- Has difficulty sleeping
- Experiences loss of appetite

It is key to discuss and plan how symptoms will be monitored (for example, by using validated self-report questionnaires, such as the Edinburgh Postnatal Depression Scale [EPDS], Patient Health Questionnaire [PHQ-9], or the 7-item Generalized Anxiety Disorder scale [GAD-7]). Refer to Chapter 24 for more details.

Source: National Institute for Health and Care Excellence. (2014). *Antenatal and postnatal mental health: Clinical management and service guidance*. Updated 2020. https://www.nice.org.uk/guidance/cg192.

Cultural issues must be considered when planning care, as childbirth occurs within a sociocultural context. The nurse must take time to interact with the patient and their extended family in order to learn and understand which practices need to be followed for the new mother and their newborn newborn. Recognizing the importance of family and community in relation to the patient and the newborn is integral to providing culturally appropriate care.

Impact of the Birth Experience. Many patients indicate a need to examine retrospectively the birth process itself and their own behaviour during labour. Their partners may express similar desires. If their birth experience was quite different from the one they had planned (e.g., induction, epidural anaesthesia, Caesarean birth), both partners may need to mourn the loss of their expectations before they can adjust to the reality of their actual birth experience. Inviting them to review the events and describe how they feel can help the nurse assess how well they understand what happened and how well they have been able to put their childbirth experience into perspective.

Maternal Self-Image. An important assessment concerns the patient's self-concept, body image, and sexuality. How this new mother feels about their own body during the **postpartum period** may affect the new parent's behaviour and adaptation to parenting. The patient's self-concept and body image may also affect their sexuality.

Adaptation to Parenthood and Parent–Infant Interactions. The psychosocial assessment includes evaluating adaptation to parenthood

as evidenced by the parents' reactions to and interactions with the new baby. Clues indicating successful adaptation begin to appear early in the postbirth period as parents react positively to the newborn and continue the process of establishing a relationship with their child.

Parents are adapting well to their new roles when they exhibit a realistic perception and acceptance of their newborn's needs and limited abilities, immature social responses, and helplessness. Examples of positive parent–newborn interactions include taking pleasure in the newborn and in providing care, responding appropriately to newborn cues, and providing comfort (see Chapter 23). If these indicators are missing, the nurse must investigate further in an attempt to identify what is hindering the normal adaptation process. The nurse can ask several questions, such as "Tell me how you are feeling?" or "What are your concerns about being a parent?" These will help determine if the mother is experiencing the normal "baby blues" or if there is a more serious underlying condition (i.e., PMD) (see Clinical Reasoning Case Study: Risk for Perinatal Mood Disorder).

CLINICAL REASONING CASE STUDY

Risk for Perinatal Mood Disorder

Elisabeth, a 38-year-old multipara, has just given birth to her fourth baby. The ages of her other children are 8, 4, and 2. During the morning nursing assessment, Elisabeth was noted to be tearful and stated that she was feeling "overwhelmed" and "very unsure" of herself and how to take care of the new baby, even though she has successfully taken care of her three previous children. She shared that her mother was diagnosed with cancer 2 months ago and is undergoing treatment. Her partner will be starting a much-needed new job next week and will not be able to get any time off for a while. Other family members do not live close by except for her sister, who is out of town often because of her job responsibilities. Elisabeth is concerned about how she will manage taking care of a newborn and three other children with a seemingly depleted support system.

1. Evidence—Is there sufficient evidence to support counselling women with psychosocial concerns in the immediate postpartum period?
2. Assumptions—What assumptions can be made about the following issues?
   a. Elisabeth's risk for a perinatal mood disorder
   b. Elisabeth's support system
   c. Elisabeth's ability to connect with community resources after discharge
3. What implications and priorities for nursing care can be drawn at this time?
4. Interprofessional care: Describe roles and responsibilities of other health care providers who should be involved in planning and implementing care for Elisabeth and her family.

Postpartum Blues. The period surrounding the first day or two after birth is characterized by heightened joy and feelings of well-being. This is often followed by a "blue" period. Approximately 50 to 80% of new mothers experience the postpartum blues or "baby blues." During this period, new mothers are emotionally labile and often cry easily for no apparent reason. This lability seems to peak around the fifth day and subside by the tenth day. Other symptoms of postpartum blues include depression, a let-down feeling, restlessness, fatigue, insomnia, headache, anxiety, sadness, and anger. Postpartum blues are transient, mild, and time limited and do not require treatment other than reassurance. Biochemical, psychological, social, and cultural factors have been explored as possible causes of the postpartum blues; however, the etiology remains unknown. Because the postpartum blues occur in up to 80% of postpartum patients, all postpartum patients and their support person(s) must be taught about the symptoms of the blues and that this is a normal postpartum occurrence (Registered Nurses' Association of Ontario, 2018).

Whatever the cause, the early postpartum period appears to be one of emotional and physical vulnerability for new mothers who may be already psychologically overwhelmed by the reality of parental responsibilities. The mother may feel deprived of the supportive care she received from family members and friends during pregnancy. Some mothers regret the loss of the mother–unborn child relationship and mourn its passing. Still others have a let-down feeling when labour and birth are complete. Most postpartum patients experience fatigue after childbirth, which is compounded by the around-the-clock demands of the new baby and can accentuate the feelings of depression. Symptoms of depression can have a negative effect on the development of a maternal role. To help mothers cope with postpartum blues, nurses can suggest various strategies (see Patient Teaching box: Coping with Postpartum Blues).

PATIENT TEACHING

Coping With Postpartum Blues

It is important to teach this information to all new mothers.

- Remember that the blues are normal.
- Get plenty of rest; nap when the baby does, if possible. Go to bed early and let friends know when to visit.
- Use relaxation techniques learned in childbirth classes (or ask the nurse to teach you and your partner some techniques).
- Do something for yourself. Take advantage of the time when your partner or family members care for the baby—soak in the tub or go for a walk.
- Plan a day out of the house—go to the mall or a park with the baby, being sure to take a stroller or carriage, or go out to eat with friends without the baby. Many communities have churches or other agencies that provide child care programs, such as Mothers' Morning Out.
- Share your feelings with your partner. For example, talk about feeling tied down, if applicable; how the birth met your expectations; and things that will help you.
- If you are breastfeeding, give yourself and your baby time to learn to do this together.
- Monitor yourself for signs of depression and anxiety.
- Seek out and use community resources, such as peer support programs to meet other new mothers, La Leche League, local public health agencies, or community health centres.

Although the postpartum blues are usually mild and short-lived, approximately 15% of women experience a PMD (see Chapter 24). PMD symptoms can range from mild to severe, with postpartum mothers having good and bad days. It can go undetected because new parents generally do not voluntarily admit to this kind of emotional distress out of embarrassment, guilt, or fear. Nurses must include teaching about the normalcy of the blues as well as how to differentiate symptoms of the blues from those of PMD and urge parents to report depressive symptoms promptly if they do occur (see Box 24.4). For further discussion of PMD and how to screen for it, see Chapter 24.

Family Structure and Functioning. A mother's adjustment to this new role is affected greatly by relationships with their partner, their mother and other relatives, and any other children (Figure 22.6). Nurses can help ease the new mother's return home by identifying possible conflicts among family members and helping them to plan strategies for dealing with these concerns before discharge. Such a conflict could arise when couples have very different ideas about parenting. Dealing with the stresses of **sibling rivalry** and unsolicited grandparent advice can also affect the person's transition to motherhood. Only by asking about other nuclear and extended family members can the nurse

Fig. 22.6 Older sibling cuddles with mother and new baby. (Courtesy Jennifer Hobgood.)

discover potential conflicts in such relationships and help plan workable solutions for them.

Impact of Cultural Diversity. The final component of a complete postpartum psychosocial assessment is the patient's cultural beliefs, values, and practices. Much of a person's behaviour during the postpartum period may be strongly influenced by their cultural background. Nurses are likely to come into contact with people from many different countries and cultures. All cultures have developed safe and satisfying methods of caring for new mothers and babies. The nurse can identify some cultural beliefs and practices through observation and interaction with the mother and the family. Asking questions of the mother and the family about their cultural practices can provide useful information to help the nurse provide optimal care. Only by understanding and respecting the values and beliefs of each individual can the nurse design a plan of care to meet individual needs.

Many traditional health beliefs and practices exist among the various cultures within the North American population. Traditional health practices used to maintain health or avoid illnesses often involve the whole person (body, mind, and spirit) and may be culturally based. While it is vital that the nurse spend time assessing and listening to the individual and their family and what they value, the nurse should not assume from their cultural background what may or may not be relevant for them. This is an important aspect of the family assessment and promotes patient- and family-centred care.

For Indigenous people the importance of traditional birth keepers, midwives, and/or birth attendants (such as aunties, grandmothers, sisters, and mothers) must be considered when providing nursing care. Ceremony and cultural practices are used to honour and ground women in two-spirit wellness, which is the backbone of the health of communities. Many effective medicines have been developed through traditional practices and have kept people strong, providing health for the community. Knowledge of traditional medicine is passed down from generation to generation. Beliefs supporting such practices involve a balance between physical, emotional, mental, and spiritual elements. The importance of balance also extends beyond the individual to include the family, the community, and the environment. Close linkages and balanced relationships with land, water, and ice and with their communities and their societies govern the sense of well-being and may be expressed among Indigenous women through distinct cultural practices in relation to labour, birth, and postpartum periods (Best Start Resource Centre, 2013; Wilson et al., 2013).

Other traditional practices among cultures may include the observance of certain dietary restrictions, wearing certain clothing, or taboos for balancing the body; participation in certain activities such as sports and art for maintaining mental health; and the use of silence, prayer, or meditation for spiritual development. Some practices (e.g., using religious objects or eating garlic) are used to protect the person from illness and may involve avoiding people who are believed to create hexes and spells or who have an "evil eye." Restoration of health may involve a person accessing alternative and complementary health models (e.g., herbs, animal substances) or using a traditional healer. It is thus vital that nurses bring a relational and nonjudgemental approach to all settings and remember that birth occurs within a sociocultural context. Supporting each person's choice is important to family-centred care. Rest, seclusion, dietary restraints, and ceremonies honouring the mother may be other traditional practices that are followed for the promotion of the health and well-being of the mother and baby.

Other postpartum traditional health practices and beliefs are those of new mothers and their families in Southeast Asia, where some families believe that pregnancy is considered to be a "hot" state and childbirth results in a sudden loss of this state. Therefore, balance needs to be restored by increasing the return of the hot state, which is present physically or symbolically in hot food, hot water, and warm air. Mothers may wish to stay warm and avoid bathing, exercising, and hair washing for 7 to 30 days after childbirth. Another belief is that the mother and baby are in a weak and vulnerable state for a period of several weeks following birth. During this time, the mother may remain in a passive role, take no baths or showers, and stay in bed to prevent cold air from entering their body. This practice is considered "doing-the-month," and while some postpartum Chinese practices might seem unusual and even unhealthy to those in Western civilizations, doing-the-month practices have a positive effect on patients; most Chinese patients believe that doing-the-month practices will help restore their health and protect them from future disease, because they have been taught to believe so from childhood. In addition, failure to follow the practices might increase maternal stress and stimulate family discord (Qun Liu et al., 2015).

Thus nurses must consider all cultural aspects when planning care and not use their own cultural beliefs as the framework for that care. In order to provide family- and patient-centred, relational care, patients' rituals and traditions should be encouraged as long as the mother and the baby experience no ill effects.

The nurse must also determine whether a person is using complementary and alternative medical therapy during the postpartum period, as active ingredients in some herbal remedies can have adverse physiological effects on the patient when ingested with prescribed medicines.

Also, people who have immigrated to Western nations without their extended families may not have much help at home, making it difficult for them to observe these activity restrictions. Many young people who are first- or second-generation Canadians may feel conflicted about following their cultural traditions and need to be supported in the decisions they make regarding postpartum care.

Discharge Teaching

Discharge planning begins at the time of admission to the unit and should be individualized for each patient. The nurse functions primarily as teacher, encourager, and supporter rather than doer, while implementing the plan of care for a postpartum patient. The goal is for all postpartum patients to be capable of providing basic care for themselves and their newborns at the time of discharge. Topics that should be included are promotion of parenting skills and adjustment

of family members to the newborn, self-care, and sexual activity and contraception.

Because of the limited time available for teaching, nurses must focus their teaching on the patient's expressed needs. Giving the patient a list of topics and asking them to indicate their teaching needs can help the nurse maximize teaching efforts and increase the patient's retention of information. Using "teachable moments" (i.e., when the topic arises during the daily routine) enhances the mother's learning. It is also important that teaching be provided when the mother is ready to learn and not distracted by pain, visitors, or a crying baby. Providing written materials on postpartum self-care, breastfeeding, and newborn care that the patient can consult after discharge may be helpful. See Chapter 5 for more information on health teaching.

Just before the time of discharge, the nurse should review the patient's chart to check that laboratory reports, medications, signatures, and other items are in order. Some hospitals use a checklist to be completed before the patient's discharge. The nurse should also verify that the newborn is ready to be discharged.

Self-Care and Signs of Complications. Every postpartum patient must be taught to recognize physical and psychological signs and symptoms that might indicate health concerns and how to obtain advice and assistance quickly if these signs appear. Table 22.2 and Box 22.3, respectively, list several common indications of maternal physical and psychosocial issues in the postpartum period. (See Chapter 24 for more information on postpartum complications.) Before discharge, postpartum patients need basic instruction in a variety of self-care topics, such as nutrition, exercise, family planning, the resumption of sexual intercourse, prescribed medications, and routine mother–baby follow-up care. No medication that would make the mother sleepy should be administered if they are the one who will be holding the baby on the way out of the hospital. In some instances, the mother is seated in a wheelchair and given the baby to hold. Some families leave unescorted and ambulatory, depending on hospital protocol. The mother's and the baby's identification bands should be carefully checked. In most hospitals, nurses must ensure that the parents are able to properly secure the baby in a car seat for the drive home (see Figure 26.25).

Sexual Activity and Contraception. Feelings related to sexual adjustment after childbirth are often a cause of concern for new parents. Postpartum patients who have recently given birth may be reluctant to resume sexual intercourse for fear of pain, or worry that coitus could damage healing perineal tissue. Because many new parents are anxious for information but reluctant to bring up the subject, postpartum nurses should matter-of-factly include the topic of postpartum sexuality during their routine physical assessment. For example, while examining a perineal laceration or episiotomy site the nurse can say, "I know you're sore right now, but it probably won't be long until you (or you and your partner) are ready to make love again. Do you have any questions about resuming sex?" This approach assures the patient and their partner that resuming sexual activity is a legitimate concern for new parents and indicates the nurse's willingness to answer questions and share information.

Discussing sexual activity with the patient and their partner is important before they leave the hospital, because many couples resume sexual activity before the traditional postpartum checkup 6 weeks after childbirth. For most postpartum patients the risk of hemorrhage or infection is minimal by approximately 2 weeks after birth. The nurse needs to discuss the physical and psychological effects that giving birth can have on sexual activity (see Patient Teaching box: Resuming Sexual Activity After Birth).

Many factors can influence the timing and quality of sexual activity after birth. Postpartum perineal pain and dyspareunia (painful intercourse) are common among patients with perineal lacerations or episiotomy. Some patients who had an episiotomy report discomfort with intercourse for months after birth. Perineal lacerations that reach the anal sphincter (third degree) and the rectal wall (fourth degree) are called *obstetrical anal sphincter injuries* (OASIS) (see Chapter 17, Evidence-Informed Practice Box: When an OASIS Is Not a Scenic Travel Destination: Minimizing Anal Sphincter Injury in Childbirth). These injuries may cause long-term postpartum anal incontinence and urgency, pelvic pain, and dyspareunia. Patients may be deeply embarrassed discussing dyspareunia and incontinence with their partners and with their health care team. Prior to hospital discharge, the nurse can initiate discussions with the patient and their partner regarding pain, dyspareunia, resumption of intercourse, and contraception. At postpartum visits, the nurse assesses bladder, bowel, and sexual function; inspects the perineum; and assesses and discusses mood and intimacy challenges such as fatigue and timing issues. Alternate positions that may help increase comfort during intercourse can be suggested.

Breastfeeding parents often experience vaginal dryness related to high prolactin levels and low estrogen levels; they need to know that they may require additional vaginal lubrication. Changes in family

PATIENT TEACHING

Resuming Sexual Activity After Birth

- Unless your health care provider indicates otherwise, you can safely resume sexual activity (intercourse) by the second to fourth week after birth, when bleeding has stopped and the perineum is healed. Many people resume sexual activity by 5 to 6 weeks after birth, although this varies and is often related to perineal discomfort. Perineal lacerations or episiotomy increases the chances of discomfort with intercourse. For the first 6 weeks to 6 months, vaginal lubrication can be decreased, especially among breastfeeding or chestfeeding people.
- Your physiological reactions to sexual stimulation for the first 3 months after birth will be slower and less intense. The strength of the orgasm is reduced.
- A water-soluble gel, or contraceptive cream or jelly might be recommended for lubrication. If some vaginal tenderness is present, your partner can be instructed to insert one or more clean, lubricated fingers into the vagina and rotate them to help the vagina relax and identify possible areas of discomfort. A position in which you have control of the depth of the insertion of the penis also is useful. The side-by-side or female-on-top position may be more comfortable than other positions.
- The presence of the baby can influence postbirth lovemaking. Parents hear every sound made by the baby; conversely, you may be concerned that the baby hears every sound you make. In either case, any phase of the sexual response cycle may be interrupted by hearing the baby cry or move, leaving both of you frustrated and unsatisfied. In addition, the amount of psychological energy you expend in child care activities may lead to fatigue. Newborns require a great deal of attention and time.
- Some people have reported feeling sexual stimulation and orgasms when breastfeeding their babies. Some breastfeeding mothers often are interested in returning to sexual activity before nonbreastfeeding mothers are, although some breastfeeding mothers may find their interest in sexual relations is decreased, as they may feel their breasts are for feeding the baby and may not find sexual stimulation desirable.
- You should be instructed to correctly perform the Kegel exercises to strengthen your pubococcygeal muscle. This muscle is associated with bowel and bladder function and with vaginal feeling during intercourse.

structure and altered sleep patterns can make it difficult for a couple to find time for privacy and intimacy. PMDs are associated with decreased sexual desire; medication used to treat depression can also reduce sexual desire and inhibit orgasm.

Contraceptive options should be discussed with postpartum patients (and their partners, if present) before discharge so that they can make informed decisions about fertility management before resuming sexual activity. Waiting to discuss contraception at the 6-week checkup may be too late. **Ovulation** can occur as soon as 1 month after birth, particularly in people who formula-feed. Breastfeeding mothers should be taught about appropriate birth control methods that include the lactational amenorrhea method or condoms. Hormonal methods of birth control (e.g., oral contraceptives) may be used once breastfeeding is well established. Contraceptive options are discussed in detail in Chapter 8.

Prescribed Medications. Postpartum patients should continue to take their prenatal vitamins for the first 6 weeks after birth. Breastfeeding mothers may be instructed to continue prenatal vitamins for the duration of breastfeeding. Supplemental iron can be prescribed for mothers with lower-than-normal hemoglobin levels. Postpartum patients with extensive episiotomies or perineal lacerations (third or fourth degree) are usually prescribed stool softeners to take at home. Pain medications (analgesics or NSAIDs) may be prescribed, especially for patients who had Caesarean birth. The nurse should make certain that the patient knows the route, dosage, frequency, and common adverse effects of all ordered medications. Written information about the medications is usually included in the discharge instructions.

Coping With Visitors. A newborn in the family or neighbourhood draws visitors. The nurse can help the parents explore ways in which they can assert their needs in such situations. When family or friends ask what they can do to help, the family can respond with "Please bring us a casserole or a meal" or "Could you please pick up some items at the grocery store?" The couple can work out a signal for alerting the partner that the new mother is becoming tired or uncomfortable and needs to have the partner invite the visitors into another part of the house. Some new mothers have found that if they remain in their robes and do not appear ready for company, visitors stay for a shorter time. A "Please Do Not Disturb" sign on the front door may be useful when the mother is resting.

Follow-up After Discharge

Routine Mother and Baby Checkups. Follow-up with the obstetrical health care provider is important to the health of the postpartum patient. It is a time for comprehensive evaluation of the new parent's physical, emotional, mental, and social well-being. Important components of the postpartum visit are review of the patient's postpartum concerns; routine screening for a PMD; review of the labour and birth experience and any complications that occurred; counselling for patients with ongoing health concerns such as diabetes; contraceptive planning; and health teaching related to weight loss.

Postpartum patients who have experienced uncomplicated vaginal births are commonly scheduled for the traditional 6-week postpartum examination. Those patients who have had a Caesarean birth are often seen in the health care provider's office or clinic within 2 weeks after hospital discharge. Early follow-up is warranted for women who experienced complications such as hypertensive disorders of pregnancy, those with chronic health conditions, patients at high risk for depression, and breastfeeding mothers who are experiencing lactation difficulties. The date and time for the follow-up appointment should be included in the discharge instructions. If an appointment is not made before the patient leaves the hospital, they should be encouraged to call the health care provider's office or clinic to schedule one.

Parents who have not already done so need to make plans for newborn follow-up at the time of discharge. Most health care providers like to see newborns for an initial examination within 3 to 5 days after birth or 48 to 72 hours after hospital discharge. If an appointment for a specific date and time was not made for the newborn before leaving the hospital, the parents should be encouraged to call the office or clinic right away.

Home Visits. Community health nurse visits to new mothers and babies can help bridge the gap between hospital care and routine visits to health care providers. Nurses are able to assess the mother, newborn, and home environment; answer questions and provide education; and make referrals to community resources, if necessary. Home visits reduce the need for more expensive health care, such as emergency department visits and rehospitalization. They can also help to improve the overall quality of care provided to newborns and their parents. Ideally, immediate follow-up contact and home visits should be available 7 days a week. The support provided by nurses and other trained community health care workers such as peer counselors can help support parent–newborn interaction and parenting skills; home visits also help to promote mutual support between the mother and their partner. Breastfeeding outcomes can be enhanced through home visitation programs.

Community nursing care may not be available, even if needed, because of funding issues, but in some provinces mothers receive a phone call within the first week after discharge. Patients who are assessed to be high risk may then receive a home visit from a community health nurse to assist with the new mother's concerns, depending on the practice of the local health department.

During the home visit, the nurse conducts an assessment of the mother and newborn to determine physiological adjustment, identify any existing complications, and answer any questions the mother has about herself or newborn care. Conducting the assessment in a separate room provides private time for the mother to ask questions on topics such as breast care, family planning, and constipation. The assessment should also include the mother's emotional adjustment and their knowledge of self-care and newborn care. During the newborn assessment, the nurse can demonstrate and explain normal newborn behaviour and capabilities and encourage the mother and family to ask questions or express concerns they may have. See Chapter 3 for more information on home visiting.

Telephone Follow-up. Many local health departments have implemented postpartum telephone follow-up calls to women for assessment, health teaching, and identification of complications to effect timely intervention and referrals. Telephonic nursing assessments may also be used after a postpartum home care visit to reassess a patient's knowledge about the signs and symptoms of adequate intake by the breastfeeding newborn or, after initiating home phototherapy, to assess the caregiver's knowledge regarding equipment complications. There is evidence that phone support for new mothers during the postpartum period is beneficial; it can contribute to improved breastfeeding outcomes, reduced depression scores, and increased patient satisfaction (Lavender et al., 2013; Miller et al., 2014).

Warm Lines. The **warm line** is another type of telephone link between the new family and concerned caregivers or experienced parent volunteers. A warm line is a helpline or consultation service, not a crisis intervention line. The warm line is appropriately used for dealing

with less extreme concerns that can seem urgent at the time the call is placed but are not actual emergencies. Calls to warm lines commonly relate to newborn feeding, prolonged crying, sibling rivalry, or perinatal mood disorder concerns. Families are encouraged to call when concerns arise. Telephone numbers for warm lines should be given to parents before hospital discharge.

Support Groups. The person adjusting to motherhood sometimes seeks a special group experience. Postpartum patients who have met earlier in prenatal clinics or on the hospital unit can begin to associate for mutual support. Members of childbirth preparation classes may decide to extend their relationship during the postpartum period.

A postpartum support group enables mothers and partners to share with and support each other as they adjust to parenting. Many new parents find it reassuring to discover that they are not alone in their feelings of confusion and uncertainty. An experienced parent can often impart concrete information to other members. Inexperienced parents can find themselves imitating the behaviour of others in the group whom they perceive to be particularly capable. There are local support groups for a variety of postpartum topics and concerns. For example, women can find breastfeeding support through local meetings of La Leche League.

Postpartum mothers can connect with support groups via the Internet and can also find support through groups on social media. They can participate in virtual meetings while in the comfort of their own homes, and they can participate in forums on specific topics.

Referral to Community Resources. In order to develop an effective referral system, it is important that the nurse have a clear understanding of the needs of the postpartum person and family and of the organization and community resources available for meeting those needs. Locating and compiling information about available community services contributes to the development of a referral system. It is important for the nurse to develop their own resource file of local and national services that are frequently useful to postpartum families.

KEY POINTS

- Postpartum care is modelled on the concept of health.
- Postpartum nursing care is influenced by knowledge of antepartum and intrapartum care.
- Cultural beliefs and practices affect the patient's response to the puerperium.
- Nursing care includes assessments to detect deviations from normal comfort measures for relieving discomfort or pain and safety measures for preventing infection.
- A postpartum assessment includes a review of breasts, uterus, bladder elimination, bowel elimination, amount and colour of lochia, swelling of legs, condition of episiotomy or laceration, and emotional status.
- Teaching and counselling measures are designed to promote the person's feelings of competence in self-management and baby care.
- Common nursing interventions in the postpartum period include evaluating and treating the boggy uterus and the full urinary bladder; providing for nonpharmacological and pharmacological relief of pain and discomfort associated with the episiotomy, lacerations, afterbirth pains, or breastfeeding; and instituting measures to promote or suppress lactation.
- Meeting the psychosocial needs of new mothers involves taking into consideration the composition and functioning of the entire family as well as an understanding of different cultural beliefs and practices.
- Many mothers may exhibit signs of postpartum blues (baby blues).
- Postpartum teaching includes self-care needs, warning signs, exercise, and sexuality and resumption of sexual relations.
- Telephone follow-up, home visits, warm lines, and support groups are effective means of facilitating physiological and psychological adjustments in the postpartum period.

Transition to Parenthood

Keri-Ann Berga

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify parental and newborn behaviours that facilitate and those that inhibit parental attachment to the newborn.
2. Describe sensual responses that strengthen attachment.
3. Examine the process of becoming a mother.
4. Compare maternal and paternal adjustments to parenthood.
5. Describe ways in which the nurse can facilitate parent–infant adjustment.
6. Examine the effects of the following on parenting responses and behaviour: parental age (i.e., adolescence and older than 35 years), same-sex parenting, social support, culture, socioeconomic conditions, personal aspirations, and sensory impairment.
7. Describe sibling adjustment.
8. Describe grandparent adaptation.

Becoming a parent creates a period of change and instability for all people who decide to have children. This period occurs whether parenthood is biological or adoptive and whether the parents are husband-and-wife couples, single mothers, single fathers, lesbian couples with one woman as biological mother, gay male couples who adopt a child, or couples who are transgender and give birth to or adopt a child. Parenting is a process of role attainment and role transition. The transition is an ongoing process as the parent(s) and infant develop and change.

A thorough understanding of the process parents go through during their transition to parenthood guides the nurse in helping family members adapt. Family-centred care supports the family as the primary source of knowledge about what is best for them as they work in collaboration with health care providers to plan care. This chapter reviews the transition to parenthood, including the parenting process and the adjustment of all family members in this transition.

PARENTAL ATTACHMENT, BONDING, AND ACQUAINTANCE

The process by which a parent comes to love and accept a child and a child comes to love and accept a parent is known as **attachment**. Using the terms *attachment* and **bonding**, Klaus and Kennell (1976) originally proposed that there is a sensitive period during the first few minutes or hours after birth when mothers and fathers must have close contact with their newborns to optimize the child's later development. Klaus and Kennel (1982) later revised their theory of parent–infant bonding, modifying their claim of the critical nature of immediate contact with the newborn after birth. They acknowledged the adaptability of parents, stating that it took longer than minutes or hours for parents to form an emotional relationship with their infants. The terms *attachment* and *bonding* continue to be used interchangeably.

Attachment is an emotional bond to another person and is described as a lasting, psychological connectedness between human beings (Bowlby, 1969). The earliest bonds formed by children with their caregivers have a tremendous impact that continues throughout life. Attachment is developed and maintained through proximity and interaction with the newborn as the parent becomes acquainted with the infant, identifies the infant as an individual, and claims the infant as a member of the family. Attachment is facilitated by positive feedback (i.e., social, verbal, and nonverbal responses, whether real or perceived, that indicate acceptance of one partner by the other). Attachment occurs through a mutually satisfying experience. One mother commented on her daughter's grasp reflex, noting, "I put my finger in her hand, and she grabbed right on. It's just a reflex, I know, but it felt good anyway" (Figure 23.1).

The concept of attachment includes mutuality (i.e., the infant's behaviours and characteristics elicit a corresponding set of parental behaviours and characteristics). The infant displays signalling behaviours such as crying, smiling, and cooing that initiate the contact and bring the caregiver to the child. These behaviours are followed by behaviours such as rooting, grasping, and postural adjustments that maintain the contact. Most caregivers are attracted to an alert, responsive, cuddly infant and repelled by an irritable, apparently disinterested infant. Attachment occurs more readily with the infant whose temperament, social capabilities, appearance, and sex fit the parent's expectations. If the child does not meet these expectations, the parent's disappointment can delay the attachment process. Table 23.1 presents a comprehensive list of classic infant behaviours affecting parental

Fig. 23.1 Grasping. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

attachment. Table 23.2 presents a corresponding list of parental behaviours that affect infant attachment.

An important part of attachment is acquaintance. Parents use eye contact (Figure 23.2), touching, talking, and exploring to become acquainted with their newborn during the immediate postpartum period. Adoptive parents undergo the same process when they first meet their new child.

During this period, families engage in the claiming process, which is the identification of the new baby. The child is first identified in terms of likeness to other family members, then in terms of differences, and finally in terms of "uniqueness." The unique newcomer is thus incorporated into the family. Parents examine their newborn carefully and point out characteristics that the child shares with other family members and that are indicative of a relationship between them. The claiming process is revealed by comments such as the following: "David held him close and said, 'He's the image of his father,' but I found one part like me—his toes are shaped like mine."

Conversely, some mothers react negatively. They "claim" the newborn in terms of the discomfort or pain the baby causes. The mother interprets the newborn's normal responses as being negative toward them and reacts to their child with dislike or indifference. They do not hold the child close or touch the child to be comforting; for example, "The nurse put the baby into Marie's arms. She promptly laid him across her knees and glanced up at the television. 'Stay still until I finish watching—you've been enough trouble already.'"

Nurses play an important role in facilitating parental attachment. They can enhance positive parent–infant contacts by heightening parental awareness of an infant's responses and ability to communicate. As the parent attempts to become competent and loving in that role, nurses can bolster the parent's self-confidence and ego. Nurses are in prime positions to identify actual and potential parenting issues and to collaborate with other health care providers who will care for the parents after discharge. Nursing interventions related to the promotion of parent–infant attachment are numerous and varied (Table 23.3).

Assessment of Attachment Behaviours

One of the most important areas of assessment is careful observation of behaviours thought to indicate the formation of emotional bonds between the newborn and family, especially the mother. Unlike physical assessment of the newborn, which has concrete guidelines to follow, assessment of **parent–infant attachment** relies more on skillful observation and interviewing. Rooming-in of mother and newborn and liberal visiting privileges for the partner, siblings, and grandparents can help nurses identify behaviours that demonstrate positive or negative attachment. An excellent opportunity exists during newborn feeding sessions. Box 23.1 presents guidelines for assessment of attachment behaviours.

TABLE 23.1 Infant Behaviours Affecting Parental Attachment

Facilitating Behaviours	Inhibiting Behaviours
Visually alert; eye-to-eye contact; tracking or following of parent's face	Sleepy; eyes closed most of the time; gaze averted
Appealing facial appearance; randomness of body movements reflecting helplessness	Resemblance to person parent dislikes; hyperirritability or jerky body movements when touched
Smiles	Bland facial expression; infrequent smiles
Vocalization; crying only when hungry or wet	Crying for hours on end; colicky
Grasp reflex	Exaggerated motor reflex
Anticipatory approach behaviours for feedings; sucks well; feeds easily	Feeds poorly; regurgitates; vomits often
Enjoys being cuddled, held	Resists being held and cuddling by crying, stiffening body
Easily consolable	Inconsolable; unresponsive to parenting, caretaking tasks
Activity and regularity somewhat predictable	Unpredictable feeding and sleeping schedule
Attention span sufficient to focus on parents	Inability to attend to parent's face or offered stimulation
Differential crying, smiling, and vocalizing; recognizes and prefers parents	Shows no preference for parents over others
Approaches through locomotion	Unresponsive to parent's approaches
Clings to parent; puts arms around parent's neck	Seeks attention from any adult in room
Lifts arms to parents in greeting	Ignores parents

Date from Gerson, E. (1973). *Infant behavior in the first year of life*. Raven Press.

TABLE 23.2 Parental Behaviours Affecting Infant Attachment

Facilitating Behaviours	Inhibiting Behaviours
Looks; gazes; takes in physical characteristics of infant; assumes en face position; eye contact	Turns away from infant; ignores infant's presence
Hovers; maintains proximity; directs attention to and points to infant	Avoids infant; does not seek proximity; refuses to hold infant when given opportunity
Identifies infant as unique individual	Identifies infant with someone parent dislikes; fails to discern any of infant's unique features
Claims infant as family member; names infant	Fails to place infant in family context or identify infant with family member; has difficulty naming
Touches; progresses from fingertip to fingers to palms to encompassing contact	Fails to move from fingertip touch to palmar contact and holding
Smiles at infant	Maintains bland countenance or frowns at infant
Talks, coos, or sings to infant	Wakes infant when infant is sleeping; handles roughly; hurries feeding by moving nipple continuously
Expresses pride in infant	Expresses disappointment, displeasure in infant
Relates infant's behaviour to familiar events	Does not incorporate infant into daily life
Assigns meaning to infant's actions and sensitively interprets infant's needs	Makes no effort to interpret infant's actions or needs
Views infant's behaviours and appearance in positive light	Views infant's behaviour as exploiting, deliberately uncooperative; views appearance as distasteful, ugly

Data from Mercer, R. (1983). Parent–infant attachment. In L. Sonstegard, K. Kowalski, & B. Jennings (Eds.), *Women's health* (Vol. 2). Grune & Stratton.

Fig. 23.2 Eye-to-eye contact. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

During pregnancy and often even before conception, parents develop an image of the "ideal" or "fantasy" newborn. At birth, the fantasy newborn becomes the real newborn. How closely the dream child resembles the real child influences the bonding process. Assessing such expectations during pregnancy and at the time of the newborn's birth enables identification of discrepancies in the parents' view of the fantasy child and the real child.

The labour process significantly affects the immediate attachment of mothers to their newborn. Factors such as a long labour, feeling tired or "drugged" after birth, difficulties with breastfeeding (Tharner et al., 2012), premature birth, and being separated from the newborn at birth (Flacking et al., 2012; Hoffenkamp et al., 2012) can delay the development of initial positive feelings toward the newborn. Nurses can provide breastfeeding support and referrals to groups such as La Leche League Canada or Postpartum Support International (see Additional Resources at the end of the chapter), which may be useful to some mothers.

TABLE 23.3 Examples of Parent–Infant Attachment Interventions

Intervention Label and Definition	Activities
Attachment Promotion Facilitating development of an affective, enduring relationship between infant and parent	Discuss with patient culture-based expressions of attachment before and after birth.
	Place newborn skin-to-skin with parent immediately after birth (if mother wishes this).
	Provide opportunity for parent or parents to see, hold, and examine newborn immediately after birth (i.e., delay unnecessary procedures and provide privacy).
	Discuss infant behavioural characteristics with parent.
	Assist parent of multiples in recognizing individuality of each infant.
	Instruct parent on attachment development, emphasizing its complexity, ongoing nature, and opportunities.

Continued

TABLE 23.3 Examples of Parent–Infant Attachment Interventions—cont'd

Intervention Label and Definition	Activities
Family Integrity Promotion: Childbearing Family Facilitation of the growth of individuals or families who are adding an infant to family unit	Respect and support family's cultural value system.
	Assist family in developing adaptive coping mechanisms to assist with the transition to parenthood.
	Prepare parent(s) for expected role changes involved in becoming a parent.
	Prepare parent(s) for responsibilities of parenthood.
	Reinforce positive parenting behaviours.
	Identify effect of newborn on family dynamics and equilibrium.
Lactation Counselling Assisting in the establishment and maintenance of successful breastfeeding	Correct misconceptions, misinformation, and inaccuracies about breastfeeding.
	Provide mother the opportunity to breastfeed after birth, when possible.
	Instruct on newborn feeding cues (e.g., rooting, sucking, and quiet alertness).
	Determine frequency of normal feeding patterns, including cluster feedings and growth spurts.
	Discuss strategies aimed at optimizing milk supply (e.g., breast massage, frequent milk expression, complete emptying of breasts, kangaroo care, and medications).
	Instruct on signs and symptoms warranting reporting to a health care provider or lactation consultant.
Parent Education: Infant Instruction on nurturing and physical care needed during the first year of life	Determine parent's (or both parents') knowledge and readiness and ability to learn about infant care.
	Provide anticipatory guidance about developmental changes during first year of life.
	Teach parent(s) skills to care for newborn.
	Demonstrate ways in which parent(s) can stimulate infant's development.
	Discuss infant's capabilities for interaction.
	Demonstrate quieting techniques.
Risk Identification: Childbearing Family Identification of individual or family likely to experience difficulties in parenting, and prioritization of strategies to prevent parenting issues	Ascertain understanding of English or other language used in community.
	Determine developmental stage of parent or parents.
	Review prenatal history for factors that predispose patient to complications.
	Monitor parent–infant interactions, noting behaviours thought to indicate attachment.
	Plan for risk-reduction activities, in collaboration with the individual or family.
	Refer to the appropriate community agency for follow-up if risk for parent concerns or a lag in attachment has been identified.

Data from Bulechek, G., Butcher, H., Dochterman, J., et al. (2013). *Nursing interventions classification (NIC)* (6th ed.). Mosby.

BOX 23.1 Assessing Attachment Behaviours

- When the newborn is brought to the parents, do they reach out for the newborn and call the child by name? (Recognize that in some cultures parents may not name the baby in the early newborn period.)
- Do the parents speak about the newborn in terms of identification—whom the newborn resembles, and what appears special about their newborn over other newborns?
- When parents are holding the newborn, what kind of body contact is seen—do parents feel at ease in changing the newborn's position, are fingertips or whole hands used, and does the newborn have parts of the body they avoid touching or parts of the body they investigate and scrutinize?
- When the newborn is awake, what kinds of stimulation do the parents provide—Do they talk to the newborn, to each other, or to no one? How do they look at the newborn—using direct visual contact, avoiding eye contact, or looking at other people or objects?
- How comfortable do the parents appear in terms of caring for the newborn? Do they express any concern regarding their ability or disgust for certain activities, such as changing diapers?
- What types of affection do they demonstrate to the newborn, such as smiling, stroking, kissing, or rocking?
- If the newborn is fussy, what kinds of comforting techniques do the parents use, such as rocking, talking, or stroking?

PARENT–INFANT CONTACT

Early Contact

Early close contact may facilitate the attachment process between parent and child. Although a delay in contact does not necessarily mean that attachment will be inhibited, additional psychological energy may be necessary to achieve the same effect. To date, no scientific evidence has demonstrated that immediate contact after birth is essential for the parent–child relationship.

Early skin-to-skin contact between the mother and newborn immediately after birth and during the first hour facilitates maternal affection and attachment behaviours and is recommended as a standard of care because of its many benefits and lack of adverse effects (Kilpatrick & Garrison, 2017; King & Pinger, 2014; Stewart & Rodgers, 2017). The newborn is placed in the prone position on the parent's bare chest; the baby and the parent's chest are covered with a warm, dry blanket (Figure 23.3). This practice promotes early and effective breastfeeding and increases breastfeeding duration. It is also associated with less newborn crying, improved thermoregulation (especially in low–birth weight infants), and improved cardiorespiratory stability in late preterm infants (Kilpatrick & Garrison, 2017; Stewart & Rodgers, 2017).

Parents who cannot have early contact with their newborn (i.e., the newborn was transferred to the intensive care nursery) can be reassured that such contact is not essential for optimal parent–infant interactions. Otherwise, adopted infants would not form ties of affection with their parents. Nurses need to stress that the parent–infant relationship is a process that develops over time.

Nurses can facilitate skin-to-skin contact in most birth settings, whether the newborn is preterm or term or birthed vaginally or by Caesarean, and with fathers or partners and mothers.

Extended Contact

Rooming-in ensures that the newborn stays in the room with the mother and is the norm in Canadian hospitals. In most facilities, the newborn never leaves the parent's presence; nurses should perform the initial and ongoing assessments and care in the room with the parents whenever possible. Nurses should encourage the partner to participate in caring for the newborn in as active a role as desired (Figure 23.4). They can also encourage siblings and grandparents to visit and become acquainted with the newborn.

Fig. 23.3 Placing the naked infant on the bare chest of the mother encourages both breastfeeding and bonding. (Leifer, G. [2015]. *Introduction to maternity and pediatric nursing* [7th ed.]. Saunders.)

Fig. 23.4 Father changes diaper of his newborn son. (Courtesy Darren Nelson.)

Extended contact with the newborn should be available for all parents but especially for those at risk for parenting difficulties, such as adolescents and those with minimal social and financial support. Perinatal nurses need to consider and encourage activities that optimize family-centred care (Public Health Agency of Canada [PHAC], 2017). Baby Friendly status for a hospital is one means to promote family-centred care (Breastfeeding Committee of Canada, 2021; Jaafar et al., 2016). See more discussion on the Baby Friendly Hospital Initiative in Chapter 27.

COMMUNICATION BETWEEN PARENT AND INFANT

The parent–infant relationship is strengthened through the use of sensual responses and abilities by both partners in the interaction. The nurse should keep in mind that there may be cultural variations in these interactive behaviours.

The Senses

Touch. Touch, or the tactile sense, is used extensively by parents as a means of becoming acquainted with the newborn. Many parents reach out for their newborns as soon as they are born. Mothers lift their newborn to their breasts, enfold them in their arms, and cradle them. Once the newborn is close, the mother begins the exploration process with their fingertips, one of the most touch-sensitive areas of the body (Figure 23.5). Within a short period of time, they use their palm to caress the baby's trunk and eventually enfold the newborn. Gentle, stroking motions are used to soothe and quiet the newborn. Patting or gently rubbing the newborn's back is a comfort after feedings. Infants also pat the parent's breast as they nurse. Both seem to enjoy sharing each other's body warmth. Parents seem to have an innate desire to touch, pick up, and hold the newborn. They comment on the softness of the baby's skin and note details of the baby's appearance. As parents become increasingly sensitive to the infant's like or dislike of different types of touch, they draw closer to their baby.

Fig. 23.5 Mother uses fingertip to explore infant. (Courtesy Rebekah Vogel.)

Variations in touching behaviours have been noted in parents from different cultural groups. For example, minimal touching and cuddling can be a traditional Southeast Asian practice, thought to protect the newborn from evil spirits. Because of tradition and spiritual beliefs, some new mothers in India and Bali have practised infant massage since ancient times. The benefits of infant massage include enhanced weight gain in preterm infants.

Eye Contact. Parents repeatedly demonstrate interest in having eye contact with the baby. Some mothers remark that, once their babies have looked at them, they feel much closer to them. Parents spend much time getting their babies to open their eyes and look at them. In North American culture, eye contact appears to reinforce the development of a trusting relationship and is an important factor in human relationships at all ages (see Figure 23.2). In other cultures, eye-to-eye contact may be perceived differently. For example, in Mexican culture, sustained direct eye contact is considered to be rude and immodest and even dangerous for some individuals. This danger may arise from the *mal ojo* (evil eye), resulting from excessive admiration. Women and children are thought to be more susceptible to the *mal ojo* (Berger, 2012).

As newborns become functionally able to sustain eye contact with their parents, time is spent in mutual gazing, often in the en face position. In this position, the parent's face and the newborn's face are approximately 20 cm apart and on the same plane (see Figure 23.2).

Nurses and other obstetrical health care providers can facilitate eye contact immediately after birth by positioning the newborn on the mother's abdomen or breasts with the mother's and the newborn's faces on the same plane. Dimming the lights encourages the newborn's eyes to open. To promote eye contact, instillation of prophylactic antibiotic ointment in the newborn's eyes can be delayed until the newborn and parents have had some time together after birth. This intervention should be provided while maintaining skin-to-skin contact between mother and newborn whenever possible.

Voice. The shared response of parents and infants to each other's voices is also remarkable. Parents wait tensely for the first cry. Once that cry has reassured them of the baby's health, they begin comforting behaviours. As the parents speak, the newborn is alerted and turns toward them. Newborns respond to higher-pitched voices and can distinguish the mother's voice from others soon after birth.

Odour. Another behaviour shared by parents and infants is a response to each other's odour. Mothers comment on the smell of their babies when first born and have noted that each newborn has a unique odour. Newborns learn rapidly to distinguish the odour of their mother's breast milk.

Entrainment

Newborns move in time with the structure of adult speech, which is termed *entrainment*. They wave their arms, lift their heads, and kick their legs, seemingly "dancing in tune" to a parent's voice. Culturally determined rhythms of speech are ingrained in the infant long before the child uses spoken language to communicate. This shared rhythm also gives the parent positive feedback and establishes a positive setting for effective communication.

Biorhythmicity

The fetus is in tune with the mother's natural rhythms, or *biorhythmicity*, such as their heartbeat. After birth, the mother's heartbeat or a recording of a heartbeat can soothe a crying newborn. One task of the newborn is to establish a personal biorhythm. Parents can help in this process by giving consistent loving care and using their newborn's alert state to develop responsive behaviour and increase social interactions and opportunities for learning (Figure 23.6). The more quickly parents become competent in child care activities, the more quickly their psychological energy can be directed toward observing the communication cues that the infant gives them.

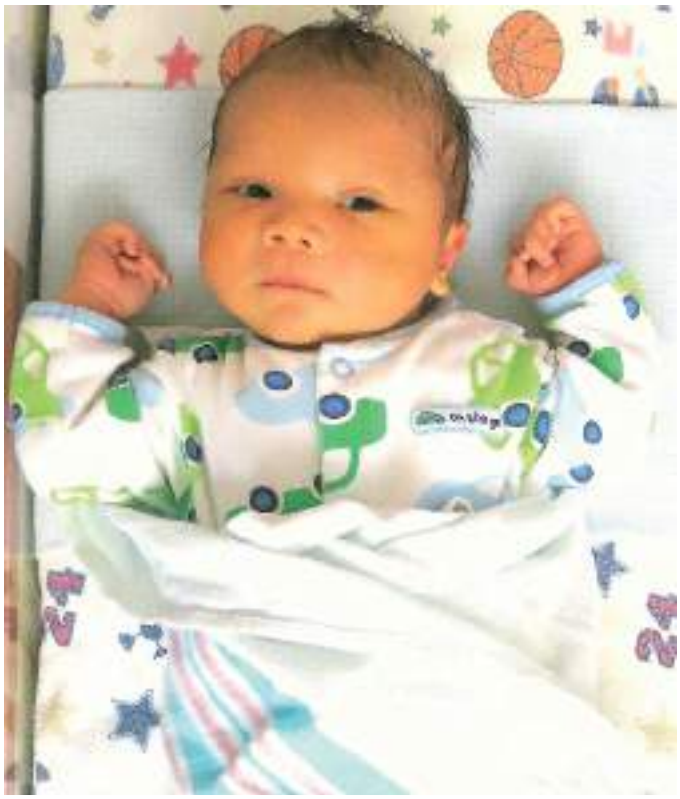

Fig. 23.6 Newborn in alert state. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

Fig. 23.7 Sharing a smile; an example of synchrony. (iStock.com/Monica Ninker).

Reciprocity and Synchrony

When they are noticing and responding appropriately to infant cues, mothers and caregivers can be regulators of their infants' states. The terms *reciprocity* and *synchrony* are used to describe these interactions as they relate to newborn cues. One of the most essential experiences in shaping the architecture of the developing brain is "serve and return" interaction between children and significant adults in their lives. Young children naturally reach out for interaction through babbling, facial expressions, and gestures, and adults respond with the same kind of vocalizing and gesturing back at them. This back-and-forth process is fundamental to the wiring of the brain, especially in the earliest years (Center on the Developing Child, Harvard University, 2020) (see Additional Resources).

Reciprocity often takes several weeks to develop with a new baby. For example, when the newborn fusses and cries, the mother responds by picking up and cradling the newborn; the baby becomes quiet and alert and establishes eye contact; and the mother verbalizes, sings, and coos while the baby maintains eye contact. As the baby habituates to the stimulus, the infant's responses stop; the baby then averts the eyes and yawns; and the mother decreases their active response. If the parent continues to stimulate the infant, the baby may become fussy.

Synchrony refers to the fit between the infant's cues and the parent's response. When parent and infant have a synchronous interaction, it is mutually rewarding (Figure 23.7). Parents need time to learn to interpret the infant's cues correctly. For example, the infant develops a specific cry in response to different situations, such as boredom, loneliness, hunger, and discomfort. The parent may need assistance in interpreting these cries, along with trial-and-error interventions, before synchrony develops.

PARENTAL ROLE AFTER BIRTH

Adaptation involves stabilizing tasks and coming to terms with commitments. Parents demonstrate growing competence in child care activities and become increasingly attuned to their newborn's behaviour. The period from the decision to conceive through the first months of having a child is termed the *transition to parenthood*.

Transition to Parenthood

Historically, the transition to parenthood was viewed as a crisis; however, the current perspective is that for most families parenthood is a developmental transition rather than a major life crisis. The transition to parenthood is described as a time of disorder and disequilibrium, as well as satisfaction, for mothers and their partners. Usual methods of coping may seem ineffective during this time. Some parents can be so distressed that they are unable to be supportive of each other. Because men often identify their spouses as their primary or only source of support, the transition can be harder for fathers or partners. They often feel deprived when the mothers, who are also experiencing stress, cannot provide their usual level of support. Many parents are unprepared for the strong emotions that can develop, such as the helplessness, inadequacy, and anger that arise when dealing with a crying newborn. However, parenthood allows adults to develop and display a selfless, warm, and caring side that may not be expressed in other adult roles.

For most mothers and their partners, the transition to parenthood is an opportunity rather than a time of danger. Parents try new coping strategies as they work to master their new roles and reach new developmental levels. As they work through the transition, they often find personal strength and resourcefulness.

Some parents have limited knowledge of what being a parent entails. These parents can benefit from more information on child care, changes in relationships, and differing views of parenting held by partners. Women tend to have more support from female relatives and postpartum groups, whereas men often lack support mechanisms and may only have health care providers and work colleagues for information and support. There is a need for more public health messaging about parenting programs and the importance of father participation, as fathers are underrepresented in parenting interventions (Panter-Brick et al., 2014; Tully et al., 2017). In the Canadian Maternity Experience Survey, women reported that they had received enough information on breastfeeding, basic newborn and self-care, and community resources; however, they did not have enough information on the transition to parenthood. The topics of particular interest were sexual changes, physical demands of newborn care, and the effects of the transition period on the relationship with their partner (PHAC, 2009). The period after birth is often referred to as the "fourth trimester."

Parental Tasks and Responsibilities

Parents may need to reconcile the actual child with the fantasy and dream child. This means coming to terms with the newborn's physical appearance, sex, innate temperament, and physical status. If the real child differs greatly from the fantasy child, parents may delay acceptance of the child. In some instances, they may never accept the child.

Many parents know the sex of the newborn before birth because of the results of prenatal testing. For those who do not have this information, disappointment over the sex can take time to resolve. The parents can provide adequate physical care but find it difficult to be sincerely involved with the newborn until this internal conflict has been resolved. See the Cultural Awareness box.

CULTURAL AWARENESS

Birth Story: It's a Girl (Again)!

Faduma is a midwife from Saudi Arabia who faced a difficult situation while assisting a woman who desperately wanted her baby to be a boy because she already had several little girls.

When the patient gave birth to yet another baby girl, Faduma says, she set the newborn aside for as long as she could and kept telling the woman she had given birth to a "beautiful, healthy baby." She shared that the baby was a girl only when the patient pressed her for the information. Her reasons for doing this were to give the mother time to stabilize physically before she received what she would consider disappointing news. Faduma reported that this was common practice among midwives in her country.

From Watts, N., & McDonald, C. (2007). The beginning of life (the perinatal period). In R. Srivastava (Ed.). *The healthcare professional's guide to clinical cultural competence*. Elsevier.

The normal appearance of the newborn—size, colour, moulding of the head, or bowed appearance of the legs—is startling for some parents. Nurses can encourage parents to examine their babies and to ask questions about newborn characteristics.

Parents need to become adept in the care of the newborn, including caregiving activities, noting the communication cues the newborn gives to indicate needs and responding appropriately to those needs. Self-esteem tends to grow with competence. Breastfeeding can help mothers feel they are contributing in a unique way to the welfare of the newborn. The parent may interpret the newborn's response to parental care and attention as a comment on the quality of that care. Newborn behaviours that parents interpret as positive responses to their care include being consoled easily, enjoying being cuddled, and making eye contact. Spitting up frequently after feedings, crying, and being unpredictable may be perceived as negative responses to parental care. Continuation of these infant responses that are viewed as negative can result in alienation of parent and infant, to the detriment of the infant.

Some people view assistance—including advice from partners, mothers, mothers-in-law, and health care providers—as supportive. Others view advice as criticism or an indication of how inept these others judge the new parents to be. Criticism, real or imagined, of the new parents' ability to provide adequate physical care, nutrition, or social stimulation for the newborn can prove to be discouraging. By providing encouragement and praise for parenting efforts, nurses can bolster the new parents' confidence.

Parents must establish a place for the newborn within the family group. Whether the baby is the firstborn or the last born, all family members need to adjust their roles to accommodate the newcomer.

Becoming a Mother

Rubin (1961) identified three phases as the mother adjusts to a parental role. These phases extend over the first several weeks and are characterized by dependent behaviour, dependent–independent behaviour, and interdependent behaviour (Table 23.4). Rubin's research was conducted when the length of stay in the hospital was for a longer period of time (3 to 5 or more days). With today's early discharge, mothers seem to move through the phases faster.

Mercer (2004) has suggested that the concept of maternal-role attainment introduced by Rubin in 1967 be replaced with *becoming a mother*, to signify the transformation and growth of the mother identity. Becoming a mother implies more than attaining a role; it includes learning new skills and increasing one's confidence as the mother meets new challenges in caring for their child or children.

Mercer identified four stages in the process of becoming a mother (Mercer & Walker, 2006):

1. Commitment, attachment to the unborn baby, and preparation for birth and motherhood during pregnancy
2. Acquaintance/attachment to the newborn, learning to care for the newborn, and physical restoration during the first 2 to 6 weeks following birth
3. Moving toward a new normal
4. Achievement of a maternal identity through redefining self to incorporate motherhood (around 4 months)

The time of achievement of the stages varies, and the stages may overlap. Achievement is influenced by mother and infant variables and the social environment.

Maternal sensitivity or maternal responsiveness is an important determinant of the maternal–infant relationship. It can be defined as the quality of a mother's sensitive behaviours that are based on the mother's awareness, perception, and responsiveness to newborn cues and behaviours. Maternal sensitivity significantly influences the newborn's physical, psychological, and cognitive development. Maternal qualities inherent to this sensitivity include awareness and responsiveness to infant cues, affect, timing, flexibility, acceptance, and conflict negotiation and develop over time.

TABLE 23.4 Phases of Maternal Postpartum Adjustment

Phase	Characteristics
Dependent: taking-in phase	First 24 hours (range of 1–2 days) Focus: self and meeting of basic needs • Reliance on others to meet needs for comfort, rest, closeness, and nourishment • Excited and talkative • Desire to review birth experience
Dependent–independent: taking-hold phase	Starts second or third day; lasts 10 days to several weeks Focus: care of newborn and competent mothering • Desire to take charge • Nurturing and acceptance by others still important • Eagerness to learn and practise—optimal period for teaching by nurses • Handling of physical discomforts and emotional changes • Possible experience with postpartum blues (see Chapter 22)
Interdependent: letting-go phase	Focus: forward movement of family as unit with interacting members • Reassertion of relationship with partner • Resumption of sexual intimacy • Resolution of individual roles

From Rubin, R. (1961). Basic maternal behavior. *Nursing Outlook, 9*, 683–686.

Not all mothers experience the transition to motherhood in the same way. For some people, becoming a mother entails multiple losses. For example, for some single people there may be a loss of the family of origin when they do not accept the person's decision to have the child. There may be loss of a relationship with the father of the baby, with friends, and with their own sense of self. Some mothers describe a loss of dreams, including loss of job, financial security, and a future profession.

More reality-based perinatal education programs are needed, to better prepare mothers and to decrease their anxiety. Classes allow time for questions to be answered and for mothers to lend support to one another. These classes can be provided in person or online, through Skype, Zoom, or video chat. Mothers need to know during the first months of parenthood that it is common to feel overwhelmed and insecure and to experience physical and mental fatigue. They need to be assured that this situation is temporary and that 3 to 6 months may be needed to become comfortable in caregiving and in being a mother. Maternal support by professionals should not end with hospital discharge but extend over the next 4 to 6 months; long-term interventions tend to be more successful than one-time encounters. Nurses can advocate for the extension of such support services well into the postpartum period. Nurses can also advocate the use of doulas, who are laypersons who provide ongoing support to pregnant and postpartum patients.

During pregnancy and after birth, nurses can discuss the usual postpartum concerns that mothers experience. They can provide anticipatory

guidance on coping strategies, such as resting when the newborn sleeps and planning with an extended family member or friend to do the housework for the first week or two after the baby is born. In some provinces, once a mother is home, she will receive a phone call and, if needed, a visit from a community health nurse. Nurses should plan additional supportive counselling for first-time mothers inexperienced in child care, people whose careers had provided outside stimulation, mothers who lack friends or family members with whom to share delights and concerns, and adolescent mothers. Whenever possible, postpartum home visits should be included in the plan of care.

Becoming a Father

The realities of the first few weeks at home with a newborn may cause fathers to change their expectations, set new priorities, and redefine their role.

They develop strategies for balancing work, their own needs, and the needs of their partner and infant. Men usually become increasingly more comfortable with infant care. During this time, they may struggle for recognition and positive feedback from their partner, the infant, and others. They may feel excluded from support and attention by health care providers. The final phase of becoming an involved father is one of reaping rewards, the most significant being reciprocity from the infant, such as a smile. This phase typically occurs at around 6 weeks to 2 months. Increased sociability of the infant enhances the father–infant relationship (Table 23.5).

First-time fathers tend to perceive the first 4 to 10 weeks of parenthood in much the same way that mothers do. It is a period characterized by uncertainty, increased responsibility, disruption of sleep, and inability to control the time needed to care for the infant and re-establish the relationship with their partner (Yu et al., 2012). Fathers express concerns about decreased attention from their partners relative to their personal relationship, the mother's lack of recognition of the father's desire to participate in decision making for the infant, and limited time for establishing a relationship with their infant (de Montigny et al., 2012). These concerns can precipitate feelings of jealousy of the infant. The father should discuss their individual concerns and needs with their partner and become more involved with the infant. This can help alleviate feelings of jealousy.

Concerns of fathers are often not addressed adequately in prenatal or postnatal education. The father's relationship with the child is fostered by time alone with the child. Health professionals need to address the father's needs to assist in infant care in the father's transition to parenthood. An excellent resource for fathers is *The New Fathers Guide,* as well the Region of Peel Health Department's website. The First Nations Health Authority (FNHA) in British Columbia provides another excellent option for fathers, called "Fatherhood is Forever." FNHA also provides various information for women, men, children, and families (see Additional Resources).

Father–Infant Relationship. As in many other cultures, in North American culture, newborns have a powerful impact on their fathers, who can become intensely involved with their babies. More and more young mothers are in the workforce, and although mothers still provide the bulk of care for their young children, fathers are playing an expanded role, with 11% of stay-at-home parents being fathers (PHAC, 2017).

The term used for the father's absorption, preoccupation, and interest in the infant is engrossment. Characteristics of **engrossment** include some of the sensual responses relating to touch and eye-to-eye contact that were discussed earlier (see section The Senses) and the father's keen awareness of features both unique and similar to himself that validate his claim to the newborn. An outstanding response is one of strong attraction to the newborn. Fathers spend considerable time "communicating" with the newborn and taking delight in the newborn's responses to them (Figure 23.8). Fathers often experience increased self-esteem and a sense of pride and of being more mature after seeing their baby for the first time.

Fathers receive less interpersonal and professional support than do mothers and can feel excluded from antenatal appointments and prenatal classes (Steen et al., 2012). They need information and encouragement during pregnancy and in the postnatal period related to infant care, parenting, and relationship changes. During the postpartum hospital stay, nurses can arrange to teach newborn care when the father is present and provide anticipatory guidance for fathers about the transition to parenthood. Mothers need to be made aware that fathers may take more time to learn certain skills and that this is normal; the father needs support and encouragement from the mother, not criticism. Separate prenatal and parenting classes and parenting support groups for fathers can provide them with an opportunity to discuss their concerns and have some of their needs met. To prepare fathers for the transition to parenthood, perinatal education should include information on role changes associated with parenting, the importance of parenting "teamwork," the increased risk for mental distress and depression, the mother's

TABLE 23.5 Early Development of the Involved Father Role

Phase	Characteristics
Expectations and intentions	Desire for emotional involvement and deep connection with infant
Confronting reality	Dealing with unrealistic expectations, frustration, disappointment, feelings of guilt, helplessness, and inadequacy
Creating the role of involved father	Altering expectations, establishing new priorities, redefining role, negotiating changes with partner, learning to care for infant, increasing interaction with infant, struggling for recognition
Reaping rewards	Infant smile, sense of meaning, completeness and immortality

Data from Goodman, J. (2005). Becoming an involved father of an infant. *Journal of Obstetrics, Gynecology, & Neonatal Nursing, 34*(2), 190–200.

experience and how to provide support, how to interpret and respond to infant behaviours, and how to cope with infant crying (May & Fletcher, 2013). Postpartum phone calls and home visits by a nurse should include time for assessment of the father's adjustment and needs.

Adjustment for the Couple

The transition to parenthood brings about changes in the relationship between the mother and their partner. A strong, healthy couple relationship is the best foundation for parenthood, although even the best relationships are often shaken with the addition of a baby. During the first few weeks after birth, parents experience a plethora of emotions. Even though they may feel an overwhelming love and a sense of amazement toward their newborn, they also feel a great responsibility. Even if the mother and their partner have attended prenatal classes, read books, or sought advice from family or friends, they are usually surprised by the realities of life with a new baby and the changes in their relationship. Because men and women experience pregnancy and birth differently, the expectation is that they will also vary in their adjustment to parenthood.

Common issues that couples face as they become parents include changes in their relationship with one another, division of household and infant care responsibilities, financial concerns, balancing work and parental responsibilities, and social activities. To assist new parents in their transition, nurses can encourage them during pregnancy and in the postpartum period to share personal expectations with each other and to assess their relationship periodically. Couples need to schedule time into their busy lives for one-on-one conversation and try to have regular "dates" or time apart from the infant. The mother and partner need to express appreciation for one another as well as for their baby. Support from family, friends, and community health professionals should be identified early and used as needed during pregnancy and in the postpartum period and beyond. The couple who is willing to experiment with new approaches to their lifestyle and habits may find the transition to parenthood less difficult.

Nurses can provide opportunities for parents to discuss concerns and ask questions about resuming sexual intimacy. Sexual intimacy enhances the adult aspect of the family, and the adult pair share a closeness denied to other family members. Changes in a woman's sexuality after childbirth are related to hormonal shifts, increased breast size, uneasiness with a body that has yet to return to a prepregnant size, fatigue related to sleep deprivation, and physical exhaustion. The resumption of sexual intimacy seems to bring the parents' relationship back into focus (see Patient Teaching box: Resuming Sexual Activity After Birth, in Chapter 22). Before and after birth, nurses should review with new parents their plans for other pregnancies and their preferences for contraception.

INFANT–PARENT ADJUSTMENT

Newborns participate actively in shaping their parents' reaction to them. Behavioural characteristics of the infant influence parenting behaviours. The newborn and parent each have unique rhythms, behaviours, and response styles that are brought to every interaction. Infant–parent interactions can be facilitated in at least three ways: (1) modulation of rhythm, (2) modification of behavioural repertoires, and (3) mutual responsivity. Nurses can teach parents about these three aspects of infant–parent interaction through discussions, written materials, and video recordings describing infant capabilities. A creative approach is to record the parent–infant pair during an interaction and then use the individualized recording to discuss the pair's rhythm, behavioural repertoire, and responsivity.

Rhythm

To modulate rhythm, both parent and newborn must be able to interact. Therefore, the newborn must be in the quiet alert state, one of the most difficult of the sleep–wake states to maintain. The alert state (Figure 23.9) occurs most often during a feeding or in face-to-face play. The parent must make an effort to help the newborn maintain the alert state long enough and often enough for interactions to take place. The en face position is usually assumed (see Figure 23.9, *B–E*). Multiparous mothers in particular are very sensitive and responsive to the newborn's

Fig. 23.9 Holding newborn in en face position, a mother works to alert her daughter, 6 hours old. **A:** Infant is quiet and alert. **B:** Mother begins talking to daughter. **C:** Infant responds, opens mouth like her mother. **D:** Infant gazes at her mother. **E:** Infant waves hand. **F:** Infant glances away, resting. Hand relaxes. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

feeding rhythms. Mothers learn to reserve stimulation for pauses in sucking activity and not to talk or smile excessively while the newborn is sucking because the baby will stop feeding to interact with the mother. With maturity, the infant can sustain longer interactions by modulating activity rhythms (i.e., limb movement, sucking, gaze alternation, and habituation). Meanwhile, the parent becomes more attuned to the infant's rhythms and learns to modulate the rhythms, facilitating a rhythmic turn-taking interaction.

Behavioural Repertoires

Both the newborn and the parent have a repertoire of behaviours they can use to facilitate interactions. Fathers and mothers engage in these behaviours, depending on the extent of their contact and caregiving with the newborn. Nurses can teach parents to recognize, interpret, and respond to newborn behaviours. An innovative program called HUG Your Baby (Help, Understanding and Guidance for Young Families) is designed to prepare health care providers to teach parents how to understand their newborns and prevent issues related to crying, sleeping, eating, attachment, and bonding (see Additional Resources and Chapter 26: Family-Centred Care box: Helping Parents Recognize, Interpret, and Respond to Newborn Behaviours).

The infant's behavioural repertoire includes gazing, vocalizing, and facial expressions. The newborn is able to focus and follow the human face from birth and to alternate the gaze voluntarily, looking away from the parent's face when understimulated or overstimulated (see Figure 23.9, *F*). Parents need to learn to be sensitive to the newborn's capacity for attention and inattention and to recognize the states and signs of overstimulation. Developing this sensitivity is especially important when interacting with preterm infants.

Body gestures form a part of the infant's early language. Babies greet parents with waving hands (see Figure 23.9, *E*) or a reaching out of hands. They can raise an eyebrow or soften their expression to elicit loving attention. Game playing can stimulate them to smile or laugh. Pouting or crying, arching of the back, and general squirming usually signal the end of an interaction.

The parents' repertoire includes various types of interactive behaviours, such as constantly looking at the infant and noting the infant's response. New parents often remark that they are exhausted from looking at the baby and smiling. Adults also "infantilize" their speech to help the infant listen. They do this by slowing the tempo, speaking loudly and rhythmically, and emphasizing key words. Phrases are repeated frequently. Infantilizing does not mean using baby talk, which involves distortion of sounds.

To communicate emotions to the infant, parents often use facial expressions such as slow and exaggerated looks of surprise, happiness, and confusion. Games such as "peek-a-boo" and imitation of the infant's behaviours are other means of interaction. For example, if the baby smiles, so does the parent; if the baby frowns, the parent responds in kind.

Responsivity

Contingent responses (*responsivity*) are those that occur within a specific time and are similar in form to a stimulus behaviour. The adult has the feeling of having an influence on the interaction. Infant behaviours such as smiling, cooing, and sustained eye contact, usually in en face position, are viewed as contingent responses. The infant's responses act as rewards to the initiator and encourage the adult to continue with the game when the infant responds positively. When the adult imitates the infant, the infant appears to enjoy it. A progression occurs in the types of behaviours that parents present for the baby to imitate; for example, in early interactions the parent will grimace rather than laugh, which is in keeping with the infant's developmental level. Such behaviours sustain interactions and promote harmony in the relationship.

SIBLING ADAPTATION

Because the family is an interactive, open unit, the addition of a new family member affects everyone in the family. Siblings have to assume new positions within the family hierarchy. Parents often face the task of caring for a new child while not neglecting the others and need to distribute their attention equitably. When the newborn was born prematurely or has special needs, this can be difficult.

Reactions of siblings result from temporary separation from the mother, changes in the mother's or father's behaviour, or the newborn coming home. Positive behavioural changes of siblings include interest in and concern for the baby and increased independence. Regression in toileting and sleep habits, aggression toward the baby, and increased seeking of attention and whining are examples of behaviours that are normal. Parents should be taught that punishing the child for these behaviours is not the best strategy, rather, diverting the child's attention is often more effective.

The parents' attitudes toward the arrival of the baby can set the stage for the other children's reactions. Because the baby absorbs the time and attention of the important people in the other children's lives, jealousy (**sibling rivalry**) is to be expected once the initial excitement of having a new baby in the home is over.

Parents, especially mothers, spend much time and energy promoting sibling acceptance of a new baby. If sibling preparation classes are available, participation in these classes can help prepare older children to understand what life may be like with a new baby and may make a difference in the ability of parents to cope with their behaviour. Older children are actively involved in preparing for the infant, and this involvement intensifies after the birth of the child. Parents have to manage their feelings of guilt that the older children are being deprived of parental time and attention. They have to monitor the behaviour of older children toward the more vulnerable infant and divert aggressive behaviour. Strategies that parents have used to facilitate siblings' acceptance of a new baby are presented in the Patient Teaching box: Strategies for Facilitating Sibling Acceptance of a New Baby.

PATIENT TEACHING

Strategies for Facilitating Sibling Acceptance of a New Baby

Prenatal

- Take your child on a prenatal visit. Let the child listen to the fetal heartbeat and feel the baby move.
- Involve the child in preparations for the baby, such as helping decorate the baby's room.
- Move the child to a bed (if still sleeping in a crib) at least 2 months before the baby is due.
- Read books, show videos or DVDs, and/or take your child to sibling preparation classes, including a hospital tour.
- Answer your child's questions about the coming birth, what babies are like, and any other questions.
- Take your child to the homes of friends who have newborns so that the child has realistic expectations of what babies are like.

During the Hospital Stay

- Have someone bring the child to the hospital to visit you and the baby (unless you plan to have the child attend the birth).
- When the child arrives, make sure your arms are open to embrace the child.
- Do not force interactions between the child and the baby. Often the child will be more interested in seeing you and being reassured of your love.

PATIENT TEACHING—CONT'D

- Help the child explore the newborn by showing how and where to touch the baby.
- Give the child a gift (from you or from you, the father or your partner, and baby).

Going Home

- Leave the child at home with a relative or babysitter or have someone such as the grandmother available to focus on the child during hospital discharge and on the trip home.
- Have someone else carry the baby from the car so that you can hug the child first.

Adjustment After the Baby Is Home

- Arrange for a special time for the child to be alone with each parent.
- Do not exclude the child during infant feeding times. The child can sit with you and the baby and feed a doll or drink juice or milk or sit quietly with a game. You can read aloud to the child while you are feeding the infant.
- Prepare small gifts for the child so that when the baby gets gifts, the sibling will not feel left out. The child can also help open the baby gifts.
- Praise the child for acting age appropriately (so that being a baby does not seem better than being older).

Fig. 23.10 Grandfather and new grandson get acquainted. (Courtesy William Perry.)

Siblings demonstrate acquaintance behaviours with the newborn. The acquaintance process depends on the information given to the child before the baby is born and on the child's cognitive development level. The initial behaviours of siblings with the newborn include looking at the infant and touching the head. The adjustment of older children to a newborn takes time, and children should be allowed to interact at their own pace rather than being forced to interact. To expect a young child to accept and love a rival for the parents' affection assumes an unrealistic level of maturity. The bond between siblings involves a secure base in which one child provides support for the other, is missed when absent, and is looked to for comfort and security.

GRANDPARENT ADAPTATION

Becoming a grandparent is usually associated with great joy and happiness. Yet it is also a time of transition as roles and relationships are changing and new opportunities arise. Emotions are varied and can change from day to day; feelings of joy, anticipation, and excitement are often intermingled with some degree of anxiety and uncertainty. Circumstances surrounding the pregnancy and birth influence the feelings, reactions, and responses of grandparents.

Pregnancy and birth necessitate redefining intergenerational roles and relationships within the family. A primary role of the grandparents is to support, nurture, and empower their child in their parenting role. Grandparents must acknowledge that things have changed since they first became parents as they deal with changes in practices and attitudes toward childbirth and child-rearing. The degree to which grandparents understand and accept current practices can influence how supportive they are to their adult children.

At the same time that they are adjusting to grandparenthood, the majority of grandparents are experiencing normative middle- and old-age life transitions, such as retirement and a move to smaller housing, and they may need support from their adult children. Some may feel regret about their limited involvement because of poor health or geographic distance.

The extent of involvement of grandparents in the care of the newborn depends on many factors—for example, the willingness of the grandparents to become involved, the proximity of the grandparents, and ethnic and cultural expectations of their role (Figure 23.10). If the new parents live in Canada and the grandparents do not, they may be asked to come to Canada to care for the baby and mother after birth. Many Canadian-born paternal grandparents, in contrast to those in other cultures, consider themselves secondary to the maternal grandparents. Less seems expected of them and they are initially less involved. Nevertheless, these grandparents are often eager to help and express great pleasure in their son's fatherhood and his involvement with the baby.

Relationships between grandparents and parents may change with the birth of a new baby. For first-time parents, pregnancy and parenthood can reawaken old issues related to dependence versus independence. Couples often do not plan on their parents' help immediately after the baby arrives. They want time "to be a family," implying a couple–baby unit, not the intergenerational family network. Intergenerational help may be perceived as interference. Contrary to their expectations, however, most new parents do call on their parents for help, especially the maternal grandmother. Many grandparents are aware of their adult children's wishes for autonomy, respect these wishes, and remain available to help, when asked.

Grandparents' classes can be used to bridge the generation gap and to help the grandparents understand their adult children's parenting concepts. The classes include information on up-to-date childbearing practices; family-centred care; infant care, feeding, and safety (car seats); and exploration of roles that grandparents can play in the family unit (see Community Focus box: Helping Grandparents Bridge the Generation Gap).

Increasing numbers of grandparents are providing permanent care to their grandchildren as a result of divorce, substance use, child abuse or neglect, abandonment, teenage pregnancy, death, incarceration, and mental health challenges. Educational and financial considerations must be addressed and available support systems identified for these families.

COMMUNITY FOCUS

Helping Grandparents Bridge the Generation Gap

Interview a grandfather and grandmother about their experiences with childbirth and infant care.

The purpose is to understand grandparents' experiences and perspectives. Ask them how they feel about their new roles; their description of their involvement in helping their son or daughter with a new baby; their description of how they view rewards and challenges of being a grandparent; and what they would like their grandchild to call them. Students can discuss findings in clinical conference and learn from one another about the various perspectives of being a grandparent.

DIVERSITY IN TRANSITIONS TO PARENTHOOD

Various factors, including age, social networks, socioeconomic conditions, and personal aspirations for the future, influence how parents respond to the birth of a child. Cultural beliefs and practices also affect parenting behaviours. Factors that influence the risk for various parenting issues include age (adolescent or older than 35 years of age), same-sex parenting, social support, culture, socioeconomic conditions, and personal aspirations.

Age

Maternal age has a definite effect on the outcome of pregnancy. The mother and fetus are at highest risk when the mother is an adolescent or is more than 35 years old (see Clinical Reasoning Case Study: Postpartum Adjustment for the Adolescent and the Older Mother).

CLINICAL REASONING CASE STUDY

Postpartum Adjustment for the Adolescent and the Older Mother

You are a community health nurse and have had two patients referred to you. Carol is a 15-year-old first-time mother of a 5-day-old girl; she lives with her mother. The father of the baby, Robert, is 17 years old and attended childbirth education classes with Carol. She is breastfeeding the baby but says that the baby sucks too slowly and takes too much time to eat. She says she thinks the baby should know enough to sleep longer at night. Robert would like to feed the baby some cereal since he heard that solid food will make a baby sleep longer at night.

Audrey is a 36-year-old lawyer who has been practising law for 7 years. She just gave birth to her first baby; she and her husband delayed parenting by choice until their careers were well established. She had an uneventful pregnancy, labour, and birth. During a telephone call 48 hours after discharge, when she was asked how things were going, Audrey burst into tears and said, "I didn't expect it to be like this! Nothing is going right."

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about both Carol's condition and Audrey's condition?
2. Assumptions—What assumptions can be made about the following?
   a. The relationship of maternal age and postpartum adjustment
   b. The need for social support in the postnatal period
   c. The need for perinatal education
   d. Long-term prognosis for positive outcomes
3. What is the nursing priority in these two situations?
4. Interprofessional care—Describe roles and responsibilities of other health care providers who would potentially be involved in the care of both of these patients.

The Adolescent Mother. Although becoming a parent is biologically possible for the adolescent, their egocentricity and concrete thinking may interfere with their ability to parent effectively. In a study of Ontario adolescent births it was shown that, compared with adults, adolescents have improved outcomes such as lower rates of gestational hypertension, gestational diabetes, antepartum hemorrhage, and operative births. However, adolescents also have higher sociodemographic risk factors and seek prenatal care later than adults. These risk factors, in combination with young age, lead to other important maternal, obstetrical, and newborn adverse outcomes (Fleming et al., 2013). These outcomes can be influenced by the mother's inexperience, lack of knowledge, and immaturity. Nevertheless, in most instances, with adequate support and developmentally appropriate teaching, adolescents can learn effective parenting skills. Strong social and functional support promotes positive outcomes for adolescent mothers.

Contrary to popular beliefs regarding the detrimental effects of adolescent pregnancy, research evidence suggests that the life course for adolescent mothers is similar to that of their socioeconomic peers. In some families or communities, adolescent parenthood is considered a normal or positive life event. Even so, adolescent pregnancy and parenting are important public health concerns.

The transition to parenthood can be difficult for adolescent parents. Because many adolescents have their own unmet developmental needs, coping with the developmental tasks of parenthood is often difficult. Some young parents experience difficulty accepting a changing self-image and adjusting to new roles related to the responsibilities of infant care. Adolescent mothers are at increased risk for postpartum mood disorders; this is often associated with a lack of social support and poor relations with their partner (Jeha et al., 2015). As adolescent parents move through the transition to parenthood, they may feel "different" from their peers, excluded from "fun" activities, and prematurely forced to enter an adult social role. The conflict between their own desires and the infant's demands, in addition to the low tolerance for frustration that is typical of adolescence, further contribute to the normal psychosocial stress of childbirth and parenting. Maintaining a relationship with the baby's father is beneficial for the teen mother and their infant, although adolescent pregnancy often heralds the departure of the young father from the relationship.

Adolescent mothers provide warm and attentive physical care; however, they use less verbal interaction than older parents, and adolescents tend to be less responsive to and interact less positively with their infants than older mothers. Interventions emphasizing verbal and nonverbal communication skills between mother and infant are important. Such strategies must be concrete and specific to match the cognitive level of adolescents. In comparison with adult mothers, teenage mothers have a limited knowledge of child development. They tend to expect too much of their children too soon and often characterize their infants as being fussy. This limited knowledge may cause teenagers to respond to their infants inappropriately.

Many young mothers pattern their maternal role on what they themselves experienced. Therefore, nurses need to determine the kind of support that people close to the young mother are able and prepared to give, as well as the kinds of community assistance available to supplement this support. Many teen mothers can identify a source of social support, the predominant source being their own mothers.

Continued assessment of the new mother's parenting abilities during this postbirth period is essential. Continued support should be provided by involving grandparents and other family members and through home visits and group sessions for discussion of infant care and parenting concerns. Community-based programs for pregnant adolescents and adolescent parents improve access to health care, education, and other support services. Outreach programs addressing

self-management, parent–child interactions, and child injuries, in addition to programs that provide prompt and effective community intervention, can prevent serious issues from occurring. As the adolescent performs their mothering role within the framework of the family, they may need to address dependence and independence issues. The adolescent's family members also may need help adapting to their new roles.

The Adolescent Father. The adolescent father and mother face immediate developmental crises, which include completing the developmental tasks of adolescence, making a transition to parenthood, and sometimes adapting to marriage. These transitions can be stressful.

The nurse can initiate interaction with the adolescent father if he is present during prenatal visits or if he is with his partner during labour and birth. The nurse can assess the relationship between the two adolescents and encourage them to discuss their plans for the father's involvement with the mother and infant after birth (Fagan, 2013). During the hospital stay, the nurse can include the adolescent father in teaching sessions about newborn care and parenting. The nurse can ask him to be present during postpartum home visits and to accompany the mother and baby to well-baby checkups at the clinic or health care provider's office. With the adolescent mother's agreement, the nurse may contact the father directly.

Adolescent fathers need support to discuss their emotional responses to the pregnancy, birth, and fatherhood. The nurse needs to be aware of the father's feelings of guilt, powerlessness, or bravado because these feelings may have negative consequences for both the parents and the child. Counselling of adolescent fathers needs to be reality oriented and should include topics such as finances, child care, parenting skills, and the father's role in the birth experience. Teenage fathers also need to know about reproductive physiology, birth control options, as well as sex practices that lower the risk for pregnancy and sexually transmitted infections.

The adolescent father may or may not continue to be involved in an ongoing relationship with the young mother and his baby. If he does, he can play an important role in the decisions about child care and raising the child. He may need help in developing realistic perceptions of his role as "father to a child" and should be encouraged to use coping mechanisms that are not harmful to his own, his partner's, or his child's well-being. The nurse can enlist support systems, parents, and professional agencies on his behalf.

Maternal Age Greater Than 35 Years. Women older than 35 years of age continue their childbearing either by choice or because of a lack or failure of contraception during the perimenopausal years. Added to this group are women who have postponed pregnancy because of careers or for other reasons, as well as women of infertile couples who finally become pregnant with the aid of reproductive technology.

Support from partners aids in the adjustment of older mothers to changes involved in becoming a parent and seeing themselves as competent. Support from other family members and friends is also important for positive self-evaluation of parenting, a sense of well-being and satisfaction, and help in dealing with stress. Women who are older can experience social isolation. Older mothers may have less family and social support than that of younger mothers. They are less likely to live near family, and their own parents, if still living, may be unable to provide assistance or support because of age or health issues. These mothers are often caught in the "sandwich generation," taking on responsibility for care of aging parents while parenting young children. Social support may be lacking because their peers are busy with their careers and have limited time to help. Their friends are likely to have older children and have less in common with the new mother.

Changes in the sexual aspect of a relationship can create a stressor for new midlife parents. Mothers report that it is difficult to find time and energy for any romance. They attribute much of this difficulty to the reality of caring for an infant, but the decreasing libido that normally accompanies getting older is also a factor.

Work and career issues tend to be sources of conflict for older mothers. Conflicts emerge over being disinterested in work, worrying about giving enough attention to work with the distractions of a baby, and anticipating what it will be like to return to work. Child care is a major factor in causing stress about work.

Another major issue for older mothers with careers is the perception of loss of control. Mothers older than 35 are at a different stage in their careers than younger mothers, often having attained high levels of education, career, and income. The loss of control experienced when going from the consistency of a work role to the inconsistency of the parent role comes as a surprise to many. Helping the older mother have realistic expectations of herself and parenthood is essential.

New mothers who are also perimenopausal may have difficulty understanding that fatigue, loss of sleep, decreased libido, or other physiological symptoms are the causes of the change in their sex drive. Although many women view menopause as a natural stage of life, for midlife mothers this cessation of menstruation coincides with the state of parenthood. The changes of midlife and menopause can add more emotional and physical stress to older mothers' lives because of the time- and energy-consuming aspects of raising a young child.

Paternal Age Greater Than 35 Years. Although many older fathers describe their experience of midlife parenting as wonderful, they also recognize the drawbacks. Positive aspects of parenthood in older years include increased love and commitment between the two parents, a reinforcement of why one committed to a relationship in the first place, a feeling of being complete, experiencing "the child" in oneself again, more financial stability than in younger years, and more freedom to focus on parenting rather than on career. Drawbacks of midlife parenting include having a young child and not being physically fit to participate in activities, being much older than other fathers, and the change it makes in the relationship with their partner.

Parenting Among LGBTQ2 Couples

Although same-sex marriage has been legal in Canada since 2003, the transition to parenting for same-sex couples can still present unique challenges. Whether the couple consists of two women (Figure 23.11), two men, or a parent who is transgender, issues such as lack of family acceptance and support, public ignorance, and social invisibility can influence their ability to adapt as new parents. The health care environment is heteronormative; for example, most educational materials for new parents include information for mothers and fathers, and photos depict the traditional heterosexual couple. Attitudes of health care providers can affect the care provided to same-sex couples either positively or negatively.

The decision for lesbian couples to conceive is intentional. Factors that influence the decision include the age, health, infertility, and career considerations of each partner. Several pathways are available for two women in a lesbian relationship who wish to become parents. The couple may decide for one of the women to conceive a child who is genetically related to her; this is usually done through donor insemination. Alternatively, the fertilized egg of one partner can be implanted into the uterus of the other partner, who carries the pregnancy. In some cases, a woman is implanted with the fertilized egg from a donor so the child is not biologically related to either partner. Another option is for a lesbian couple to adopt an infant born to a surrogate mother. They can also

Fig. 23.11 Lesbian couple welcoming a new member of the family. (Courtesy Elliana Gilbert Photography.)

choose to adopt an infant through an adoption agency or by private arrangement.

Health care providers have demonstrated a variety of reactions to lesbian couples, ranging from rejection and exclusion to complete acceptance and inclusion. Some couples attempt to hide their relationship because they fear a homophobic response. Judgemental attitudes, confusion, or lack of understanding can affect the quality of care provided to these families (Dahl et al., 2013). Although the traditional roles of the mother and father in heterosexual relationships are well recognized, the role of the lesbian non-birth parent can be questioned, misunderstood, and ignored by society and by health care providers. Intentionally or accidentally, health care providers may exclude partners or fail to acknowledge their roles in pregnancy, birth, and parenting. Integration of the non-birth parent into care includes offering opportunities afforded male partners of heterosexual women, such as cutting the cord and rooming in with the mother and baby during hospitalization.

An option not available to male partners is to actually breastfeed the infant. The non-birth female partner can stimulate milk production through induced lactation using medications and regular pumping. A supplemental feeding device containing expressed breast milk or formula can be used to provide additional milk to the breastfeeding infant. Women who choose not to induce lactation yet desire to have the breastfeeding experience can put the baby to breast using a supplemental feeding device containing formula or expressed breast milk (Wambach & Spencer, 2021).

Similar to heterosexual parents, lesbian couples face challenges in adjusting to life with a new baby. After birth, the birth mother tends to be the one most responsible for child care because she is likely to be working fewer hours than her partner. As in heterosexual relationships, tensions can arise between the partners in relation to their roles. This can be compounded by the lack of a formal, recognized relationship between the non-birth parent and the infant and issues surrounding her legal rights in relation to her partner and the infant (Abelsohn et al., 2013).

Men in same-sex relationships, or gay couples, can become parents by adoption or by impregnating a surrogate by artificial insemination or sexual intercourse. Same-sex male couples face the same social sanctions regarding pregnancy and parenting that lesbian couples encounter. Both lesbian and gay couples may have children from previous heterosexual relationships.

Nurses are likely to encounter gay couples in the hospital setting if they are present for birth by a surrogate or if they are adopting a newborn and visit the hospital to spend time with the newborn and learn about newborn care. Nurses can help these men locate support groups that will address their needs. They need to ensure that these families receive effective health care.

Data on gay and lesbian parenting are limited and focus more on developmental outcomes of the children than on parenting styles or parental caregiving. Research is needed to identify the needs of gay and lesbian parents and ways to support them in their parenting.

People who are transgender may also decide to become pregnant. Transmasculine individuals are people who were assigned as female at birth, but identify on the male side of the gender spectrum and as such may choose to use and engage their bodies to become pregnant, birth a baby, and chestfeed (MacDonald et al., 2016). Gendering has the potential to impact caregiving and infant feeding practices for lesbian, gay, bisexual, transgender, queer, intersex, or two-spirited (LGBTQ2) parents; all families require respectful, supportive care and the appropriate space to feel comfortable (Wambach & Spencer, 2021). A recent case report describes a transgender woman who was able to breastfeed their baby along with supplementation after taking feminizing hormone for several years, followed by a lactation-inducing medication regimen (Reisman & Goldstein, 2018).

Non-birth parents deserve to have their unique experiences validated and celebrated in their personal relationships and social networks, through accessible and appropriate resources that address their health and wellness needs, and through policies that respect the creation of their families and facilitate a supportive legal environment in which to do so (Abelsohn et al., 2013). In situations in which family support is limited or absent, the nurse can help LGBTQ2S couples locate supportive social groups.

Social Support

Social support is strongly related to positive adaptation by new parents, especially adolescent parents, during the transition to parenthood. Social support is multidimensional and includes the number of members in a person's social network, the types of support, perceived general support, actual support received, and satisfaction with support available and received. Partner support in pregnancy can decrease emotional distress in the postpartum period (Stapleton et al., 2012). The type and satisfaction of support appear to be more important than the total number of support network members.

Across cultural groups, families and friends of new parents form an important dimension of the parents' social network. Through seeking help within the social network, new mothers learn culturally valued practices and develop competency in their role as mother.

While social networks provide a support system on which parents can rely for assistance, they also can be a source of conflict. Sometimes a large network can cause difficulties because it results in conflicting advice coming from numerous people. Grandparents or in-laws are most appreciated when they assist with household responsibilities and do not intrude on the parents' privacy or judge them critically.

Because of the extent of restructuring and reorganization that occurs in a family with the birth of a child, the mother's moods and fatigue in the postpartum period can be helped more by situation-specific support from family and friends than by general support. General support addresses feeling loved, respected, and

valued. Situation-specific support relates to practical concerns, such as physical needs and child care. For example, the practical support of a grandparent bathing the infant can help lessen a second-time mother's feelings of loss by providing her time to be with her firstborn child.

Culture

Cultural beliefs and practices are important determinants of health for the mother and infant and also influence parenting behaviours. Culture influences interactions with the baby and the parents' or family's caregiving style. For example, providing for a period of rest and recuperation for the mother after birth is prominent in several cultures. Asian mothers are encouraged to remain at home with the baby up to 30 days after birth and are not supposed to engage in household chores, including care of the baby. Often, the grandmother takes over the newborn's care immediately, even before discharge from the hospital. Jordanian mothers may have a 40-day lying-in after birth, during which their mothers or sisters care for the newborn. Japanese mothers rest for the first 2 months after childbirth. Latin Americans may practise an intergenerational family ritual, *la cuarentena*: for 40 days after birth, the mother is expected to recuperate and get acquainted with their newborn. Traditionally, this involves many restrictions concerning food, exercise, and activities, including sexual intercourse.

All cultures place importance on desiring and valuing children. In many families, children are a source of family strength and stability, are perceived as wealth, and are objects of parental love and affection.

Knowledge of cultural beliefs can help the nurse make more accurate assessments and diagnoses of observed parenting behaviours. For example, nurses may become concerned when they observe cultural practices that appear to reflect poor maternal–infant bonding. Algerian mothers may not unwrap and explore their newborns as part of the acquaintance process because in Algeria babies are wrapped tightly in swaddling clothes to protect them physically and psychologically (D'Avanzo, 2008). A Vietnamese woman may give minimal care to her newborn and refuse to cuddle or further interact with her baby. This apparent lack of interest in the newborn is this cultural group's attempt to ward off evil spirits and actually reflects an intense love and concern for the child (Galanti, 2015). An Asian mother might be criticized for almost immediately relinquishing the care of the newborn to the grandmother and not attempting to hold her baby when it is brought to her room; in Asian extended families, members show their support for a new mother's need for rest and recuperation by assisting with the care of the baby. Contrary to the guidance given to new mothers in Canada to watch for breastfeeding difficulties when using a mix of breastfeeding and bottle-feeding initially, this mix of feeding is standard practice for Japanese mothers. This tradition is related to concern for the mother's rest during the first 2 to 3 months and does not usually lead to any issues with lactation; breastfeeding is widespread and successful among Japanese women.

Cultural beliefs and values give perspective to the meaning of childbirth for a new mother. Nurses can provide an opportunity for a new mother to talk about their perception of the meaning of childbearing. In helping new families adjust to parenthood, nurses must provide culturally competent care by following principles that facilitate nursing practice within transcultural situations. At the same time, because not all members of a cultural group adhere to traditional practices, nurses need to validate which cultural practices are important to individual parents.

CULTURAL AWARENESS

Fostering Bonding: Women of Varying Ethnic and Cultural Groups

Canadian women, families, and health care workers are influenced by their various cultures, socioeconomic backgrounds, and ethnicities. Childbearing practices and rituals may be incongruent with Anglo-Canadian standards but that does not mean they are incorrect and should not be used. New mothers from China as well as from India and Thailand may practice a 40-day "confinement" period after giving birth, often called "doing the month." During this time, extended family members help provide care for the newborn so the mother can rest and recover. Some Asian and Latin American women do not initiate breastfeeding until their breast milk comes in. Indigenous persons may consciously place long silences in conversation for reflection and engage in minimal eye contact. It would be easy for Anglo-Canadian health care workers to perceive this behaviour as disrespect and indifference.

Nurses must become knowledgeable about childbearing beliefs and practices of diverse cultural and ethnic groups. They must also develop cultural sensitivity and use relevant cultural resources to promote cultural safety (see Chapter 2). Because individual cultural variations exist within groups, nurses need to clarify with the patient and family members or friends the cultural norms that the patient follows. Incorrect judgements may be made about mother–infant bonding if nurses do not practise culturally sensitive care.

(2007). *Embracing cultural diversity in health care: Developing cultural competence.* http://rnao.ca/bpg/guidelines/embracing-cultural-diversity-health-care-developing-cultural-competence; Srivastava, R. H. (2007). *The healthcare professional's guide to cultural competence.* Elsevier Canada.

Indigenous Families

Given the legacy of residential schools in the Indigenous community, there continue to be parents who have difficulty being effective parents to their children (see Chapter 1, Indigenous People). One of the greatest impacts of residential schools is the breakdown of family relationships, as families were separated for months or years. Children were deprived of the positive family environment necessary for the transmission of parenting knowledge and skills. Survivors describe being removed from loving families into situations that were deplorable and "loveless" (Truth and Reconciliation Commission, 2012). The impact of this institutionalization and separation continues to be seen to this day and is evidenced in high rates of child apprehensions by social services and Indigenous youth involvement in crime. The Truth and Reconciliation Commission (TRC) (2015) has recommended that families not be separated, if possible, and that adequate housing, addiction resources, and educational supports for parents be provided to help overcome some of the negative impact of residential schools.

Nurses should be aware of the potential impact of residential schools on any Indigenous family and be able to incorporate this knowledge into the care provided. Nurses can also work with partner groups to develop culturally appropriate early childhood and parent programs that assist young parents and families affected by the impact of residential schools and historical policies of cultural oppression in the development of parental understanding and skills (TRC, 2015). See Additional Resources at the end of the chapter for resources for caring Indigenous families.

Socioeconomic Conditions

Socioeconomic conditions, a key determinant of health, often determine access to available resources. Parents who have low socioeconomic status

may find childbirth complicated by concern for their own health and a sense of helplessness. Serious financial concerns may override any desire for mothering the infant. Similarly, fathers who are overwhelmed with financial stresses may lack effective parenting skills and behaviours. Families who have limited access to social support and financial resources may require extra education and support to access necessary supports.

Personal Aspirations

For some people, parenthood may interfere with their plans for personal freedom or advancement in their careers. Unresolved resentment can affect caregiving activities and adjustment to parenting. This situation may result in indifference and neglect of the infant or in excessive concerns; the mother may set impossibly high standards for their own behaviour or the child's performance.

Nursing interventions include providing opportunities for mothers to express their feelings freely to an objective listener, discuss measures to enable personal growth, and learn about the care of their infant. Referring the woman to a support group of other mothers who are in similar circumstances may also be helpful.

Nurses also can be proactive in influencing changes in work policies related to work sharing and to promoting family-friendly work environments. Some corporations already structure their workplace to support new mothers (e.g., by providing on-site day care facilities and lactation rooms).

PARENTAL SENSORY IMPAIRMENT

In the early interactions between parent and newborn, each uses all senses—sight, hearing, touch, taste, and smell—to initiate and sustain the attachment process. A parent who has an impairment of one of the senses needs to maximize use of the remaining senses. Parents with disabilities tend to value performing parenting tasks in a way perceived as culturally normative. It is important for nurses and other health care providers to remember that these individuals are parents living with a disability; they are not disabled parents. Most provinces now have legislation to ensure that people with disabilities have access to required resources.

Visually Impaired Parent

Visual impairment alone does not appear to have a negative effect on parents' early parenting experiences. These parents, just as sighted parents, express the wonders of parenthood, and they encourage other visually impaired persons to become parents.

Although visually impaired mothers initially feel pressure to conform to traditional, sighted ways of parenting, they soon adapt these ways and develop methods better suited to themselves. For example, visually impaired parents may prepare the infant's nursery, clothes, and supplies in a way that is different from a sighted person's routine. Some parents put an entire clothing outfit together and hang it in the closet rather than keeping the items separate in drawers. Some develop a labelling system for the infant's clothing and put diapering, bathing, and other care supplies where these will be easy to locate. A strength that visually impaired parents have is a heightened sensitivity to other sensory outputs. A visually impaired parent can tell when their infant is facing them because they can feel the baby's breath on the face.

One of the major difficulties that visually impaired parents experience is the skepticism, open or hidden, of health care providers. Visually impaired people may sense reluctance on the part of others to acknowledge that they have a right to be parents. All too often, health care providers lack the experience to deal with the childbearing and child-rearing needs of visually impaired parents and those of parents with other disabilities (such as the hearing impaired, physically impaired, and mentally challenged). The nurse's best approach here is to assess the parent's capabilities. From that basis the nurse can make plans to assist the parent, often in much the same way as for a parent with sight. Visually impaired mothers have made suggestions for providing care to persons such as themselves during childbearing (Box 23.2). The nurse can use such approaches to help a parent avoid feeling increased vulnerability.

Eye contact with others is considered important in North American culture. With a parent who is visually impaired, this critical factor in the parent–child attachment process is obviously missing. However, the visually impaired parent who may never have experienced this method of strengthening relationships does not miss it. The infant will need other sensory input from that parent. An infant looking into the eyes of a mother who is visually impaired may not be aware that the eyes are unseeing. Other people in the newborn's environment can participate in active eye-to-eye contact to supply this need. A difficulty may arise, however, if the visually impaired parent has an impassive facial expression. The infant, making repeated unsuccessful attempts to engage in face play with the mother, will abandon the behaviour with them and intensify it with the father or other persons in the household. Nurses can provide anticipatory guidance regarding this situation and help the mother learn to nod and smile while talking and cooing to the infant.

Hearing-Impaired Parent

A parent with a hearing impairment faces challenges in caregiving and parenting, particularly if the deafness dates from birth or early childhood. Whether one or both parents are hearing impaired, they are likely to have established an independent household. Devices that transform sound into light flashes can be fitted into the infant's room to enable immediate detection of crying. Even if the parent is not speech trained, vocalizing can serve as both a stimulus and a response to the infant's early vocalizing. Deaf parents can provide additional

BOX 23.2 Nursing Approaches for Working With Parents With a Visual Impairment

- Parents who are visually impaired need oral teaching by health care providers because pregnancy and childbirth information is usually not accessible to visually impaired people.
- A visually impaired parent needs an orientation to the hospital room that enables the parent to move about the room independently; for example, "Go to the left of the bed and trail the wall until you feel the first door. That is the bathroom."
- Parents who are visually impaired need explanations of routines.
- Parents who are visually impaired need to feel devices (e.g., portable sitz bath equipment, breast pump) and to hear descriptions of the devices.
- Visually impaired parents need a chance to ask questions.
- Visually impaired parents need the opportunity to hold and touch the newborn after birth.
- Nurses need to demonstrate newborn care by touch and to follow with "Now show me how you would do it."
- Nurses need to give instructions, such as "I'm going to give you the baby. The head is to your left side."

BOX 23.3 Nursing Approaches for Working With Parents with a Hearing Impairment

- Before initiating communication, be aware of the parents' preferences and capabilities: Do they wear a hearing aid? Do they read lips? Do they wish to have an interpreter?
- Make certain that the parent(s) sees you approaching to avoid startling the parent.
- Before speaking, be directly in front of the parent and have that person's full attention.
- When speaking, face the parent directly and be at the same level.
- Avoid standing in front of a light or a window while speaking to the parent.
- Keep your hands away from your face while speaking, to minimize distractions.
- If the parent relies on lip-reading, sit close enough so that the parent can easily see your lip movements.
- Speak clearly with a regular voice volume and lip movements, while maintaining eye contact.
- Speak in short, simple sentences to facilitate understanding.
- If the parent does not understand something, it is better to find a different way to say what needs to be communicated rather than repeating the same words over and over.
- Written messages aid in communication. A small white or black erasable board can be useful.
- Give educational materials to parents with a hearing impairment and ask them to read the materials before doing parent teaching. They can refer to the materials after discharge.
- Use visual aids such as pictures, diagrams, or other devices when doing parent teaching.
- When doing parent teaching, it is helpful for a hearing person (partner or family member) to be present.
- Allow ample time to communicate with the parent with a hearing impairment; being in a rush can evoke stress and create barriers to effective communication.

vocal training by use of recordings and television so that from birth the child is aware of the full range of the human voice. Young children acquire sign language readily, and the first sign used is as varied as the first word.

Hospitals and other institutions use various communication techniques and resources with the hearing-impaired, including having staff members or certified interpreters who are proficient in sign language. For example, providing written materials with demonstrations and having nurses stand where the parent can read their lips (if the parent practises lip-reading) are two techniques that can be used. A creative approach is for the nursing unit to develop movies in which information on postpartum care, newborn care, and parenting issues is signed by an interpreter and spoken by a nurse or that has closed-captioning. Many resources are available to the deaf parent via the Internet (see Additional Resources at the end of the chapter). Box 23.3 lists suggestions for working with hearing-impaired parents.

NURSING CARE

Numerous changes occur during the first weeks of parenthood. Nursing care should be directed toward helping parents cope with newborn care, role changes, altered lifestyle, and change in family structure resulting from the addition of a new baby. Developing skill and confidence in caring for a newborn can be anxiety provoking. Anticipatory guidance can help prevent or minimize parents' shock of reality in the transition from the hospital or birthing centre to home that might negate the parents' joy or cause them undue stress. Key messages for families should be individualized, family-centred information that is relevant for each unique family situation and context. All children deserve the best possible start in life, and a child's early years from before birth to age 6 years are very important to their healthy development and long-term health. This is a time in life when children's brains and bodies are developing at a rapid pace. Healthy babies are more likely to continue to be healthy through their childhood, teen, and adult years (see Patient Teaching Box: Key Messages for Parents).

PATIENT TEACHING

Key Messages for Parents

Teach Parents About the Following Key Messages:

Your baby is constantly learning about you and the world around them, and you are your baby's best teacher. How you care for and talk and play with your infant will influence how your child learns and grows. Here are some suggestions to help you enjoy your time with your new baby in the first year:

- Babies love to be held. Take time to cuddle and hold your child.
- Comfort your baby when they cry.
- Learn your baby's cues—when they are hungry or sleepy or want to play with you.
- Breast milk provides all the nutrition your baby needs for the first 6 months. Feeding can be a special way to feel close to your baby.
- Speak in a soft, gentle voice to your baby.
- Talk to your baby and tell them about the things that are around them. The way you talk to, play with, teach, and love your child will help them grow and learn.
- Help your child explore safely. Share different textures, colours, sounds, and smells.
- Share picture books and read simple stories, including in your first language. This is also an opportunity to cuddle with your child.
- Babies learn naturally through play. Have fun and play with your child, sing to them, play music, and dance with your child.
- Taking care of yourself is important too! Ask a trusted friend or family member to watch your baby so you can take a break.

Source: Ontario Ministry of Children, Community and Social Services. (2014). *Tips for new parents: Making the best of the early years*. http://www.children.gov.on.ca/htdocs/English/documents/earlychildhood/tips/Tips-EN.pdf

Through education, support, and encouragement, nurses can be instrumental in assisting mothers and their partners in the transition to parenthood, whether they are first-time parents or parents of several other children. Early and ongoing assessment and intervention promote positive outcomes for parents, infants, and family members

(see Community Focus box: Identifying Parenting Resources on the Web). (See also Nursing Care Plan: Home Care Follow-up: Transition to Parenthood, available on Evolve.)

COMMUNITY FOCUS

Identifying Parenting Resources on the Web

- Visit the website of a hospital that provides maternity services in your community. Does the hospital offer childbirth education, parenting, sibling, or infant/child cardiopulmonary resuscitation (CPR) classes? Are group tours of the birthing centre provided for expectant parents?
- Visit a local health department website. Look for information for parents about pregnancy, parenting, and children's health. Review the information about postpartum emotional health, causes and treatments of baby blues, and baby blues versus postpartum mood disorder. Is there adequate information there for new families?
- Research the availability of support groups for parents in your community.

KEY POINTS

- The birth of a child necessitates changes in the existing interactional structure of a family.
- Attachment is the process by which the parent and infant come to love and accept each other.
- Attachment is strengthened through the use of sensual responses or interactions by both partners in the parent–infant interaction.
- A person goes through stages in becoming a mother.
- Fathers and non-birth parents experience emotions and adjustments during the transition to parenthood that are similar to and also distinctly different from those of mothers.
- Modulation of rhythm, modification of behavioural repertoires, and mutual responsivity facilitate infant–parent adjustment.
- Sibling adjustments to a new baby require creative parental interventions.
- Grandparents can have a positive influence on the postpartum family.
- LGBTQ2 families require respectful support when becoming parents, as they may face different challenges, including legal aspects of parenting.
- Many factors (e.g., age, culture, socioeconomic level, and expectations of what the child will be like) influence adaptation to parenthood.

Postpartum Complications

Janet Andrews

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Identify causes, signs and symptoms, possible complications, and medical and nursing care of postpartum hemorrhage.
2. Describe hemorrhagic shock (hypovolemic shock) as a complication of postpartum hemorrhage, including the collaborative care necessary.
3. Identify causes, signs and symptoms, possible complications, and medical and nursing care of postpartum infection.
4. Describe thromboembolic disorders, including incidence, etiology, signs and symptoms, and related medical and nursing care.
5. Differentiate among perinatal mood disorders, including incidence, risk factors, signs and symptoms, severity, and collaborative care.
6. Describe the nurse's role in assisting families who are grieving from perinatal loss.

The postpartum period is a time of change and transition for mothers and newborns. Mothers experience incredible physiological shifts and emotional adjustments in the hours and days following birth. Perinatal nurses provide education, care, and support for mothers and newborns during this important time. In addition, nurses have the responsibility to pay careful attention to signs and symptoms of complications. The nurse works collaboratively with the interprofessional health care team to provide safe and effective care to patients experiencing postpartum complications. In most instances, patients respond to treatment, and outcomes are positive. Whenever possible, the mother–baby dyad must be supported to remain together. Involvement of partners and families in caring for the postpartum parent and baby is important in the face of postpartum complications. This chapter focuses on the postpartum complications of hemorrhage, infection, thromboembolic disorders, psychological complications, and loss and grief.

POSTPARTUM HEMORRHAGE

Definition and Incidence

Postpartum hemorrhage (PPH) is the leading cause of maternal death worldwide. All patients who give birth are at risk for PPH. It is a life-threatening event that can occur with little warning and is often unrecognized until the patient has profound symptoms. With prevention and treatment interventions, most of the deaths could be avoided (World Health Organization [WHO], 2019). Definitions of PPH in the literature are varied. PPH is often defined as the loss of 500 mL or more of blood after vaginal birth and 1 000 mL or more after Caesarean birth, although normal blood loss for some patients approaches these amounts. PPH may be defined as a 10% decline in hemoglobin concentration and the need for a transfusion (Francois & Foley, 2017). Diagnosis is frequently based on subjective observations, with blood loss often being underestimated by as much as 50% (Cunningham et al., 2018). For clinical purposes, any blood loss that has the potential to produce hemodynamic instability should be considered PPH. The amount of blood loss required to cause hemodynamic instability will depend on the pre-existing condition of the patient (Leduc et al., 2018).

PPH is classified as primary or secondary with respect to the birth. *Primary* PPH occurs within 24 hours of the birth. *Secondary* PPH occurs more than 24 hours but less than 12 weeks after the birth and is due to retained products, infection, or both (Francois & Foley, 2017) (see Clinical Reasoning Case Study: Postpartum Hemorrhage).

CLINICAL REASONING CASE STUDY

Postpartum Hemorrhage

A nurse on the mother–baby unit is assigned to Ms. Avery. She is a G4 T3 P0 A0 L3 who gave birth to a 4 080-g baby boy this morning. Ms. Avery had an uncomplicated but precipitous vaginal birth. Her perineum is intact. She is breastfeeding. All labs are normal. She is now 3 hours postpartum. A family member calls out from the patient's room for assistance. When the nurse walk into the room Ms. Avery is standing up on her way to the bathroom with a large pool of blood on the floor. She states, "I don't know what happened; it all just came when I stood up. I am so dizzy and lightheaded."

1. Evidence—Is there sufficient evidence to draw conclusions about what the nurse should do next?
2. Assumptions—Describe underlying assumptions about each of the following:
   a. Risk factors for early postpartum hemorrhage (PPH) and specifically those described for Ms. Avery
   b. Need for frequent assessments in the early postpartum period
   c. Use of oxytocics for prevention and management of PPH
3. What implications and priorities for nursing care can be made at this time?
4. Interprofessional care: Describe roles and responsibilities of health care providers who would potentially be involved in care management for Ms. Avery.

Etiology and Risk Factors

When excessive bleeding is observed, it is important to note the colour and consistency of the blood. For example, dark red blood is likely of venous origin, perhaps from varices or superficial lacerations of the birth canal. Bright red blood is arterial and can indicate deep lacerations of the cervix. Failure of blood to clot or remain clotted indicates a pathological condition or coagulopathy such as disseminated intravascular coagulation (DIC) (see discussion below; Thrombin).

Excessive bleeding can occur during the period from the separation of the placenta to its expulsion or removal. This can result from incomplete placental separation, undue manipulation of the fundus, or excessive traction on the cord. After the placenta has been expelled or removed, persistent or excessive blood loss usually is the result of uterine atony or prolapse of the uterus into the vagina.

Secondary postpartum bleeding may occur as a result of **subinvolution** of the uterus (delayed return of the enlarged uterus to normal size and function). Recognized causes of subinvolution include retained placental fragments (discussed below, in the section Tissue) and pelvic infection. Signs and symptoms include prolonged **lochial** discharge, foul odour, pain, fever, irregular or excessive bleeding, and sometimes hemorrhage. The patient is often at home when the symptoms occur. Discharge teaching should emphasize the signs of normal involution, potential complications, and the importance of prompt assessment by a health care provider in the event of PPH.

Risk factors for and causes of PPH are listed in Box 24.1. It is common to look at the etiology of PPH within four categories: tone, tissue, trauma, and thrombin. These are referred to as the four T's of PPH.

Tone (Uterine Atony). **Uterine atony** is marked hypotonia (relaxation) of the uterine muscle. Normally, placental separation and expulsion are facilitated by contraction of the uterus, which also prevents hemorrhage from the placental site. The uterine corpus is in essence a basket weave of strong, interlacing smooth-muscle bundles through which many large maternal blood vessels pass (see Figure 7.3). Bleeding is controlled by the contraction of smooth muscle in the uterus. If the uterus is flaccid after detachment of all or part of the placenta, brisk bleeding occurs, and normal coagulation of the open vasculature is impaired and continues until the uterine muscle is contracted. This marked hypotonia of the uterus is called *uterine atony*.

Uterine atony is the leading cause of early PPH. It is associated with high parity, polyhydramnios, fetal macrosomia, and multiple gestation. In such conditions, the uterus is "overstretched" and contracts poorly after birth. Other causes of atony include traumatic birth, use of halogenated anaesthetic (e.g., halothane), use of magnesium sulphate, rapid or prolonged labour, chorioamnionitis, use of oxytocin for labour induction or augmentation, fibroids, and uterine atony in a previous pregnancy (Leduc et al., 2018).

Trauma. Any lacerations of the genital tract, extensions or lacerations during Caesarean birth, uterine rupture, and uterine inversion are all considered trauma and can cause PPH. Lacerations of the perineum are the most common of all injuries in the lower portion of the genital tract. These are classified as first, second, third, and fourth degree (see Chapter 17, Vaginal Lacerations). An **episiotomy** may extend to become either a third- or fourth-degree laceration.

Hemorrhage related to lacerations should be suspected if bleeding continues despite a firm, contracted uterine fundus. This bleeding can be a slow trickle, oozing, or frank hemorrhage.

Factors that influence the causes and incidence of obstetrical lacerations of the lower genital tract include operative birth, precipitous

BOX 24.1 Risk Factors and Causes of Postpartum Hemorrhage

Tone: Uterine Atony
- Overdistended uterus—large fetus, multiple fetuses, hydramnios, distension with clots
- Anaesthesia and analgesia—conduction anaesthesia
- Previous history of uterine atony
- High parity
- Prolonged labour, oxytocin-induced labour
- Magnesium sulphate administration during labour or postpartum period
- Chorioamnionitis
- Uterine subinvolution
- Obesity

Trauma
- Lacerations of the birth canal
- Trauma during labour and birth—forceps-assisted birth, vacuum-assisted birth, Caesarean birth
- Ruptured uterus
- Inversion of the uterus
- Manual removal of a retained placenta

Tissue
- Retained placental fragments
- Placenta accreta, increta, percreta
- Placental abruption
- Placenta previa

Thrombin
- Coagulation disorders

birth, congenital abnormalities of the maternal soft parts, and contracted pelvis. Size, abnormal presentation, and position of the fetus; relative size of the presenting part and the birth canal; and deep engagement in the pelvis prior to Caesarean birth may all lead to tissue trauma.

Hematomas. Pelvic hematomas (i.e., a collection of blood in the connective tissue) can be vulvar, vaginal, or retroperitoneal in origin. Vulvar hematomas are the most common type. Persistent perineal, vaginal, or rectal pain and pressure are the most common symptoms, and most vulvar hematomas are visible. Vaginal hematomas occur more commonly in association with a forceps-assisted birth, an episiotomy, or primigravidity (Francois & Foley, 2017).

Retroperitoneal hematomas are least common but are life-threatening. They are caused by laceration of one of the vessels attached to the hypogastric artery, usually associated with rupture of a Caesarean scar during labour. During the postpartum period, if the patient reports persistent perineal or rectal pain or a feeling of pressure in the vagina, a careful examination is made. A retroperitoneal hematoma can also cause minimal pain, and the initial symptoms can be signs of shock (Francois & Foley, 2017; Rafi & Khalil, 2018).

Hematomas may self-absorb or they may require surgical evacuation. Once the bleeding has been controlled, usual postpartum care is provided with careful attention to pain relief, monitoring the amount of bleeding, replacing fluids, and reviewing laboratory results (hemoglobin and hematocrit).

Inversion of the uterus. Uterine inversion (turning inside out) after birth is a rare but potentially life-threatening complication. The incidence of uterine inversion varies, from 1 in 1 200 to 1 in 57 000 births, and differs depending on whether the birth was vaginal or Caesarean (Francois & Foley, 2017). Uterine inversion can recur with a subsequent birth. Uterine inversion may be incomplete, complete, or prolapsed. Incomplete inversion cannot be seen; a smooth mass can be palpated through the dilated cervix. In complete inversion, the lining of the fundus crosses through the cervical os and forms a mass in the vagina. Prolapsed inversion of the uterus is obvious; a large, red, rounded mass (perhaps with the placenta attached) protrudes 20 to 30 cm outside the introitus.

Factors contributing to uterine inversion include short umbilical cord, adherent placental tissue, weakness of uterine wall or cervix, fundal implantation of the placenta, uterine tumours, uterine atony, sudden uterine emptying, manual removal of the placenta, inappropriate fundal pressure, excessive traction on the umbilical cord, and uterotonic medications prior to placenta removal (Gilmandyar & Thornburg, 2019). The primary presenting signs of uterine inversion are sudden and include hemorrhage, shock, and pain and the uterus is not palpable abdominally. (Gilmandyar & Thornburg, 2019).

Prevention—always the easiest, cheapest, and most effective therapy — is especially appropriate for uterine inversion. The umbilical cord should not be pulled unless the placenta has definitely separated.

Uterine inversion is an emergency situation requiring immediate interventions that include maternal fluid resuscitation, repositioning of the uterus within the pelvic cavity, and correction of associated clinical conditions. Tocolytics or halogenated anaesthetics may be given to relax the uterus before attempting replacement (Francois & Foley, 2017). Oxytocic agents are given after the uterus is repositioned to control bleeding and broad-spectrum antibiotics should be initiated to prevent infection. The patient requires further monitoring for recurrence of uterine inversion (Gilmandyar & Thornburg, 2019).

Tissue. Uterine involution and the prevention of PPH rely on expulsion of the entire placenta. Retained placental segments (tissue) may result from partial separation of a normal placenta, the existence of an additional succenturiate lobe, entrapment of the partially or completely separated placenta by an hourglass constriction ring of the uterus, mismanagement of the third stage of labour, or abnormal adherence of the entire placenta or a portion of the placenta to the uterine wall.

Delivery of the placenta occurs in the third stage of labour. When the placenta has not been delivered within 30 to 60 minutes after birth despite gentle traction on the umbilical cord and uterine massage, it is described as "retained." Initial management of a retained placenta consists of manual separation and removal by the obstetrical health care provider. This involves the provider reaching into the uterus and gently separating the placenta from the uterine wall and removing it manually. When the patient has regional anaesthesia for labour, supplementary anaesthesia is usually not needed. For other patients, administration of light nitrous oxide and oxygen inhalation anaesthesia or intravenous (IV) pain medications should be considered (Francois & Foley, 2017). After removal of a retained placenta, the postpartum patient is at continued risk for PPH and infection.

In rare instances there is abnormal adherence of the placenta to the myometrium, which is beyond the endometrium. Attempts to remove the placenta in the usual manner are unsuccessful, and laceration or perforation of the uterine wall can result, putting the patient at great risk for severe PPH and infection (Booker & Moroz, 2019).

PPH can be due to abnormally implanted, invasive, or adhered placenta; this is known as *placenta accrete syndrome*. Unusual placental adherence can be total, partial, or focal, depending on how much placental tissue is involved. The following degrees of abnormal placental attachment are recognized:

- **Placenta accreta**—Slight penetration of myometrium
- **Placenta increta**—Deep penetration of myometrium
- **Placenta percreta**—Perforation of myometrium and uterine serosa, possibly involving adjacent organs (e.g., bladder)

Placenta accrete syndrome has demonstrated an increased incidence in association with the rise in Caesarean birth rates (Cunningham et al., 2018). Other risk factors include placenta previa, prior uterine surgery, endometrial defects, submucosal fibroids, multiparity, and older maternal age (Francois & Foley, 2017). Placenta accrete syndrome can be diagnosed before the birth using ultrasonography and magnetic resonance imaging (MRI), but often it is not recognized until there is excessive bleeding after birth. Caesarean birth is recommended when the diagnosis is made prenatally. Bleeding may not occur unless manual removal of the placenta is attempted. With more extensive involvement, bleeding becomes profuse when removal of the placenta is attempted. Less blood is lost if the diagnosis is made antenatally and no attempt is made to manually remove the placenta. Treatment includes blood component replacement therapy. Hysterectomy can be indicated for all three types of placental adherence if bleeding is uncontrolled (Cunningham et al., 2018). Attempts to remove the placenta in the usual manner are unsuccessful, and laceration or perforation of the uterine wall can result, putting the patient at great risk for severe PPH and infection (Francois & Foley, 2017).

Thrombin (Coagulopathies). The final T in the etiology of PPH stands for thrombin, or coagulopathies. When bleeding is continuous and there is no identifiable source, a coagulopathy may be the cause. The patient's coagulation status must be assessed quickly and continuously. Abnormal results depend on the cause and may include increased prothrombin time, increased partial thromboplastin time, decreased platelets, decreased fibrinogen level, increased fibrin degradation products, and prolonged bleeding time. Causes of

coagulopathies may be pre-existing (von Willebrand disease, hemophilia A, immune thrombocytopenic purpura) or pregnancy related, such as thrombocytopenia with pre-eclampsia or DIC. Coagulopathies may also develop as a result of therapeutic anticoagulation, fetal demise, severe infection, placental abruption, or amniotic fluid embolus (Leduc et al., 2018).

Immune thrombocytopenic purpura (ITP). Immune thrombocytopenic purpura (ITP) is an autoimmune disorder in which antiplatelet antibodies decrease the lifespan of the platelets. Thrombocytopenia, capillary fragility, and increased bleeding time are diagnostic findings. ITP may cause severe hemorrhage after Caesarean birth or from cervical or vaginal lacerations. The incidence of postpartum uterine bleeding and vaginal hematomas is also increased.

Medical management focuses on control of platelet stability. If ITP was diagnosed during pregnancy, the pregnant patient likely was treated with corticosteroids or IV immune globulin. Platelet transfusions are usually given when there is significant bleeding. A splenectomy may be needed if the ITP does not respond to medical management (Cunningham et al., 2018).

von Willebrand disease (vWD). **von Willebrand disease (vWD)**, a type of hemophilia, is probably the most common of all hereditary bleeding disorders. Although vWD is rare, it is among the most common congenital clotting defects in North American patients of childbearing age. It results from a deficiency or defect in a blood-clotting protein called *von Willebrand factor (vWF).* There are as many as 20 variations of vWD, most of which are inherited as autosomal dominant traits—types I and II are the most common ones (Cunningham et al., 2018). Symptoms include recurrent bleeding episodes, such as nosebleeds or after tooth extraction, bruising easily, heavy menstrual bleeding, prolonged bleeding time (the most important test), factor VIII deficiency (mild to moderate), and bleeding from mucous membranes. Although factor VIII increases during pregnancy, a risk for PPH still exists as levels of vWF begin to decrease (Cunningham et al., 2018). The patient may be at risk for bleeding for up to 4 weeks after birth.

The treatment of choice is administration of desmopressin, which promotes the release of vWF and factor VIII. It can be given nasally, intravenously, or orally. Transfusion therapy with plasma products that have been treated for viruses and contain factor VIII and vWF also may be used. Concentrates of antihemophiliac factor (Humate) may be used (Cunningham et al., 2018).

Disseminated intravascular coagulation (DIC). **Disseminated intravascular coagulation (DIC)**, also known as *consumptive coagulopathy,* is an imbalance between the body's clotting and fibrinolytic systems. It is a pathological form of clotting that is diffuse and consumes large amounts of clotting factors, including platelets, fibrinogen, prothrombin, and factors V and VII. Widespread external bleeding, internal bleeding, or both can result. DIC also causes vascular occlusion of small vessels that results from small clots forming in the microcirculation. In the obstetrical population, DIC may occur as a result of massive antepartum or postpartum hemorrhage; sepsis; severe pre-eclampsia; hemolysis, elevated liver enzymes, low platelets (HELLP) syndrome; amniotic fluid embolism; fetal demise; placental abruption; septic abortion; or acute fatty liver of pregnancy (Erez et al., 2015; Francois & Foley, 2017).

The diagnosis of DIC is made according to clinical findings and laboratory markers. Physical examination reveals unusual bleeding; spontaneous bleeding from the patient's gums or nose may be noted. **Petechiae** may appear around a blood pressure cuff placed on the patient's arm. Excessive bleeding may occur from the site of a slight trauma (e.g., venipuncture sites, intramuscular or subcutaneous injection sites, nicks from shaving the abdomen, and injury from insertion of a urinary catheter). Hypotension is out of proportion to the observed blood loss. Other symptoms include tachycardia and diaphoresis. Laboratory tests reveal decreased levels of platelets, fibrinogen, proaccelerin, antihemophiliac factor, and prothrombin (the factors consumed during coagulation). Fibrinolysis is increased at first but is later severely depressed. Degradation of fibrin leads to the accumulation of fibrin split products in the blood; these have anticoagulant properties and prolong the prothrombin time. Bleeding time is normal, coagulation time shows no clot, clot-retraction time shows no clot, and partial thromboplastin time is increased. DIC must be distinguished from other clotting disorders before therapy is initiated. DIC may cause critical bleeding and multi-organ failure requiring admission to the critical care unit and may cause maternal death (Takeda & Takeda, 2019).

Primary medical management in all cases of DIC involves correction of the underlying cause (e.g., removal of the dead fetus, treatment of existing infection or of pre-eclampsia or eclampsia, or removal of a placental abruption). If the fetus is alive, expedient birth is recommended. Volume replacement, blood component therapy, optimization of oxygenation and perfusion status, and continued reassessment of laboratory parameters are the usual forms of treatment. Resolution of DIC usually begins with the birth of the newborn and as coagulation abnormalities resolve (Takeda & Takeda, 2019).

Nursing interventions include frequent and accurate assessment of bleeding; frequent monitoring for uterine atony; timely communication with the interprofessional team; additional IV line insertion; administration of fluid, blood products, and coagulation factors as ordered; observing for signs of complications from the administration of blood and blood products; and protecting the patient from injury. Because multi-organ failure, specifically renal failure, may be a result of DIC, insertion of an in-dwelling urinary catheter for close monitoring of urine output is recommended. Urinary output of less than 30 mL/hr must be reported to the primary health care provider.

The patient and their family will be extremely anxious or concerned about the patient's condition and prognosis. The nurse should offer explanations about care and provide emotional support to them throughout this critical time.

Collaborative Care

Care of patients experiencing PPH requires collaboration of an interprofessional health care team. Nurses and obstetrical care providers work closely with personnel from the transfusion services department (blood bank), pharmacy, and laboratory to manage the emergent situation that occurs when a patient begins to bleed excessively after birth.

Assessment. Early recognition and treatment of PPH are critical to care management. Risk assessment beginning during pregnancy and continuing during the intrapartum and postpartum periods is important in identifying patients who are at risk for PPH (see Box 24.1). This increases the awareness of the health care team in planning and implementing care and in preventing hemorrhage and its sequelae. Team members should be made aware when a patient with identified risk factors is admitted to the birthing facility (Fleischer & Meirowitz, 2016).

Excessive blood loss is the clinical finding that warrants prompt action. In general, health care providers are highly inaccurate in estimating blood loss in terms of volume (Hancock et al., 2015). Nurses must be able to quantify blood loss accurately. The Association of

Women, Obstetric and Neonatal Nurses (AWHONN) (2015b) states that visual estimation of blood loss can be inaccurate, with underestimates of 33 to 55%, which can delay life-saving treatment. Weighing perineal pads is a much more accurate method of determining blood loss and is recommended by AWHONN.

Whenever blood loss appears to be excessive, the first step is to evaluate the contractility of the uterus and the amount of bleeding. If the uterus is hypotonic, management is directed toward increasing contractility, primarily with active uterine massage and uterotonic medication to minimize blood loss (Leduc et al., 2018). If the uterus is firmly contracted and bleeding continues, the source of bleeding must be identified and treated. Assessment may include visual or manual inspection of the perineum, vagina, uterus, cervix, or rectum and laboratory studies (e.g., hemoglobin, hematocrit, coagulation studies, platelet count). Treatment depends on the source of the bleeding.

Medical Management. The Society of Obstetricians and Gynaecologists of Canada (SOGC) recommends active management of the third stage of labour in order to prevent PPH, where possible (Leduc et al., 2018). This involves administering oxytocin intramuscularly or by IV push after delivery of the anterior shoulder, considering delayed cord clamping, gentle cord traction, and immediate fundal massage and IV infusion of oxytocin after the complete birth. If it takes longer than 30 minutes to deliver the placenta, the risk of PPH increases (Leduc et al., 2018).

The initial management of excessive postpartum bleeding due to uterine atony is firm massage of the uterine fundus. Expression of any clots in the uterus, elimination of bladder distension, and continuous IV infusion of 10 to 40 units of oxytocin in 1 000 mL of Ringer's lactate or normal saline solution are also primary interventions. If the uterus fails to respond to oxytocin, other uterotonic medications are administered. Misoprostol (Cytotec), a synthetic prostaglandin E_1 analogue, is often used as it can be given rectally, sublingually, or orally. Methylergonovine may be given intramuscularly to produce sustained uterine contractions. A derivative of prostaglandin $F_{2\alpha}$ (carboprost tromethamine [Carboprost; Hemabate]) may be given intramuscularly. It can also be given intramyometrially at Caesarean birth or intra-abdominally after vaginal birth (see Medication Guide: Uterotonic Medications to Manage Postpartum Hemorrhage for a comparison of uterotonic medications and common dosages used to manage PPH). In addition to the medications used to contract the uterus, rapid administration of crystalloid solutions or blood or blood products, or both will be needed to restore the patient's intravascular volume (Francois & Foley, 2017).

MEDICATION GUIDE

Uterotonic Medications Used to Manage Postpartum Hemorrhage

Medication	Action	Adverse Effects	Contradictions	Dosage and Route	Nursing Considerations
Oxytocin (Syntocinon)	Contraction of uterus; decreases bleeding	Infrequent: water intoxication, nausea and vomiting	None for PPH	20–40 units/L diluted in 1 000 mL lactated Ringer's solution or normal saline at 150 mL/hour; or 10 units IM or 5 to 10 units IV push (over 1 to 2 minutes)	Continue to monitor vaginal bleeding and uterine tone
Misoprostol (Cytotec)*	Contraction of uterus	Headache, nausea, vomiting, diarrhea, fever, chills	Do not use if history of allergy to prostaglandins	600 to 800 mcg rectal, sublingual, or PO	Continue to monitor vaginal bleeding and uterine tone
Methylergonovine; Ergonovine Maleate	Contraction of uterus	Hypertension, hypotension, nausea, vomiting, headache	Hypertension, pre-eclampsia, cardiac disease	0.25 mg IM	Check blood pressure before giving, and do not give if >140/90 mm Hg; continue monitoring vaginal bleeding and uterine tone
Carboprost tromethamine (Hemabate)	Contraction of uterus	Headache, nausea, vomiting, diarrhea, fever, chills, tachycardia, hypertension	Avoid with asthma or hypertension	250 mcg IM	Continue to monitor vaginal bleeding and uterine tone
Tranexamic acid (Cyclokapron)	For blood clotting and to stop prolonged bleeding	Nausea, vomiting, diarrhea, dizziness	History of blood clots or taking any anticoagulant	1 g IV	Often given to prevent PPH in someone with a bleeding disorder

IM, Intramuscular; *IV,* intravenous; *PO,* by mouth; *PPH,* postpartum hemorrhage.

*Off-label use; research reports vary in conclusions about dosage and efficacy of use in comparison to other medications used to manage postpartum hemorrhage.

Source: Leduc, D., Senikas, V., & Lalonde, A. (2018). SOGC clinical practice guideline No. 235—Active management of the third stage of labour: Prevention and treatment of postpartum hemorrhage. *Journal of Obstetrics and Gynaecology Canada, 40*(12), e841–e855.

Oxygen can be given by nonrebreather face mask to enhance oxygen delivery to the cells. Assessment of bladder status is also essential as a full bladder will impede contraction of the uterus. An in-dwelling urinary catheter is usually inserted to monitor urine output as a measure of intravascular volume and to keep the bladder empty. Laboratory studies usually include a complete blood count with platelet count, fibrinogen, fibrin split products, prothrombin time, and partial thromboplastin time. Blood type and antibody screen are done if not previously performed (Cunningham et al., 2018).

If bleeding persists, bimanual compression may be performed by an obstetrical health care provider. One hand is placed over the uterus externally; the other is placed in the vagina to apply pressure on the lower segment. Consistent compression with the two hands results in external compression of the uterus to reduce blood flow (Leduc et al., 2018). If the uterus still does not become firm, the physician or midwife will perform manual exploration of the uterine cavity for retained placental fragments. If all of these procedures are ineffective, surgical management is needed. Surgical management options include uterine tamponade (uterine packing or an intrauterine tamponade balloon), bilateral ligation of the internal iliac artery, or uterine compression suturing (using, for example, B-Lynch or Hayman vertical sutures). If other treatment measures are ineffective, hysterectomy will likely be needed (Leduc et al., 2018).

! NURSING ALERT

Use of ergonovine or methylergonovine is contraindicated in the presence of hypertension or cardiovascular disease.

Nursing Care. The nurse must be alert to the symptoms of hemorrhage and hypovolemic shock and be prepared to act quickly to minimize blood loss (Figure 24.1). Astute assessment of circulatory status can be done with noninvasive monitoring (Box 24.2). Frequent monitoring of the patient's vital signs and encouraging them to empty their bladder are important nursing interventions for treatment and prevention of PPH. Interventions are based on the cause of PPH, as previously discussed.

The patient and their family may be anxious about what is happening. The nurse can intervene by calmly providing explanations about interventions being performed and the need to act quickly.

Once the patient's condition is stabilized, preparations for discharge can be made. Discharge instructions for a patient who has experienced PPH are similar to those for any postpartum patient. In addition, the patient should be told that they will probably feel fatigue, even exhaustion, and will need to limit their physical activities to conserve their strength. They may require instructions in increasing their dietary iron and protein intake as well as using iron supplementation to rebuild lost red blood cell (RBC) volume. They may need assistance with newborn care and household activities until they have regained strength. Some postpartum patients who have experienced a PPH may have difficulties involving delayed lactogenesis or insufficient milk production, or they may develop a perinatal mood disorder (PMD). Referrals for home care follow-up or to community resources may be needed (see Nursing Care Plan: Postpartum Hemorrhage, available on Evolve).

Hemorrhagic (Hypovolemic) Shock

Hemorrhage may result in **hemorrhagic (hypovolemic) shock**. Shock is an emergency situation in which the perfusion of body organs may become severely compromised; death may occur. Physiological compensatory mechanisms are activated in response to hemorrhage. See Table 24.1 for severity of shock symptoms. The adrenal glands release catecholamines, causing arterioles and venules in the skin, lungs, gastrointestinal tract, liver, and kidneys to constrict. The available blood flow is diverted to the brain and heart and away from other organs, including the uterus. If shock is prolonged, the continued reduction in cellular oxygenation results in an accumulation of lactic acid and acidosis (from anaerobic glucose metabolism). Acidosis (lowered serum pH) causes arteriolar vasodilation; venule vasoconstriction persists. A circular pattern is established (i.e., decreased perfusion, increased tissue anoxia and acidosis, edema formation, and pooling of blood further decrease the perfusion). Cellular death occurs. See the Emergency box: Hemorrhagic Shock for assessment of and interventions for hemorrhagic shock.

EMERGENCY

Hemorrhagic Shock

Assessment	Characteristics
Respirations	Rapid and shallow
Pulse	Rapid, weak, irregular
Blood pressure	Decreasing (late sign)
Skin	Cool, pale, clammy
Urinary output	Decreasing
Level of consciousness	Lethargy → coma
Mental status	Anxiety → coma
Central venous pressure	Decreased

Interventions

Summon assistance and equipment.
Start intravenous infusion per standing orders.
Ensure patent airway; administer oxygen.
Continue to monitor status.

Collaborative Care. Interprofessional teamwork and collaboration are key to managing care of postpartum patients who experience hemorrhagic shock. The patient is likely to be transferred to a critical care unit for stabilization and ongoing care and monitoring.

Vigorous treatment is necessary to prevent adverse outcomes. Management of hypovolemic shock involves restoring circulating blood volume and eliminating the cause of the hemorrhage (e.g., lacerations, uterine atony, or inversion). Venous access with a large-bore IV catheter is critical to successful care management of the patient with a hemorrhagic complication. Establishing two IV lines facilitates fluid resuscitation, which includes the administration of crystalloids (lactated Ringer's, normal saline solution), colloids (albumin), blood, and blood components. To restore circulating blood volume, a rapid IV infusion of crystalloid solution is given at a rate of 3 mL infused for every 1 mL of estimated blood loss (e.g., 3 000 mL infused for 1 000 mL of blood loss). Packed RBCs are usually infused if the patient is still actively bleeding and no improvement in their condition is noted after the initial crystalloid infusion. Infusion of fresh frozen plasma may be needed if clotting factors and platelet counts are below normal values (Francois & Foley, 2017; Leduc et al., 2018).

Hemorrhagic shock can occur rapidly, but the classic signs of shock may not appear until the postpartum patient has lost 30 to 40% of their blood volume. By the time vital signs are abnormal, the patient may be in an advanced stage of shock. The nurse must continue to reassess the patient's condition as evidenced by the degree of measurable and anticipated blood loss and mobilize appropriate resources.

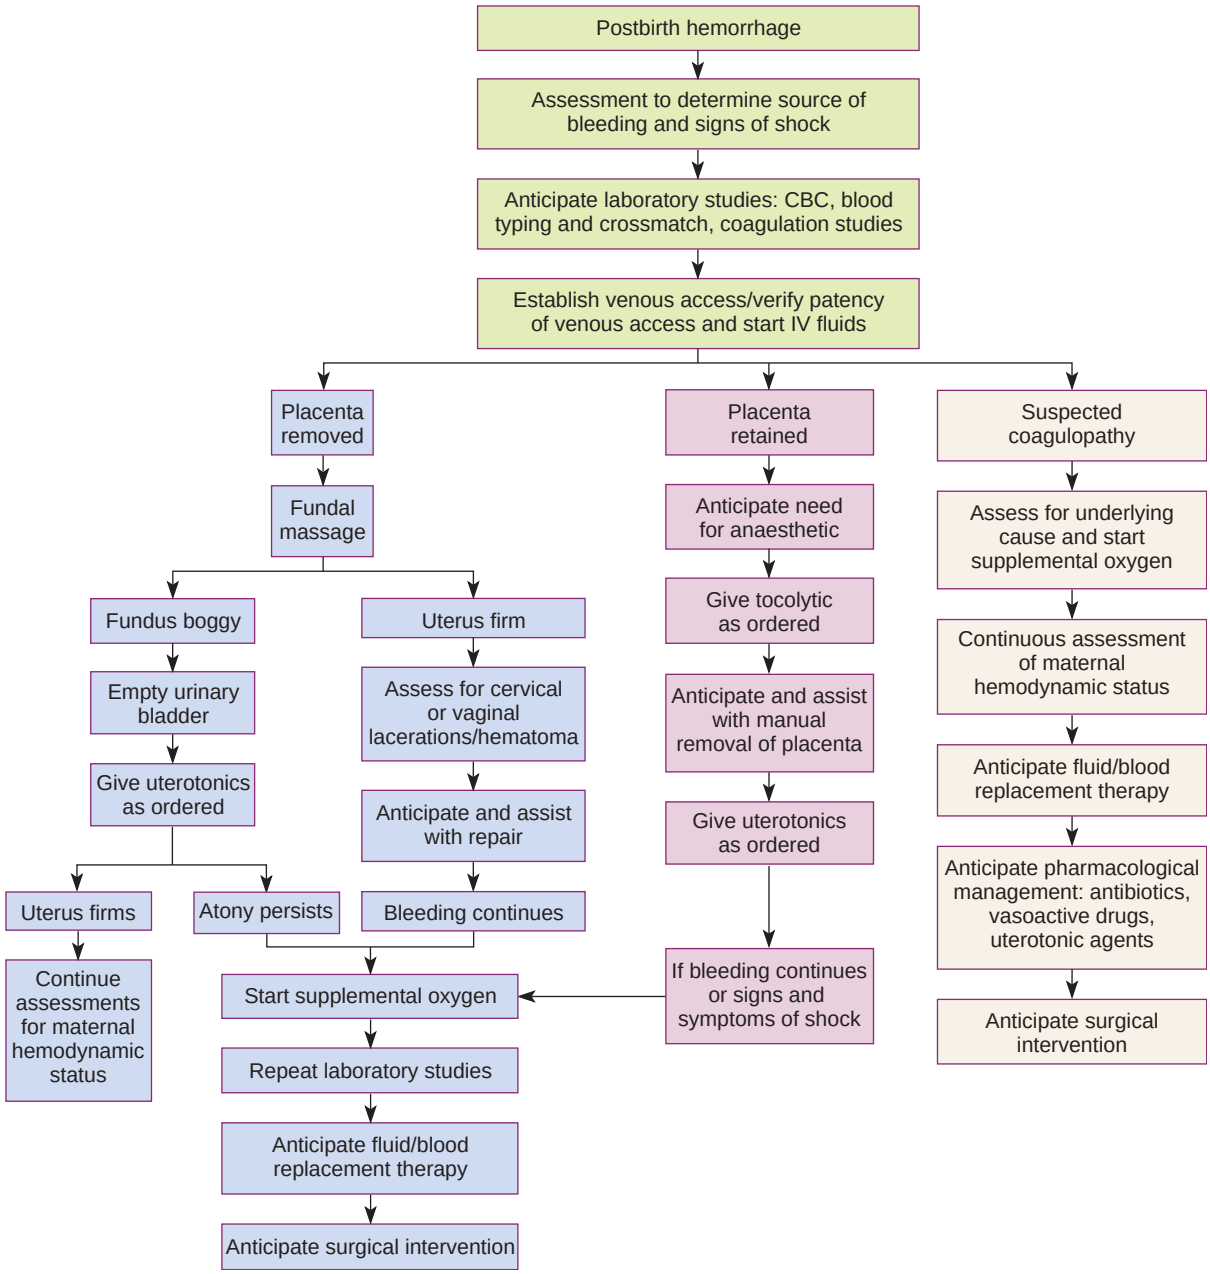

Fig. 24.1 Nursing assessments and interventions for excessive postpartum bleeding. *CBC,* Complete blood count; *IV,* intravenous; *tocolytics,* medications to relax the uterus; *uterotonics,* medications to contract the uterus.

BOX 24.2 Noninvasive Assessments of Circulatory Status in Postpartum Patients Who Are Bleeding

Palpation of Pulses (Rate, Quality, Equality)
- Arterial

Inspection
- Skin colour, temperature, turgor
- Level of consciousness
- Capillary refill
- Neck veins
- Mucous membranes

Auscultation
- Heart sounds/murmurs
- Breath sounds

Observation
- Presence or absence of anxiety, apprehension, restlessness, disorientation

Measurement
- Blood pressure
- Pulse oximetry
- Urinary output

TABLE 24.1 Degree of Hypovolemic Shock

Degree of Shock	Blood Loss	Signs and Symptoms
Mild	<20%	Diaphoresis; increased capillary refilling Cool extremities and anxiety
Moderate	20–40%	As above, as well as tachycardia and tachypnea Postural hypotension and oliguria
Severe	>40%	As above, as well as hypotension, agitation/confusion Hemodynamic instability

Source: Leduc, D., Senikas, V., & Lalonde, A. (2018). SOGC clinical practice guideline No. 235—Active management of the third stage of labour: Prevention and treatment of postpartum hemorrhage. *Journal of Obstetrics and Gynaecology Canada, 40*(12), e841–e855.

Major goals of care are to restore oxygen delivery to the tissues and maintain cardiac output. Fluid resuscitation must be monitored carefully because fluid overload can occur. Intravascular fluid overload occurs most often with colloid therapy.

If the patient is actively bleeding and unstable despite fluid boluses, transfusion of blood products is needed. Protocols need to be in place for emergency release of blood products; these products may be universally compatible (e.g., O-negative RBCs or AB plasma) or type-specific if the patient's blood type is known and the supply is available. A massive transfusion protocol facilitates timely access to and administration of blood products (Fleischer & Meirowitz, 2016).

Transfusion reactions can follow administration of blood or blood components, including cryoprecipitates. Even in an emergency, each unit of blood or blood products should be carefully checked per hospital protocol. Complications of fluid or blood replacement therapy include hemolytic reactions, febrile reactions, allergic reactions, circulatory overloading, and air embolism.

LEGAL TIP: Standard of Care for Bleeding Emergencies
The standard of care for obstetrical emergency situations such as PPH or hypovolemic shock is that provision should be made for the nurse to implement nursing actions independently. Policies, procedures, standing orders or protocols, and clinical guidelines should be established by each health care facility in which births occur and should be agreed on by health care providers involved in the care of obstetrical patients.

The nurse needs to continue to monitor the postpartum patient's pulse and blood pressure. If invasive hemodynamic monitoring is ordered, the nurse may assist with placement of an arterial line or central venous pressure (CVP) or pulmonary artery (Swan-Ganz) catheter. The nurse then monitors CVP, pulmonary artery pressure, or pulmonary artery wedge pressure as ordered.

Additional assessments to be made include evaluation of skin temperature, colour, and turgor and assessment of the patient's mucous membranes. Breath sounds should be auscultated before fluid volume replacement to provide a baseline for future assessment. Inspection for oozing at the sites of incisions or injections and assessment of the presence of petechiae or ecchymosis in areas not associated with surgery or trauma are critical in the evaluation for DIC.

Oxygen is administered and titrated to maintain oxygen saturation. Oxygen saturation should be monitored with a **pulse oximeter**, although measurements may not always be accurate in a patient with hypovolemia or decreased perfusion. Level of consciousness is assessed frequently and provides additional indications of blood volume and oxygen saturation. In early stages of decreased blood flow, the patient may report "seeing stars" or feeling dizzy or nauseated. They may become restless and orthopneic. As cerebral hypoxia increases, the patient may become confused and react slowly to stimuli or not at all. Some patients state they have headaches. An improved sensorium is an indicator of improved perfusion.

Continuous electrocardiographic monitoring may be indicated for the patient who is hypotensive or tachycardic, continues to bleed profusely, or is in shock. A Foley catheter with a urometer is inserted to allow hourly assessment of urine output. The most objective and least invasive assessment of adequate organ perfusion and oxygenation is a urine output of at least 30 mL/hr (Cunningham et al., 2018). Hemoglobin and hematocrit levels, platelet count, and coagulation studies need to be closely monitored.

VENOUS THROMBOEMBOLIC DISORDERS

Venous thromboembolism (VTE) results from the formation of a blood clot or clots inside a blood vessel and is caused by inflammation (thrombophlebitis) or partial obstruction of the vessel (Figure 24.2). Three thromboembolic conditions are of concern in the postpartum period:

- **Superficial venous thrombosis**—Involvement of the superficial saphenous venous system
- **Deep venous thrombosis (DVT)**—Involvement varies but can extend from the foot to the iliofemoral region
- **Pulmonary embolism (PE)**—Complication of DVT occurring when part of a blood clot dislodges and is carried to the pulmonary artery, where it occludes the vessel and obstructs blood flow to the lungs

Fig. 24.2 Deep vein thrombophlebitis. (From Murphy, E. H., Davis, C. M., Journeycake, J. M., et al. [2009]. Symptomatic ileofemoral DVT after onset of oral contraceptive use in patients with previously undiagnosed May-Thurner syndrome. *Journal of Vascular Surgery, 49*[3], 697–703.)

Incidence and Etiology

Pregnant patients have a 15 times increased risk of thromboembolism (Bates et al., 2016; Cunningham et al., 2018). The incidence of VTE is approximately 1 in 1 500 pregnancies and is a leading cause of mortality and serious morbidity in pregnant patients (Pettker & Lockwood, 2017). This rate represents a nearly ten-fold increase compared with nonpregnant patients of comparable age. VTE can occur in any trimester of pregnancy or during the postpartum period. DVT occurs most often during pregnancy, although it can occur up to 12 weeks postpartum, and PE is more common in the postpartum period. The incidence of VTE in the postpartum period has declined in the last 30 years because early ambulation after childbirth, a preventive measure, has become standard practice (Cunningham et al., 2018). However, PE is a major cause of maternal death (Bates et al., 2018; Chan et al., 2014).

The major causes of thromboembolic disease are venous stasis and hypercoagulation, both of which are present in pregnancy and continue into the postpartum period. Caesarean birth nearly doubles the risk for VTE; other risk factors include operative vaginal birth; history of venous thrombosis, PE, or varicosities; body mass index (BMI) greater than 30; prolonged immobility; and smoking (Bates et al., 2018; Pettker & Lockwood, 2017). Patients who experience complications such as pre-eclampsia, hemorrhage, or postpartum infection also have an increased risk for VTE (Tepper et al., 2014).

The SOGC recommends that each patient be evaluated for risk, and consideration for thromboprophylaxis should be individualized (Chan et al., 2014). Patients who are at risk for VTE should consider wearing TED stockings shortly after birth. If compression stockings do not fit, then a sequential compression device (SCD) may be used. Because these stockings and pneumatic compression devices pose no hemorrhagic risk and do little harm, they should be strongly considered for thromboprophylaxis in all patients with risk factors, such as those patients who are hospitalized or immobilized, including pregnant or postoperative Caesarean patients (Chan et al., 2014).

Clinical Manifestations

Superficial venous thrombosis is the most common form of postpartum thrombophlebitis. It is characterized by pain and tenderness in the lower extremity. Physical examination may reveal warmth, redness, and an enlarged, hardened vein over the site of the thrombosis. DVT is more common in pregnancy and is characterized by unilateral leg pain, calf tenderness, and swelling. Physical examination may reveal redness and warmth, but patients may also have a large clot with few symptoms.

Acute PE usually results from dislodged deep vein thrombi. Presenting symptoms are dyspnea and tachypnea (more than 20 breaths/min). Other signs and symptoms frequently seen include tachycardia (more than 100 beats/min), apprehension, cough, hemoptysis, elevated temperature, and syncope (Cunningham et al., 2018).

Physical examination is not a sensitive diagnostic indicator for DVT. D-dimer assays and diagnostic imaging are used for diagnosis. With PE, ventilation-perfusion scanning and computed tomography pulmonary angiography are the most validated diagnostic tests (Lim et al., 2018).

Collaborative Care

Superficial venous thrombosis is also treated with analgesia (nonsteroidal anti-inflammatory medications), rest with elevation of the affected leg, and elastic compression stockings and heat (Cunningham et al., 2018).

DVT is initially treated with anticoagulant therapy (usually continuous IV heparin), bed rest with the affected leg elevated, and analgesia. After the symptoms have decreased, the patient may be fitted with elastic compression stockings to wear when they are allowed to ambulate. They need to be taught how to put on the stockings before getting out of bed. IV heparin therapy continues for 3 to 5 days or until symptoms resolve. Oral anticoagulant therapy (warfarin [Coumadin]) is started during this time and is continued for about 3 months. If a breastfeeding mother is on long-term anticoagulant therapy, the infant's prothrombin time should be monitored at least monthly and vitamin K given to the infant, if necessary (Lawrence & Lawrence, 2016).

Acute PE is an emergent situation that requires prompt treatment. Massive pulmonary emboli can lead to pulmonary hypertension and hemodynamic instability; mortality is increased to 25% in these cases (Cunningham et al., 2018). Immediate treatment of PE is anticoagulant therapy. Continuous IV heparin therapy is used for PE until symptoms have resolved. Intermittent subcutaneous heparin or oral anticoagulant therapy is often continued for up to 6 months (Pettker & Lockwood, 2017).

In the hospital, nursing care of the patient with a thrombosis consists of ongoing assessments: inspecting and palpating the affected area; palpating the peripheral pulses; and measuring and comparing leg circumferences. Signs of PE, including chest pain, coughing, dyspnea, and tachypnea, and respiratory status for presence of crackles are also assessed. Laboratory reports are monitored for prothrombin or partial thromboplastin times. The nurse needs to assess for unusual bleeding. Increased lochia, generalized petechiae, hematuria, or oozing from venipuncture sites should be immediately reported to the health care provider. In addition, the patient and their family are assessed for their level of understanding about the diagnosis and their ability to cope during the unexpected extended period of recovery.

Interventions include explanations and education about the diagnosis and treatment. The patient will need assistance with personal care as long as they are on bed rest. The family should be encouraged to participate in the patient's care if the patient and they wish. While the patient is on bed rest, they should be encouraged to change positions frequently but not to place the knees in a sharply flexed position that could cause pooling of blood in the lower extremities. They should also be cautioned not to rub the affected areas, because rubbing could cause the clot to dislodge. Heparin and warfarin are administered as ordered, and the health care provider is notified if clotting times are outside the therapeutic level. If the patient is breastfeeding, they should be informed that neither heparin nor warfarin is excreted in significant quantities in breast milk (Lawrence & Lawrence, 2016). If the newborn has been discharged, the family is encouraged to bring the newborn for feedings as permitted by hospital policy; the patient also can express breastmilk to be sent home.

Pain can be managed with a variety of measures. Changing of positions, elevation of the leg, and application of moist heat may decrease discomfort. It may be necessary to administer analgesics and anti-inflammatory medications.

! NURSING ALERT

Medications containing Aspirin are not given to patients on anticoagulant therapy because Aspirin inhibits synthesis of clotting factors and can lead to prolonged clotting time and increased risk of bleeding.

The patient is usually discharged home on oral anticoagulants and will need an explanation of the treatment schedule and possible adverse effects. If subcutaneous injections are to be given, the patient and family need to be taught how to administer the medication and about site rotation. They should also be given information about dietary restrictions (e.g., limited intake of green, leafy vegetables) and safe care practices to prevent bleeding and injury while the patient is on anticoagulant

therapy (e.g., using a soft toothbrush and an electric razor). They will need information about follow-up with their health care provider to monitor clotting times and regulate the correct dosage of anticoagulant therapy. The patient should also use a reliable form of contraception if taking warfarin because this medication is considered teratogenic. Oral contraceptives are contraindicated because of the increased risk for thrombosis (Cunningham et al., 2018).

POSTPARTUM INFECTIONS

Postpartum infection or *puerperal infection* is any clinical infection that occurs within 42 days after miscarriage, induced abortion, or birth (WHO, 2015). The most common symptoms of postpartum infection are pyrexia (presence of fever of greater than 38°C), tachycardia, and subjective feelings of localized pain (Cunningham et al., 2018). Common postpartum infections include uterine, wound, breast, urinary tract, and respiratory infections (Cunningham et al., 2018).

The most common infecting organisms are the numerous streptococcal and anaerobic organisms. *Staphylococcus aureus*, gonococci, coliform bacteria, and *Clostridia* are less common but serious pathogenic organisms that can cause puerperal infection. Postpartum infections are more common in patients with obesity, who have concurrent medical or immunosuppressive conditions, or who had a Caesarean or other operative birth. Intrapartal factors such as prolonged rupture of membranes, prolonged labour, and internal fetal monitoring also increase the risk of infection (Cunningham et al., 2018). Factors that predispose the patient to postpartum infection are listed in Box 24.3.

Endometritis

Endometritis (infection of the lining of the uterus) usually begins as a localized infection at the placental site but can spread to the entire endometrium. It is the most common postpartum infection, occurring in up to 3% of vaginal births and 5 to 10% of Caesarean births (Duff & Birsner, 2017). The highest incidence occurs in patients who gave birth by Caesarean after prolonged labour and rupture of membranes. Prophylactic antibiotics administered during labour and during Caesarean surgery can help reduce the incidence and severity of endometritis.

Signs of endometritis include fever (usually greater than 38°C [100.4°F]), increased pulse, chills, anorexia, nausea, fatigue and lethargy, pelvic pain, uterine tenderness, and foul-smelling, profuse lochia. Leukocytosis and a markedly increased RBC sedimentation rate are typical laboratory findings. Anemia can also be present. Blood cultures or intracervical or intrauterine bacterial cultures (aerobic and anaerobic) should reveal the offending pathogens within 36 to 48 hours. The most common cause of uterine infections is from organisms transmitted from hands to vagina to uterine placental site (Cunningham et al., 2018).

Management. Management of endometritis consists of IV broad-spectrum antibiotic therapy (cephalosporins, penicillins, or clindamycin and gentamicin) and supportive care, including hydration, rest, and pain relief. Most uterine infections respond to antibiotics, and the treatment continues until the patient has been afebrile for 48 hours.

Assessments of lochia, vital signs, and changes in the patient's condition continue during treatment. Comfort measures depend on the symptoms and may include cool compresses, warm blankets, perineal care, and sitz baths. Patient education should include adverse effects of therapy, prevention of spread of infection, signs and symptoms of worsening condition, importance of completing the treatment, and the need for follow-up care. Patients may need to be encouraged or assisted to maintain mother–infant interactions and breastfeeding.

Wound Infections

Wound infections are common postpartum infections that often develop after the patient is at home. Sites of infection include the Caesarean incision and repaired laceration or episiotomy site. Predisposing factors are similar to those for endometritis (see Box 24.3). Signs of wound infection include fever, **erythema**, edema, warmth, tenderness, pain, seropurulent drainage, and wound separation. In order to decrease the risk of wound infections in patients who have a Caesarean birth, the SOGC recommends that all patients undergoing elective or emergency Caesarean birth receive antibiotic prophylaxis. The timing of the antibiotic should be 15 to 30 minutes before the skin incision (van Schalkwyk & Van Eyk, 2017). Prophylactic antibiotics may also be considered for patients who have third- and fourth-degree perineal injury, and the dose may be doubled for patients who have a BMI greater than 35 (van Schalkwyk & Van Eyk, 2017).

Management. Culture of wound exudate is performed to identify the causative organism. Wound infections are treated with IV antibiotic therapy. When pus is present in the incision, the wound is opened and drained. Wounds are irrigated with normal saline and re-dressed several times daily; healing occurs by secondary intention. In some cases, a wound vacuum device is used. Antibiotic treatment is continued until the base of the wound appears clear and there are no apparent signs of cellulitis (Duff & Birsner, 2017).

Nursing care includes frequent assessments of temperature and vital signs; wound assessment and care; and comfort measures such as analgesics, sitz baths, warm compresses, and perineal care. Teaching includes hygienic care techniques (e.g., changing perineal pads front to back, hand hygiene before and after perineal care), self-care measures, and signs of worsening conditions to report to the obstetrical health care provider. Wound care and assessment will continue after

BOX 24.3 Predisposing Factors for Postpartum Infection

Preconception or Antepartal Factors

- History of previous venous thrombosis, urinary tract infection, mastitis, pneumonia
- Diabetes mellitus
- Alcohol misuse
- Substance misuse
- Immunosuppression
- Anemia
- Malnutrition
- Obesity
- Pre-eclampsia

Intrapartal Factors

- Caesarean birth
- Operative vaginal birth
- Prolonged rupture of membranes
- Chorioamnionitis
- Prolonged labour
- Bladder catheterization
- Internal fetal or uterine pressure monitoring
- Multiple vaginal examinations after rupture of membranes
- Epidural anaesthesia
- Retained placental fragments
- Postpartum hemorrhage
- Episiotomy or lacerations
- Hematomas

discharge from the birthing facility. The patient and their family are instructed in how to perform wound care and dressing changes. Home visits by nurses may be provided to assess the wound, reinforce teaching, and offer support. If IV antibiotic therapy is continued in the home, it is likely to be administered by the family with regular monitoring by the visiting nurse.

Urinary Tract Infections

Urinary tract infections (UTIs) occur in 2 to 4% of postpartum patients. Risk factors include urinary catheterization, frequent pelvic examinations, epidural anaesthesia, genital tract injury, history of UTI, and Caesarean birth (Simpson et al., 2020). Signs and symptoms include dysuria, frequency and urgency, low-grade fever, urinary retention, hematuria, and pyuria. Costovertebral angle tenderness or flank pain may indicate an upper UTI. The most common infecting organism is *Escherichia coli*, although other Gram-negative aerobic bacilli also may cause UTIs.

Management. Medical management for UTIs consists of antibiotic therapy, analgesia, and hydration. Postpartum patients are usually treated on an outpatient basis; therefore teaching should include instructions on how to monitor temperature, bladder function, and appearance of urine. The patient should also be taught about signs of potential complications and the importance of taking all antibiotics as prescribed. Other suggestions for prevention of UTIs include proper perineal care, wiping from front to back after urinating or having a bowel movement, and increasing fluid intake.

Mastitis

Mastitis, or breast infection, affects 2 to 10% of patients after childbirth. Mastitis is almost always unilateral and develops well after the flow of milk has been established (Figure 24.3). The infecting organism generally is the hemolytic *S. aureus*. An infected nipple fissure usually is the initial lesion, followed by ductal system involvement. Inflammatory edema and engorgement of the breast obstruct the flow of milk in a lobe; regional, then generalized, mastitis follows. If treatment is not prompt, mastitis may progress to a breast abscess.

Symptoms rarely appear before the end of the first postpartum week and are more common in the third to fourth weeks (Simpson et al., 2020). Chills, fever, malaise, and local breast tenderness are noted first. Localized breast tenderness, pain, swelling, redness, and axillary adenopathy may also occur. Antibiotics are prescribed for treatment. Lactation can be maintained by emptying the breasts every 2 to 4 hours by breastfeeding, manual expression, or a breast pump.

Because mastitis rarely occurs before the postpartum patient is discharged, they should be taught in the hospital about its warning signs and receive counselling about prevention of cracked nipples, incomplete breast emptying, and plugged milk ducts (Simpson et al., 2020). Management includes intensive antibiotic therapy (e.g., cephalosporins and vancomycin, which are particularly useful in staphylococcal infections), support of breasts, local heat or cold, adequate hydration, and analgesics.

Almost all instances of acute mastitis can be avoided by using proper breastfeeding technique to prevent cracked nipples. Missed feedings, waiting too long between feedings, and abrupt weaning may lead to clogged nipples and mastitis. Cleanliness practised by all who have contact with the newborn and new mother also reduces the incidence of mastitis. See also Chapter 27.

Nursing Care

Postpartum patients with factors predisposing to postpartum infection (see Box 24.3) should be assessed carefully. Signs and symptoms associated with postpartum infection were discussed earlier with each infection. Elevation of temperature, redness, and swelling are common signs. The mother may also have chills, fever, localized tenderness, pain, and foul-smelling lochia or urine. Depending on the type of infection, laboratory tests include a complete blood count, venous blood cultures, urine cultures, and uterine tissue cultures. Review of the patient's history and the laboratory results should be included in the assessment. The nurse also needs to monitor for signs of sepsis, including hypotension, tachypnea, decreased urine output, and decreased level of consciousness (Cunningham et al., 2018).

The most effective and least expensive treatment of postpartum infection is prevention. Preventive measures include good prenatal nutrition to reduce the risk for anemia. Good maternal perineal hygiene with thorough hand hygiene should be emphasized. Use of aseptic techniques by all health care personnel during childbirth and the postpartum period is essential.

Postpartum patients are usually discharged home before 48 hours after birth, which is often before signs of infection are evident. Nurses in birth centres and hospital settings need to be able to identify patients at risk for postpartum infection and provide anticipatory teaching and counselling before the patient's discharge. After discharge, telephone follow-up, hot lines, support groups, lactation consultants, home visits by a community health nurse, and teaching materials (movies, written materials, apps) are all interventions that can be implemented to decrease the risk of postpartum infections. Nurses working in the community must be able to recognize signs and symptoms of postpartum

Fig. 24.3 Mastitis.

infection and convey these to the patient so that they know when to contact their primary health care provider. Community nurses must also be able to provide the appropriate nursing care for patients who need follow-up home care.

PERINATAL MOOD DISORDERS

For many postpartum patients the weeks after birth are a time of vulnerability to psychological complications, causing significant distress for the patient, disrupting family life, and, if prolonged, negatively affecting the couple's relationship and the child's emotional and social development. **Perinatal mood disorders (PMDs)** have traditionally been called *postpartum mood disorders*, but the terminology has been revised to *perinatal mood disorders* because these mental health issues may affect persons any time during pregnancy and in the first year after the birth of the baby, although they most commonly begin within the first 4 to 6 weeks following birth (Registered Nurses' Association of Ontario [RNAO], 2018a). PMDs include anxiety, depression, and psychosis.

It is important to identify the difference between mood changes and mood disorders. A common mood change in the postpartum period is postpartum blues. Within 3 to 5 days postpartum up to 75% of patients will experience episodes of tearfulness, agitation, mood swings, anxiety, sleep and appetite disturbances, and feelings of being overwhelmed (RNAO, 2018a). The distinguishing factor between this and a mood disorder is that it resolves within 2 weeks and does not disrupt the postpartum patient's ability to care for themselves and their baby. Nursing care for patients with postpartum blues involves validation, reassurance, and education. See Chapter 22, Postpartum Blues, for further discussion of postpartum blues.

Pregnant and postpartum patients with a mood disorder need to have their condition diagnosed because untreated perinatal depression and other mood disorders can have devastating effects on all members of the family (American College of Obstetricians and Gynecologists, Committee on Obstetric Practice [ACOG], 2015). Pre-existing mood and anxiety disorders are particularly likely to recur or worsen during these weeks. Because birth is usually thought to be a happy event, a new parent's emotional distress can puzzle and alienate family and friends. Nurses can offer anticipatory guidance, assess the mental health of new mothers, offer therapeutic interventions, and make referrals, when necessary. Failure to do so can result in tragic consequences.

In 2018, in Canada, almost one-quarter (23%) of mothers who had recently given birth reported feelings consistent with either postpartum depression or an anxiety disorder. The proportion of mothers reporting these feelings varied across provinces, ranging from 16% in Saskatchewan to 31% in Nova Scotia (Statistics Canada, 2019b). PMD affects patients from all cultures, although the implications and manifestations of PMD and the barriers to obtaining treatment vary. Indigenous people have an 87% higher chance of developing postpartum depression than non-Indigenous patients (Black et al., 2019). This vulnerability could be due to history of colonization, intergenerational trauma, discrimination, racism, and marginalization (Black et al., 2019) (see Chapter 1, Indigenous People). Indigenous people may experience significant barriers to care, including geographic barriers, poverty, and lack of culturally safe care (Black et al., 2019). Negative social determinants of mental health can increase the risk for PMD with inequities such as poverty and intimate partner violence (RNAO, 2018b).

The cause of a PMD can be biological, psychological, situational, or multifactorial. Estrogen fluctuations and postpartum hypogonadism (the change from the high levels of estrogen and progesterone at the end of pregnancy to the much lower levels of both hormones present after birth) are important etiological factors. Patients at greatest risk for PMD are those with a history of anxiety or depression and especially those who have had a previous episode of major depressive disorder whether during or after pregnancy (Cunningham et al., 2018; RNAO, 2018a). Box 24.4 lists risk factors for PMD.

PMD affects parental infant attachment and the quality of parenting, and affected children are at increased risk of developing mental, social, and behavioural difficulties (Letourneau et al., 2017). The complications of having a PMD are listed in Box 24.5. Some patients have more serious mood disorders that can eventually incapacitate them to the point of being unable to care for themselves and their babies and may include thoughts of self-harm and suicide. Suicide is the leading cause of maternal death during the perinatal year (RNAO, 2018b).

BOX 24.4 Risk Factors for Perinatal Mood Disorders

Strongest Risk Factors

- A history of psychiatric illness, including depression or anxiety at any time, including, but not limited to, during the perinatal period
- Prenatal symptoms of anxiety
- Onset of depression during pregnancy or postpartum

Moderate Risk Factors

- Stressful life events (e.g., relationship breakdown or divorce, losing a job, incarceration, housing insecurity)
- Refugee or immigrant status
- Low social support or perception of low support
- Unfavourable obstetrical outcome(s)
- Low self-esteem
- A history of physical or sexual abuse during childhood or adulthood
- Intimate partner violence
- A history of reproductive trauma (e.g., infertility)
- Grief related to miscarriage, stillbirth, or infant loss
- Substance use, including the use of tobacco

Weak Risk Factors

- Low socioeconomic status
- Lack of significant other or partner; lone parent
- Pregnancy, as defined by the person, as unplanned or unwanted
- Breastfeeding challenges

BOX 24.5 Potential Complications of Having a Perinatal Mood Disorder

- Mother–infant attachment issues
- Depression in the partner
- Long-term emotional behavioural and cognitive issues in the child
- Relationship issues and family breakdown
- Social, financial, and occupational complications
- Self-harm and suicide
- Infant and sibling neglect and occasionally infanticide

From Lazarus, R., & Gutteridge, K. (2013). Post-natal psychiatric disorders. In S. E. Robson & J. Wough (Eds.), *Medical disorders in pregnancy: A manual for midwives*. Wiley Blackwell.

Perinatal Anxiety Disorders

One out of every five patients suffers from perinatal anxiety disorder (Fawcett et al., 2019). Anxiety disorders include generalized anxiety disorder, obsessive-compulsive disorder (OCD), panic disorder and panic attacks, specific phobias, social anxiety disorder, and post-traumatic stress disorder (PTSD). Patients with a history of anxiety disorder are at greatest risk. Anxiety disorders and depression may occur at the same time (RNAO, 2018a).

With generalized anxiety disorder, patients have a pervasive feeling of anxiety most of the time and worry excessively about multiple concerns. Anxiety symptoms can interfere with the mother's ability to care for themselves, the infant, and their family. Patients with generalized anxiety disorder may experience chest tightness, shortness of breath, tachycardia, dizziness or lightheadedness, sweating, trembling, nausea, abdominal pain, fatigue, constant worry, a sense of doom, and difficulty concentrating (Wisner et al., 2017).

Panic disorder consists of unpredictable, intermittent episodes (attacks) of symptoms similar to those of generalized anxiety disorder. Panic attacks are discrete periods of sudden onset of intense apprehension, fearfulness, or terror (Fawcett et al., 2019). During these attacks, symptoms such as shortness of breath, palpitations, chest pain, choking, smothering sensations, and fear of losing control are present. Patients with panic attacks have reported having intrusive thoughts about terrible injury done to the infant, such as stabbing or burns, sometimes by themselves. Rarely do these patients harm their baby. Patients with panic disorder may develop agoraphobia or fear of leaving home because they fear having another panic attack (Wisner et al., 2017). Nurses need only to listen to a mother with such attacks to hear symptoms of panic disorder. Usually these patients are so distraught that they will share their thoughts with whoever will listen. Often the family has tried to tell them that what they are experiencing is normal; however, they know that their symptoms are not normal. These patients need to have their feelings validated, and they need monitoring or treatment.

Patients with OCD often find their symptoms increase during pregnancy and in the postpartum period (Fawcett et al., 2019). Onset of OCD can occur after birth. Patients with postpartum OCD tend to have obsessive, intrusive thoughts, and they perform compulsive actions that temporarily reduce or alleviate the distress caused by the intrusive thoughts. In the postpartum period, compulsive checking on the sleeping baby and repetitive ritualistic washing are common. Obsessions are usually focused and specific and associated with fear of consequences (Fawcett et al., 2019). The obsessive thoughts can be incapacitating. Patients fear they will lose control and act on their thoughts. Patients with OCD are afraid they will harm their infant but are unlikely to do so. Patients with postpartum psychosis who have the same thoughts are more apt to actually cause harm (Fawcett et al., 2019; Wisner et al., 2017).

Postpartum PTSD is the result of exposure to trauma, either during the prenatal or intrapartum period, or it may be related to previous life experiences and events such as childhood sexual abuse or intimate partner violence. Risk factors for postpartum PTSD include history of pregnancy loss, high-risk pregnancy, preterm birth, having an infant in the neonatal intensive care unit (NICU), painful and/or difficult vaginal birth, instrument-assisted vaginal birth, and emergency Caesarean birth (Vesel & Nickasch, 2015–2016).

Anxiety disorders in the prenatal period are strongly related to the development of postpartum depression. In addition, anxiety disorder in pregnancy is related to negative obstetrical outcomes and in the postpartum period. These can result in negative attachment as well as behavioural and emotional sequelae on the infant and siblings (Biaggi et al., 2016; Fawcett et al., 2019).

Collaborative Care. Effective treatments are available for anxiety disorders, and affected patients need to be given this information. Anxiety disorders may be treated with psychotherapy; cognitive behavioural therapy (CBT) and exposure response prevention (ERP) are often used. These therapies may be provided individually, in groups, or online and are recommended as the first line of treatment, as many patients prefer not to take medications (RNAO, 2018b). Pharmacological treatment includes selective serotonin reuptake inhibitors (SSRIs) and antianxiety medications, although it can take 2 weeks for these medications to be effective. Benzodiazepines provide short-term relief from anxiety symptoms but should be used judiciously as they can be addictive. Medications should be prescribed with careful consideration of safety for the fetus during pregnancy and for the breastfeeding infant postpartum. Each patient should be treated on an individualized basis: the severity of their symptoms needs to be assessed, their history and response to any previous treatments should be obtained, their preferences need to be acknowledged, and the potential benefits and risks of each treatment must be conveyed.

Education is a crucial nursing intervention. New mothers should be provided with anticipatory guidance concerning the possibility of anxiety disorders during the perinatal period. Preparing for the attacks can help offset their unexpected, terrifying nature. Patients can be reassured that it is common to feel a sense of impending doom and fear of insanity during panic attacks. Nurses can help patients identify panic triggers that are particular to their own lives. Keeping a diary can help in identifying such triggers.

Family and social supports are often helpful. The new mother needs to be encouraged to put usual chores on hold and to ask for and accept help when needed. Support groups can help these mothers experience some comfort in seeing others in similar circumstances.

Perinatal Depression

Perinatal depression is the most common complication of childbirth, with approximately half of cases starting in the prenatal period (RNAO, 2018a). Rates of depression during the postpartum period are approximately 10 to 15% in Canadian patients (Lanes et al., 2011). It is likely that the actual occurrence of perinatal depression exceeds the reported estimates because it is often unrecognized and undiagnosed.

Perinatal depression can be mild to severe. It is characterized by an intense and pervasive sadness with severe and labile mood swings. It is more serious and persistent than postpartum blues, lasting more than 2 weeks. Intense fears, anger, anxiety, and despondency that persist past the baby's first few weeks are not a normal part of postpartum blues.

The symptoms of perinatal depression do not differ from those of nonpostpartum depression except that the mother's ruminations of guilt and inadequacy feed worries about being an incompetent and inadequate parent. New mothers report an increased yearning for sleep, sleeping heavily but awakening instantly with any infant noise, and an inability to go back to sleep after infant feedings. Determining difficulty falling asleep is a relevant screening question to ascertain risk for depression (see Clinical Reasoning Case Study: Perinatal Depression).

A distinguishing feature of major depression is irritability. These episodes of irritability may flare up with little provocation and may sometimes escalate to violent outbursts or dissolve into uncontrollable sobbing. Many of these outbursts are directed against significant others. Postpartum patients with major depressive episodes often have spontaneous crying long after the usual duration of baby blues.

Feelings of detachment toward the newborn and not feeling love for the newborn are common symptoms of perinatal depression. Patients feel guilt and shame for having these feelings at a time when they believe they should be happy. They can be reluctant to discuss their

symptoms or their negative feelings toward the infant. A postpartum patient with depression may have obsessive thoughts about harming the infant, and this can be very frightening to them. Often they do not share these thoughts because of embarrassment; when they do, other family members become very frightened. On the other hand, some postpartum patients feel very emotionally attached and connected to their infants; this can prevent them from experiencing total despair (RNAO, 2018a).

These symptoms rarely disappear without outside help. Many patients are reluctant to seek assistance. Loneliness, lack of social support, and language barriers also affect the ability to attain treatment.

CLINICAL REASONING CASE STUDY

Perinatal Depression

Jennifer is a 35-year-old G1 T1 P0 A0 L1 who gave birth by emergency Caesarean 2 weeks ago, to a 3500-g baby. She has come to the OB clinic for her 2-week follow-up visit and is accompanied by her partner and her mother. Jennifer appears tired, her colour is pale, and she has dark circles under both eyes. Her affect is flat. Jennifer's partner reports that she is not sleeping, she cries often, her appetite is poor, and she seems to be constantly worried about breastfeeding. Jennifer's mother states that the baby cries much of the time and never seems satisfied after breastfeeding. She says that there have been times in the past when Jennifer was depressed and she took antidepressant medication, although she did not want to take any medication during pregnancy.

1. Evidence—Is there sufficient evidence to draw conclusions about Jennifer's current condition?
2. Assumptions—What assumptions can be made about the following?
   a. Jennifer's risk factors for perinatal depression
   b. Jennifer's support system
   c. Jennifer's concern with breastfeeding
   d. Jennifer's reluctance to take antidepressant medication
3. Priority: What is the nursing priority in this situation?
4. Interprofessional care—Describe roles and responsibilities of health care providers who would potentially be involved in care management for Jennifer.

Collaborative Care. Treatment options for perinatal depression include psychotherapy and antidepressant and antianxiety medication. Psychotherapy without the use of medication can be effective for mild cases of perinatal depression. It is often used in combination with antidepressants for moderate to severe cases. Psychotherapy methods include general counselling (listening visits), interpersonal psychotherapy, CBT, and psychodynamic therapy (RNAO, 2018a). Peer support may be helpful; some patients find that postpartum support groups are very beneficial. Internet-based and telephone-based psychotherapy are increasing in use. For some patients with severe perinatal depression, hospitalization is necessary.

The key to treatment of depression is to screen all patients to determine who may need treatment. All health care providers who come in contact with families in the perinatal period must be knowledgeable and prepared to screen all patients for PMDs (see discussion later in chapter).

Postpartum Psychosis

The most severe of the PMDs, **postpartum psychosis**, is rare, affecting approximately 0.1% of postpartum patients (Holford et al., 2018). This disorder tends to show onset within 2 weeks postpartum, although a small number of patients may develop psychosis with a later onset (Brockington, 2017; Holford et al., 2018). Once a patient has had one episode of postpartum psychosis they are 50 to 80% more likely to develop a psychiatric disorder, often bipolar disorder (Tinkelman et al., 2017). There is also a 50% recurrence rate of postpartum psychosis. Postpartum psychosis is a psychiatric emergency and often requires hospitalization.

Episodes of postpartum psychosis are characterized by rapid onset of bizarre behaviour, auditory or visual hallucinations, paranoid or grandiose delusions, elements of delirium or disorientation, and extreme deficits in judgement accompanied by high levels of impulsivity that can contribute to increased risk for suicide or infanticide (Tinkelman et al., 2017).

Pre-existing bipolar disorder is a risk factor for postpartum psychosis (Holford, 2018). This mood disorder is defined by the presence of one or more episodes of abnormally elevated energy levels, cognition, and mood and one or more depressive episodes. The elevated moods are clinically referred to as *mania.* Clinical manifestations of a manic episode include at least three of the following: grandiosity, decreased need for sleep, pressured speech, flight of ideas, distractibility, psychomotor agitation, and excessive involvement in pleasurable activities without regard for negative consequences (American Psychiatric Association, 2017). While in a manic state, mothers need constant supervision when caring for their infant. Usually, however, they are too preoccupied to provide child care. Individuals who experience manic episodes also commonly experience depressive episodes or symptoms or mixed episodes, in which features of both mania and depression are present at the same time. These episodes are usually separated by periods of "normal" mood, but in some individuals, depression and mania may rapidly alternate. These rapid changes in mood are known as *rapid cycling.*

Collaborative Care. Postpartum psychosis carries a relatively good prognosis with early detection and aggressive treatment (Hardy & Reichenbacker, 2019). Postpartum psychosis is a psychiatric emergency, and the mother will probably need inpatient psychiatric care. Antipsychotics, mood stabilizers, and benzodiazepines are the treatments of choice. Other psychotropic medications such as antidepressants may be used on the basis of the underlying diagnosis (e.g., bipolar mania, bipolar depression). Electroshock therapy (ECT), especially when bilaterally administered, has also been shown to be highly effective in the treatment of postpartum psychosis. It is usually advantageous for the mother to have contact with their baby if they desire, but visits must be closely supervised. Psychotherapy is indicated after the period of acute psychosis has passed.

Interdisciplinary and Nursing Care

An interprofessional team approach to care is needed for the patient who presents with signs and symptoms of a PMD. A nurse in the role of case manager can coordinate care management. The obstetrical health care provider assesses the patient's physical condition in relation to postbirth recovery as well as their current symptoms. The provider may order pharmacological treatment (e.g., antidepressant medications) or may refer the patient to a psychiatric care provider for treatment of symptoms. A pharmacist may consult with the provider regarding the optimal medications and their safety during breastfeeding and may provide education to the patient about the medications (dose, schedule, adverse effects, when to expect improvement in symptoms). If the patient is experiencing a loss of appetite, a dietitian may be a part of care management. A lactation consultant and pediatric health care provider may need to be consulted if the patient is experiencing breastfeeding difficulties. The pediatric health care provider will monitor the infant's weight and health status. Close follow-up and ongoing monitoring of the patient's mental and physical status and the infant's health, growth, and development are vital to optimizing outcomes.

Even though the prevalence of PMD is fairly well established, patients may be unlikely to seek help from a mental health care

provider. This reluctance can be related to social stigma of mental illness, cultural beliefs, lack of knowledge, or fear of child custody implications (Yonkers et al., 2011). Primary health care providers can usually recognize severe depression or postpartum psychosis but may miss milder forms; even if it is recognized, the patient may be treated inappropriately or subtherapeutically. Nurses are strategically positioned to offer anticipatory guidance, assess the mental health of new mothers, offer therapeutic interventions, and make referrals when necessary. Failure to do so may result in tragic consequences. In practice, it is the responsibility of all who are in contact with the patient to provide screening, assessment, and education to facilitate early detection and treatment.

Identification and treatment of PMD must be continued beyond the immediate postbirth period to prevent negative effects of maternal mood disorders on the children of these mothers. To recognize symptoms of PMD as early as possible, the nurse should be an active listener and demonstrate a caring attitude. Nurses cannot depend on patients to volunteer unsolicited information about their mental health or ask for help. Examples of ways to initiate conversation include the following: "Now that you've had your baby, how are things going for you? Have you had to change many things in your life since having the baby?" and "How much time do you spend crying?" If the nurse assesses that the new mother is depressed, the nurse must ask if the mother has thought about hurting themselves or the baby. The patient may be more willing to answer honestly if the nurse says, "Many people feel depressed after having a baby, and some feel so bad that they think about hurting themselves or the baby. Have you had these thoughts?"

! NURSING ALERT

Because mothers with postpartum psychosis may harm their infants, extra precaution is needed in assessment and intervention. The nurse needs to ask specifically if the mother has had thoughts about harming their baby.

Screening for Perinatal Mood Disorders. When PMD is identified early, it is highly treatable. Screening for anxiety or depression during pregnancy and the postpartum period aids in prevention and early intervention for PMD. Patients at risk should be identified (see Box 24.4), although all patients should be screened during pregnancy and postpartum (ACOG, 2015; AWHONN, 2015a; RNAO, 2018a).

Screening for PMD can be done before patients are discharged from the hospital, although this may be too early. While the screening may identify some who are at risk, it is important that follow-up screening also be done. PMD is most likely to occur around 4 weeks after birth but can occur any time within the perinatal period up to 1 year postpartum. Follow-up assessments for risks and signs of PMD can be done by primary care providers during pediatric care visits for the infant and during postpartum follow-up visits for the mother. Patients with a positive screen should be referred appropriately for evaluation and treatment.

In perinatal populations the most widely used and validated tools are the Edinburgh Postnatal Depression Scale (EPDS) and the Postpartum Depression Screening Scale (PDSS). Both are brief, self-report questionnaires specifically developed for use with perinatal patients, which take between 5 and 10 minutes to complete (RNAO, 2018a).

With the EPDS the person is asked to respond to 10 statements about the common symptoms of depression (Figure 24.4). It has been used and validated in studies in numerous cultures and is viewed as a valid screening tool throughout pregnancy and postpartum for PMD. The patient is asked to choose the response that is closest to describing how they have felt for the past week. A maximum score on the EPDS is 30; patients with scores of 12 or higher may possibly have depression and need further assessment. One item on the tool addresses suicidal thoughts; responses to this item should be carefully examined (Cox et al., 2014).

The effectiveness of screening for PMD is related to the follow-up for positive screening results. If PMD screening results are positive or if the patient's self-report shows signs that they might be depressed, a formal screening is needed to determine the urgency of the referral and the type of provider. Also important is the need to assess the patient's family because they may be able to offer valuable information, as well as need to express how they have been affected by the patient's emotional disorder.

Nursing Considerations. Postpartum nurses need to carefully observe all new postpartum patients for signs of anxiety, depression, and disinterest in the newborn and conduct further assessments as necessary. Prior to discharge from the birthing facility, nurses educate the mother and their partner about signs of postpartum blues, PMD, as well as when and where to seek help (see Patient Teaching box: Signs of Postpartum Blues, Depression, and Psychosis). Nurses also need to provide information about how to prevent postpartum depression (see Patient Teaching box: Preventing a Perinatal Mood Disorder). Nurses can assist patients by teaching them self-care, especially the symptoms and risk factors for PMD; helping them to feel safe and empowered in discussing their mental and social health; and facilitating adequate social and partner support. Patients and their families should be given written resources in their native language and emergency numbers to call. Nurses should provide patients and their families with a current list of available community resources for treating postpartum depression. Nurses must also stress the importance of seeking help from a health care provider if PMD symptoms are present at any time within the year postpartum. The family must be able to recognize the symptoms and know where to go for help. Printed materials and online resources that explain what the patient can do to prevent a mood disorder can be used as part of discharge education. Pregnant persons need to be taught self-care strategies including exercise, relaxation, adequate sleep, and time for themselves as both a prevention and treatment strategy for depression and anxiety (RNAO, 2018a).

PATIENT TEACHING

Signs of Postpartum Blues, Depression, and Psychosis

Signs of baby blues (these should go away in a few days or 1 week):
- Sad, anxious, or overwhelmed feelings
- Crying spells
- Loss of appetite
- Difficulty sleeping

Signs of postpartum depression (can begin any time in the first year):
- Same signs as baby blues, but they last longer and are more severe
- Thoughts of harming yourself or your baby
- Not having any interest in the baby

Signs of postpartum psychosis:
- Seeing or hearing things that are not there
- Feelings of confusion
- Rapid mood swings
- Trying to hurt yourself or your baby

When to call your health care provider:
- The baby blues continue for more than 2 weeks
- Symptoms of depression get worse
- Difficulty performing tasks at home or at work
- Inability to care for yourself or your baby
- Thoughts of harming yourself or your baby

Edinburgh Postnatal Depression Scale (EPDS)

Name: _____ Address: _____

Your Date of Birth: _____ Baby's Date of Birth: _____ Phone: _____

As you are pregnant or have recently had a baby, we would like to know how you are feeling. Please check the answer that comes closest to how you have felt IN THE PAST 7 DAYS, not just how you feel today.
Here is an example, already completed.

I have felt happy:

- ☐ Yes, all the time
- ☒ Yes, most of the time
- ☐ No, not very often
- ☐ No, not at all

(This would mean: "I have felt happy most of the time" during the past week.)

Please complete the other questions in the same way.

1. I have been able to laugh and see the funny side of things.
   - ☐ As much as I always could
   - ☐ Not quite so much now
   - ☐ Definitely not so much now
   - ☐ Not at all
2. I have looked forward with enjoyment to things.
   - ☐ As much as I ever did
   - ☐ Rather less than I used to
   - ☐ Definitely less than I used to
   - ☐ Hardly at all

*3. I have blamed myself unnecessarily when things went wrong.
   - ☐ Yes, most of the time
   - ☐ Yes, some of the time
   - ☐ Not very often
   - ☐ No, never

4. I have been anxious or worried for no good reason.
   - ☐ No, not at all
   - ☐ Hardly ever
   - ☐ Yes, sometimes
   - ☐ Yes, most of the time

*5. I have felt scared or panicky for no good reason.
   - ☐ Yes, quite a lot
   - ☐ Yes, sometimes
   - ☐ No, not much
   - ☐ No, not at all

*6. Things have been getting on top of me.
   - ☐ Yes, most of the time I have not been able to cope at all
   - ☐ Yes, sometimes I have not been able to cope as well as usual
   - ☐ No, most of the time I have coped quite well
   - ☐ No, I have been coping as well as ever

*7. I have been so unhappy that I have had difficulty sleeping.
   - ☐ Yes, most of the time
   - ☐ Yes, sometimes
   - ☐ Not very often
   - ☐ No, not at all

*8. I have felt sad or miserable.
   - ☐ Yes, most of the time
   - ☐ Yes, quite often
   - ☐ Not very often
   - ☐ No, not at all

*9. I have been so unhappy that I have been crying.
   - ☐ Yes, most of the time
   - ☐ Yes, quite often
   - ☐ Only occasionally
   - ☐ No, never

*10. The thought of harming myself has occurred to me.
   - ☐ Yes, quite often
   - ☐ Sometimes
   - ☐ Hardly ever
   - ☐ Never

Administered/Reviewed by: _____

SCORING

QUESTIONS 1, 2, & 4 (without an *)

Are scored 0, 1, 2 or 3 with top box scored as 0 and the bottom box scored as 3.

QUESTIONS 3, 5–10

(marked with an *)

Are reverse scored, with the top box scored as a 3 and the bottom box scored as 0.

Maximum score: 30

Possible Depression: 10 or greater

Always look at item 10 (suicidal thoughts)

Instructions for using the Edinburgh Postnatal Depression Scale:

1. The mother is asked to check the response that comes closest to how she has been feeling in the previous 7 days.
2. All the items must be completed.
3. Care should be taken to avoid the possibility of the mother discussing her answers with others. (Answers come from the mother or pregnant woman.)
4. The mother should complete the scale herself, unless she has limited English or has difficulty with reading.

Detection of postnatal depression: Development of the 10-item Edinburgh Postnatal Depression Scale. *British Journal of Psychiatry, 150*, 782–786. Translations of the scale, and guidance as to its use, may be found in Cox, J. L., Holden, J., & Henshaw, C. [2014]. *Perinatal mental health: The Edinburgh Postnatal Depression Scale (EPDS) manual* [2nd Ed.]. RCPsych Publications.

! NURSING ALERT

Because the newborn may be scheduled for a checkup before the mother's 6-week checkup, nurses in well-baby clinics or physician offices should be alert for signs of PMD in new mothers and be knowledgeable about community referral resources.

PATIENT TEACHING

Preventing a Perinatal Mood Disorder

- Share knowledge about postpartum emotional issues with close family and friends.
- At least once each day or every other day, purposely relax for 15 minutes, using deep breathing or meditating or by taking a hot bath.
- Take care of yourself: eat a balanced diet.
- Exercise on a regular basis, at least 30 minutes a day.
- Sleep as much as possible; make a promise to yourself to try to sleep when the baby sleeps.
- Get out of the house: try to leave home for 30 minutes a day; take a walk outdoors or walk at the mall.
- Share your feelings with someone close to you; don't isolate yourself at home with the TV.
- Don't overcommit yourself or feel like you need to be a supermom. Ask for help from family and friends.
- Don't place unrealistic expectations on yourself; you don't need to be a perfect mother.
- Be flexible with your daily activities.
- Go to a new mothers' support group: for example, take a postpartum exercise class or attend a breastfeeding support group.
- Don't be ashamed of having emotional challenges after your baby is born.

Patients who are at risk for PMD and those showing early signs of anxiety or depression may be followed after discharge from the birthing facility through home visits or telephone calls. Postpartum home visits can reduce the incidence of or complications from PMD. A brief home visit or phone call at least once a week until the new mother returns for their postpartum visit may save the life of a mother and their infant; however, home visits may not be feasible or available. Some provinces have mandatory telephone follow-up of all new mothers after the birth, and patients who are identified as high risk should receive more comprehensive follow-up. Supervision of the mother with emotional complications may become a prime concern. Because PMD can greatly interfere with mothering functions, family and friends may need to participate in the infant's care. This is a time for extended family and friends to determine what they can do to help; the nurse can work with them to ensure adequate supervision and their understanding of the family member's mental illness.

When the postpartum patient has a PMD, a partner often reacts with confusion, shock, denial, and anger and feels neglected and blamed. The nurse can provide nonjudgemental opportunities for the partner to express feelings and concerns, help the partner identify positive coping strategies, and be a source of encouragement for the partner to continue supporting the patient. Suggestions for partners of patients with PMD include helping around the house, setting limits with family and friends, going with the patient to doctor's appointments, educating themselves about PMD, writing down concerns and questions to take to the primary care provider or therapist, and just being with their partner—sitting quietly, hugging them, and demonstrating concern and compassion. Both the patient and their partner need an opportunity to express their needs, fears, thoughts, and feelings in a nonjudgemental environment.

Even if the patient is severely depressed, hospitalization can be avoided if adequate resources can be mobilized to ensure safety for both mother and infant. The community health nurse will need to make frequent phone calls or home visits for assessment and counselling. Community resources that may be helpful are temporary child care or foster care, homemaker service, meals on wheels, parenting guidance centres, mother's-day-out programs, and telephone support groups.

Providing Safety. If delusional thinking about the baby is suspected, the nurse should ask the patient, "Have you thought about hurting your baby?" When PMD is suspected, the nurse asks, "Have you thought about hurting yourself?" Four criteria measure the seriousness of a suicidal plan: method, availability, specificity, and lethality. Has the patient specified a method? Is the method of choice available? How specific is the plan? If the method is concrete and detailed, with access to it right at hand, the suicide risk is increased. How lethal is the method? The most lethal method is shooting, with hanging being a close second. The least lethal method is slashing one's wrists.

! NURSING ALERT

Suicidal thoughts or attempts are among the most serious symptoms of PMD. This is considered a psychiatric emergency and warrants immediate assessment, evaluation, and intervention by a mental health care provider.

Psychiatric Hospitalization. Patients with postpartum psychosis have a psychiatric emergency and must be referred immediately to a psychiatrist who is experienced in working with patients with psychosis, can prescribe medication and other forms of therapy, and can assess the need for hospitalization.

LEGAL TIP: Commitment for Psychiatric Care

If a patient with PMD is experiencing active suicidal ideation or harmful delusions about the baby and is unwilling to seek treatment, legal intervention may be necessary to commit the patient to an inpatient setting for treatment.

Within the hospital setting, the reintroduction of the baby to the mother can occur at the mother's own pace. A schedule is set for increasing the number of hours during which the mother cares for the baby over several days, culminating in the infant staying overnight in the mother's room. This enables the mother to experience meeting the infant's needs and giving up sleep for the baby, a situation that is difficult for new mothers even under ideal conditions. The mother's readiness for discharge and caring for the baby should be assessed. The mother's interactions with the baby should also be carefully supervised and guided. A postpartum nurse may be asked to assist the psychiatric nursing staff in assessment of the mother–infant interactions.

Nurses need to observe the mother for signs of bonding with the baby. Attachment behaviours are defined as eye-to-eye contact; physical contact that involves holding, touching, cuddling, and talking to the baby and calling the baby by name; and the initiation of appropriate care. A staff member should be assigned to keep the baby in sight at all times. Indirect teaching, praise, and encouragement are designed to bolster the mother's self-esteem and self-confidence.

Psychotropic Medications. If a patient is diagnosed with depression, antidepressant medications will often be used. Antidepressant medications are the most widely used treatment for perinatal depression. Paroxetine, sertraline, fluoxetine, venlafaxine, nortriptyline, and nefazodone have been evaluated and are associated with improvement in depression symptoms over 2 to 3 months of treatment (O'Hara & Wisner, 2014) (Table 24.2). If the person with a PMD is not breastfeeding, in most cases antidepressants can be prescribed without special

TABLE 24.2 Medications for Perinatal Mood Disorders

Class	Medication	Indications	Maternal Adverse Effects	Infant Exposure Effects	Comments
SSRIs	Citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, sertraline	Anxiety disorders, depression	Gastrointestinal distress, nervousness, headache, sexual dysfunction, sedation	All SSRIs are detectable in human milk. Paroxetine and sertraline are usually undetectable in infant serum; fluoxetine and citalopram >10% maternal level. Infant effects: irritability, uneasy sleep, drowsiness, colic, feeding difficulties. Fluoxetine is contraindicated during lactation.	Sertraline is most common; undetectable to low levels in human milk. Long-term effects of SSRI exposure on infants: more evidence is needed; recent evidence is reassuring.
SNRIs	Venlafaxine, duloxetine, desvenlafaxine	Depression	Galactorrhea	SNRIs are detectable in human milk and infant serum. No proven adverse effects; assess weight gain and sedation.	Lack of evidence on outcomes for breastfed infants
Other antidepressants (norepinephrine/ dopamine/ serotonin reuptake blockers)	Bupropion, mirtazapine	Depression	Drowsiness, increased appetite, weight gain, dizziness, dry mouth; dose-dependent	Limited data; concerns range from possible irritability to seizures.	Not a reason to stop breastfeeding; another medication may be preferable.
TCAs/ heterocyclics	Amitriptyline, amoxapine, clomipramine, desipramine, doxepin, maprotiline, nortriptyline, protriptyline, trimipramine	Anxiety disorders, depression	Hypotension, sedation, urinary retention, dry mouth, weight gain, sexual dysfunction, constipation; overdose can cause cardiac arrhythmias and death.	Lack of evidence on most medications; nortriptyline is undetectable in infant serum, no adverse effects are reported.	Older class of medications
Antipsychotic	Quetiapine	Bipolar disorder, schizophrenia	Sedation	Sedation	
Mood stabilizer	Lithium	Postpartum psychosis	Diarrhea, vomiting	Elevated TSH	Dosage is based on maternal blood levels, which should be checked frequently.
Herbal/natural remedy	St. John's wort	Depression		Poorly excreted into human milk; possible drowsiness, lethargy	Used in Europe for many years to treat depression; use in Canada is controversial.

SNRI, Serotonin-norepinephrine reuptake inhibitor; *SSRI,* selective serotonin reuptake inhibitor; *TCA,* tricyclic antidepressant; *TSH,* thyroid-stimulating hormone.

Adapted from Sriraman N. K., Melvin K., Meltzer-Brody S., & Academy of Breastfeeding Medicine. (2015). ABM clinical protocol no. 18: Use of antidepressants in breastfeeding mothers. *Breastfeeding Medicine, 10*(6), 290–299.

precautions. Patients who are breastfeeding need assessments to determine the risks and benefits of each medication, although there are several medications that can be taken (see further discussion below).

Mood stabilizers are used in the treatment of severe psychiatric syndromes such as schizophrenia, bipolar disorder, or psychotic depression. Patients taking mood stabilizers must be taught about the many adverse effects; especially for those taking lithium, serum lithium levels need to be determined every 6 months. Most of the mood-stabilizing medications can cause sedation and orthostatic hypotension—both of which can interfere with the mother being able to care safely for their baby. They also can cause peripheral nervous system effects such as constipation, dry mouth, blurred vision, tachycardia, urinary retention, weight gain, and agranulocytosis. Central nervous system effects may include akathisia, dystonias, parkinsonian-like symptoms, tardive dyskinesia (irreversible), and neuroleptic malignant syndrome (potentially fatal). Medication education is especially important when caring for patients who are taking antipsychotic medications. The nurse should use discretion in selecting the content to be shared because of the patient's altered thought processes and the large number of adverse effects. The nurse may choose to provide more extensive education to a close family member. The newer, atypical antipsychotic medications such as aripiprazole, olanzapine, quetiapine, risperidone, and ziprasidone are usually safer and have fewer adverse effects than the older, more traditional antipsychotics. Their safety in breastfeeding patients, however, has not been established.

Psychotropic Medications and Lactation. Use of any psychotropic medication in a breastfeeding mother is done with consideration of risks and benefits. The risk of not treating the mother versus not breastfeeding the infant prompts providers to prescribe medications that reduce maternal symptoms without harming the infant. Concerns about many psychotropic drugs are related to the long-term use and potential effects on the infant (Hardy & Reichenbacker, 2019; Lawrence & Lawrence, 2016).

SSRIs are the most common treatment for postpartum depression; they are also prescribed for anxiety disorders. Research has shown that the majority of the SSRIs taken by breastfeeding mothers pass through the milk to the infant in small amounts and have minimal effects on the infant (Hardy & Reichenbacker, 2019). Paroxetine, sertraline, and nortriptyline provide less infant exposure than fluoxetine and citalopram. All breastfeeding mothers who take SSRIs should be taught to monitor their infants for signs of irritability, poor feeding, and alterations in sleep pattern (Sriraman et al., 2015) (see Clinical Reasoning Case Study: Medications for Perinatal Depression).

CLINICAL REASONING CASE STUDY

Medications for Perinatal Depression

Jenna, 31, gave birth to a 3400-g boy 4 weeks ago. She has been diagnosed with depression, and an SSRI (sertraline [Zoloft]) medication has been prescribed. Jenna is breastfeeding and has concerns about taking the medication.

Questions

1. Evidence—Is there sufficient evidence regarding the safety of psychotropic medications and lactation?
2. Assumptions—What assumptions can be made about the following?
   a. Timing of feeding and medication administration
   b. Risks of discontinuing medications while breastfeeding
3. What is the nursing priority in this situation?
4. Does the evidence objectively support your conclusion?

SSRI, Selective serotonin reuptake inhibitor.

Benzodiazepines, mood stabilizers, and antipsychotic medications are all used frequently in the treatment of postpartum psychiatric disorders despite the lack of research in this population. No long-term effects have been reported in exclusively breastfed infants whose mothers were taking benzodiazepines on a regular basis. The shorter-acting medications (alprazolam, lorazepam) are favoured over those with longer half-lives (clonazepam, diazepam) (Lawrence & Lawrence, 2016).

Mood-stabilizing medications are present in the breast milk of patients who take these drugs. Lithium has been the most extensively studied. Lithium has been linked to several serious adverse effects in breastfeeding infants, including hypotonia, hypothermia, cyanosis, and electrocardiogram abnormalities. Therefore, its use is not recommended in breastfeeding mothers. Valproic acid and carbamazepine are considered reasonably safe for use while breastfeeding, although careful monitoring for infant hepatotoxicity is recommended. The benefits of breastfeeding and the potential risks must be carefully considered before using lithium or other mood stabilizers.

In summary, all psychotropic medications studied to date are excreted in breast milk. The best psychotropic medications for breastfeeding patients are those with the greatest documentation of prior use, lower Hale risk category, few or no metabolites, and fewer adverse effects. The Hale risk category provides classification of medications used during lactation according to risk. The risk categories are L1 Safest, L2 Safer, L3 Moderately safe, L4 Possibly hazardous, and L5 Contraindicated.

When breastfeeding patients have emotional complications and need psychotropic medications, referral to a mental health care provider who specializes in postpartum disorders is preferred. The patient should be informed of the risks and benefits to themselves and their infant of the medications to be taken. Depressed patients will need the nurse to reinforce the importance of taking antidepressants as ordered. Because antidepressants usually do not exert any significant effect for approximately 2 weeks and usually do not reach full effect for 4 to 6 weeks, many patients discontinue taking the medication on their own. Patient and family teaching should reinforce the schedule for taking medications until therapeutic effects are present and for as long as prescribed by the health care provider.

Other Treatments for Perinatal Mood Disorders. Other treatments for PMD include hormone therapy (often combined with antidepressant medication), complementary and alternative health modalities (e.g., yoga, massage, relaxation techniques), ECT, and psychotherapy. ECT may be used for patients with depression who have not improved with antidepressant therapy. Psychotherapy in the form of group therapy or individual (interpersonal) therapy has been used with positive results alone and in conjunction with antidepressant therapy; however, more studies are needed to determine what types of professional support are most effective. Fatigue may be associated with PMD, and development of interventions targeting stabilization of sleep and circadian rhythms in the perinatal period may improve outcomes (Krawczak et al., 2016). Alternative therapies may be used alone but often are used with other treatments for PMD. Safety and efficacy studies of these alternative therapies are needed to ensure that care and advice are based on evidence.

Perinatal Depression in Male Partners. Often, postpartum patients are not alone in their experience of a mood disorder; partners may have depression or anxiety as well. The incidence is unclear, with reports varying from 10 to more than 25% (RNAO, 2018a). The best predictor of paternal perinatal depression (PPND) is having a partner with postpartum depression (Glasser & Lerner-Geva, 2019). Male partners who are underemployed, under financial stress, are older, and are

experiencing a difference between parenting expectations and reality and those who feel excluded from the maternal infant bond are at higher risk of postpartum depression (RNAO, 2018a). Men may not exhibit classic symptoms of PMD but are likely to display fatigue, frustration, anger, irritability, and somatic symptoms (RNAO, 2018a) (see Evidence-Informed Practice: Paternal Perinatal Depression).

Men are not routinely screened for perinatal depressive symptoms. There is no depression scale designed for this specific use. Some experts recommend using the EPDS in combination with the Gotland Male Depression Scale to identify men with signs of PPND (Habib, 2012).

When both the father and the mother are depressed, life can be very difficult. Routine tasks of caring for the newborn and maintaining a household can present significant challenges. Interaction with the infant can be affected, and there can be negative effects on parenting.

Nurses should include partners in discussions about postpartum depression, raising awareness that they can also suffer from depression, describing symptoms, and providing information about resources for help if the symptoms occur. During interactions with fathers, nurses can assess for signs of PPND, provide support and encouragement, and offer information about resources for further assessment and treatment (Letourneau et al., 2012; Stadtlander, 2015).

EVIDENCE-INFORMED PRACTICE

Paternal Perinatal Depression

Ask the Question

For new fathers, what are the risks and protective factors for depression? What are the best ways to screen for depression?

Search for the Evidence

Search Strategies: English-language research-based publications on depression, fathers, anxiety, and paternal, perinatal, peripartum, and postpartum depression

Databases Used: Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, and the professional website for ACOG

Critical Appraisal of the Evidence

When a mother develops perinatal depression, the evidence for poorer growth and cognitive and behavioural outcomes for their baby is indisputable. Much research continues our understanding of decreased maternal responsiveness to infant's cues. Because family dynamics extend beyond the mother–baby dyad, new research is investigating the implications of paternal depression for the family system (Freitas et al., 2016):

- Incidence of paternal depression (10%) is about half that of maternal depression (up to 20%), but about twice the male baseline rate of 5%.
- Experts from many fields reached structured consensus about defining paternal depression markers as low mood, negative thoughts, feeling inadequate, weight loss, sleep deprivation, and "masked" male depressive symptoms of irritability, isolation or withdrawal, substance use, cheating, or gambling.
- Risk factors for paternal depression include prior depression, poor social and relationship support, partner experiencing depression, and financial and work stress. Young paternal age, first child, and unrealistic expectations may also be risk factors.

Massoud, Hwang, and Wickberg (2016) surveyed 885 Swedish couples at 3 months postpartum with the Edinburgh Postnatal Depression Scale (EPDS), which is also validated for fathers, and found the following:

- Risk for depression doubled when the partner had depression, regardless which partner was the first to develop depression.
- Other risk factors included prior depression, lower education level, lack of support from their partner, sleep deprivation, work stress, or conflicts. High EPDS scores for fathers were more likely to represent general distress, worry, anxiety, or unhappiness than actual depression.
- Paternal depressive symptoms were associated with behavioural and relational issues in their offspring and increased conflict and violence in the home.

Apply the Evidence: Nursing Implications

Nurses who encounter new fathers, especially young and first-time fathers, in any setting should be alert to symptoms of distress and understand that depression may manifest differently in fathers than in mothers.

- Reaching out to fathers should be a routine part of family-based care, beginning at pregnancy or before. Assessment begins with questions about physical issues such as sleep quality and diet changes and proceeds sensitively to questions about relational and life distress. Universal screening with validated screening tools and psychosocial interviews are recommended (Registered Nurses' Association of Ontario [RNAO], 2018; Siu & US Preventive Services Task Force, 2016).
- Starting with prenatal visits and continuing with well-child visits, nurses who reach out and include fathers may be in the best position to screen for depression in both parents and refer for early intervention (Vismara et al., 2016).
- Discussing the transition to parenthood, life balance, and distress, and teaching about open communication, partner support, and self-care, especially adequate sleep, may be preventive for depression (RNAO, 2018).
- Fathers do not like to be labelled. To avoid stigma, the health care team can call it whatever he wants (Freitas et al., 2016).
- Spreading awareness of perinatal depression in society at large, and education for perinatal families in particular, can foster increased open communication and early identification of parents' issues. Advocating for strong health care team relationships with parents and supportive employer, community, and government policies can also help, especially with unexpected stressors such as the special needs of a baby.

LOSS AND GRIEF

Situational life crises can be superimposed on the experiences of childbearing. Examples may include infertility, premature labour or premature birth, a Caesarean birth, any perception of loss of control during the birthing experience, the birth of a boy when the parents wanted a girl or vice versa, the birth of a child with a disability, a maternal death, or fetal or newborn death (see Community Focus box). All of these situations have a common denominator: they are losses of what was hoped for, dreamed about, and planned.

COMMUNITY FOCUS

Community Resources for Loss and Grief

Investigate what resources and support groups exist in your community to assist parents who have experienced a maternal death; birth of a child with physical or intellectual challenges; a Caesarean birth if they hoped for a vaginal birth; or the death of a baby through miscarriage, stillbirth, or newborn death. Are resources available? Are there groups available for people who speak a language other than English? Are there enough of these resources to assist parents? How difficult was it for you to identify these resources? What could you do to make resources more known to bereaved parents and families?

These crises vary in degree, and every situation requires empathy, knowledge, and compassion from the health care provider. At the birth, the patient, partner, and family may be mourning instead of celebrating life.

Newborn deaths within the first month of life have plateaued in Canada, with a rate of 3.3 deaths per 1 000 live births in 2019, and 4.4 per 1 000 within the first year of life (Statistics Canada, 2021). The leading cause of death is prematurity. Infants may die in the early postpartum period from prematurity, birth defects, birth trauma, or other acute illnesses. Thus, parents can experience grief before or during the childbearing experience.

The focus of this section is to prepare the nurse to provide sensitive, supportive, and therapeutic interventions to parents and families experiencing perinatal loss in a variety of settings. An overview of the grief process is presented as a guide for assessing and understanding the responses of bereaved patients and their families. Guidelines for intervention are given, and specific intervention approaches are discussed.

Grief Responses

Grief is the process of recovering from a loss, and in that process individuals experience many emotional, cognitive, behavioural, and physical responses. Grief is a normal process; however, complicated or prolonged grief responses including anxiety and depression are three times higher for the perinatal population than for other bereaved populations (Lundroff et al., 2017). Parental grief responses occur in four overlapping phases. According to Wilke and Limbo (2012) there is an early period of acute distress, shock, and numbness, which is most intense for the first 2 weeks. The second phase, from the second week to the fourth month, is characterized by searching and yearning. The fifth through the ninth month comprise the third phase, defined as disorientation. The final phase, reorganization or resolution, may be reached in the tenth through the twenty-fourth month, when parents return to their usual level of functioning in society, although the pain associated with the death remains. The duration of grief varies with the individual, but there is general agreement that grief is a long-term process that can extend for months and years. With a very close relationship such as with one's baby, some aspects of grief never truly end.

Phase One: Shock and Numbness. The loss of a pregnancy or death of a newborn is an acute and distressing experience for families who planned for and expected a normal, healthy baby as the outcome. The loss encompasses a loss of their identity as parents and of their many dreams related to parenthood. The immediate reaction to news of a perinatal loss or newborn death is a period of acute distress. Parents generally are in a state of shock and numbness. They may feel a sense of unreality, loss of innocence, and powerlessness, as though they were in a bad dream or in a fog or trancelike state. Disbelief and denial can occur. Sadness, devastation, depression, and intense outbursts of emotion and crying are common. Individuals describe feeling stunned, having a short attention span, and having an inability to concentrate or make decisions. In contrast, lack of affect, euphoria, and calmness may occur and may reflect numbness, denial, or a personal way of coping with stress.

Much of the attention during the time of a loss is on the birthing parent. The response of partners may vary more than that of mothers and depends on the level of identification with the pregnancy. Partners may be profoundly affected and grieve deeply for a perinatal loss, and it is important that they are supported in their grief as well as the mother.

Partners are often distressed by the grief of the mother and may feel helpless in comforting them with the intense pain. Some partners may appear stoic and unemotional, to maintain the societal expectation that they be "strong" for the mother and other family members. Because many men do not easily share their feelings or ask for help, special efforts may be needed to help them acknowledge these feelings and realize that they, too, have a right to support from others in their pain.

During this time of acute distress, parents face the first task of grief: accepting the reality of the loss. The pregnancy has ended, or the baby has died, and their lives have changed. Although parents are often required to make many decisions, such as having an autopsy, naming the newborn, and making funeral arrangements, normal functioning is impeded and decisions are difficult to make. Grandparents, friends, clergy, or other relatives may be available to help the couple cope. However, it is important that the parents ultimately make the decisions that are right for them.

Phase Two: Searching and Yearning. The phase of intense grief encompasses many difficult emotions as the parents work through their pain and adjust to life without the wished-for child. In the early months after the loss, parents often experience feelings of loneliness, emptiness, and yearning. The mother may report that their arms ache to hold or nurse their baby and that they wake to the sound of a baby crying. Both parents may be preoccupied with thoughts about the wished-for child. Some parents cope with these feelings by avoiding memories and not talking about the baby, whereas others want to reminisce and discuss their loss over and over.

Deciding what to do about the nursery and baby clothes is particularly difficult during this period. Some parents may want the room taken down before they go home, whereas others want the room left intact until they have had time to grieve their loss. It is not unusual for a grandparent or other family member to want to rush home to take down the nursery, thinking that the parents would be spared additional grief. In fact, their actions might only complicate the grief if the parents were not involved in the decision. The bereaved parents must go through these types of experiences in their own time frame so that healing can take place.

During this phase of intense grief, guilt may emerge from the deep feelings of helplessness in not somehow preventing the pregnancy loss or the death of the newborn. Mothers are particularly vulnerable to feeling guilt because of their sense of responsibility for the well-being of the fetus and baby. With many perinatal losses, there is no clear cause of the event, leaving the patient to speculate about what they might have done or not done to bring about the loss. Guilt may be intense if the parent thinks they are being punished for some unrelated event, such as having had a prior induced abortion. Many patients describe feeling tortured by "self-blame" and they need repeated emotional reassurance that they are not at fault.

Other common responses during this phase are anger, resentment, bitterness, and irritability. Anger may be focused on the health care team who failed to save the pregnancy or newborn; toward a God who allowed the loss to occur; or toward family, friends, or peers when

they do not provide the support that the bereaved parents need and want. Some parents focus their resentment on parents who do not appreciate their children or neglect and abuse them. A sense of bitterness or generalized irritability rather than frank anger may be another response. Physical symptoms of grief may include fatigue, headaches, palpitations, and lack of strength.

During the grief process, fear and anxiety can occur as a profound worry that something else bad might happen to another pregnancy. Some parents, especially mothers, are almost obsessed with the desire to become pregnant again; others struggle with whether they can cope with the possibility of another loss.

Phase Three: Disorientation. Deep sadness and depression can arise when the parent has full awareness of the loss. This often occurs several months after a perinatal loss and can continue for some time. Sadness and depression can be accompanied by disorganization and difficulties with cognitive processing, memory, and organization. This, coupled with insomnia, social withdrawal, and lack of energy, can lead to behavioural changes, such as difficulty getting things done, an inability to concentrate, restlessness, confused thought processes, difficulty solving problems, and poor decision making. Disorganization, feelings of failure, and depression often cause difficulties in keeping up with work and family expectations. In addition, parents returning to work face issues such as handling well-meaning but painful comments or the silence of co-workers.

Physical symptoms of grief include fatigue, headaches, dizziness, and altered appetite and exhaustion. Parents are at risk for developing health conditions and chronic undefined feelings of illness. It may be difficult to sleep; appetite may be depressed or voracious. Lack of sleep and inadequate nutrition and fluids can complicate other grief responses.

Grief responses are very personal, ongoing, and difficult to handle. Some parents may suppress or deny their feelings because of perceived societal indifference toward pregnancy loss and infant death. On the surface, suppression of feelings may be more socially acceptable. However, denying the pain of grief may lead to eventual physical and emotional distress or illness. Although bereaved parents have many ups and downs for many months and even years after a child's death, few parents actually become mentally ill or commit suicide. Knowing that these feelings are normal and that others have had similar feelings can be helpful to them. The grief process during this phase is often difficult for partners. Some may continue to have difficulty sharing their feelings. A rift can occur if one parent, usually the mother, wants to talk about the loss and pain, and the other parent—often, but not always, the partner—withdraws. Other signs of difficulties include reliance on alcohol and drugs, extramarital affairs, prolonged hours at work, and overinvolvement in activities outside the home as an escape.

Phase Four: Reorganization and Resolution. Reorganization and resolution continue beyond 24 months for many parents (Wilke & Limbo, 2012). From the time of the pregnancy loss or newborn death, parents attempt to understand why this happened. This leads to a long and intense search for meaning. At first the "why" is focused on the cause of death, which is often never determined. Finding few good answers, parents next focus on "why me, why mine?" These questions can lead some parents into an existential search about the meaning of life and death. This search continues into the phase of reorganization and may lead to profound changes in the parents' view of the fragility of life.

Time helps to slowly ease the painful feelings of grief. Reorganization occurs when parents are better able to function at home and work, experience a return of self-esteem and confidence, can cope with new challenges, and have placed the loss in perspective. Reorganization begins to peak sometime after the first year, as parents begin to achieve the task of moving on with their lives as they feel renewed energy and a sense of release. Enjoying the simple pleasures of life without feeling guilty, nurturing self and others, developing new interests, and re-establishing relationships are all signs of moving on. For some families, another pregnancy and the birth of a subsequent child are important steps in moving on with their lives; however, the term *recovery* is used because the grief related to perinatal loss can continue to varying degrees throughout life.

Parents who have suffered a pregnancy loss or newborn death have shared that they will never forget the baby who died and they are not the same people as before the loss (Box 24.6). The term *bittersweet grief* refers to the grief response that occurs with reminders of the loss. This

BOX 24.6 I Am Strong

I am strong.

I am strong because at my 38 week OB appointment, I listened to a strong heartbeat and the doctor said everything was great.

I am strong because she told me I was 3 cm dilated and labour could begin at any time.

I am strong because I left the office, completely excited and happy and couldn't wait to be able to meet my new love shortly!

I am strong because the next day at 1130 pm labour and contractions began. They weren't very strong or close together yet at that point.

I am strong because the following morning at 9 am the contractions began to get closer together so I slipped into the tub to relax just a bit.

I am strong because by 930 am contractions became so strong and frequent, I got out of the tub and called the hospital triage.

I am strong because they told me to make my way over to the hospital.

I am strong because, although I was in an amazing amount of pain, and contractions were now just under 2 minutes apart, I was so excited. I had arrived at labour and delivery around 10 am.

I am strong because they took me into the triage room and began the routine.

I am strong because I immediately knew there was a problem when the nurse seemed to be having a hard time locating the heartbeat.

I am strong because she called in the doctor on call who tried to locate a heartbeat also.

I am strong because he gave us the news, news no parent should ever have to hear, "I'm so sorry, but the baby doesn't have a heartbeat."

I am strong because I cried.

I am strong because I then had to make a decision, to deliver my sleeping baby or proceed with a Caesarean section.

I am strong because I choose to continue with the labour and contractions, I wanted to deliver this baby. I am strong because I was planning a VBAC and I wanted it to be that way.

I am strong because I laboured for hours and at 6 pm I gave birth to my baby.

I am strong because I had a son, a beautiful baby boy, 3500 g.

I am strong because we named him Matteo.

I am strong because the nurse cleaned up my baby and brought him over to me. I am strong because I had the opportunity to hold, cuddle and kiss my sleeping, stillborn son.

Continued

BOX 24.6 I Am Strong—cont'd

I am strong because I cried.
I am strong because my husband and my daughter were able to hold their baby son and baby brother.
I am strong because my family was able to come and meet my new baby.
I am strong because I knew he wouldn't be coming home.
I am strong because at midnight I had to let him go.
I am strong because I cried.
I am strong because the next day I was discharged and was able to go home. I sobbed as my husband wheeled me out of the room and down the hall.
I am strong because I had to leave the hospital, after a day of labour, contractions, pains and sadness without my baby.
I am strong because I cried.
I am strong because we then had to go about and make arrangements for the baby boy I wasn't able to take home.
I am strong because we chose a spot for him among other sleeping babies, he could sleep with them, under a large green tree.
I am strong because I chose a cozy little pajama with elephants for my baby to sleep in and a soft warm blanket for him to snuggle in.
I am strong because I cried.
I am strong because one week later, my husband, daughter, sleeping baby and myself, were allowed to be in a room together for one last time.
I am strong because this is where I held his tiny hand in my fingers, I am strong because I was able to kiss his tiny nose, his perfect lips. I am strong because I spoke to him softly.
I am strong because this is where we had to say goodbye to baby Matteo.
I am strong because I cried.
I am strong because we proceeded to the cemetery where we had a simple, sweet ceremony for our baby.
I am strong because we all cried.
I am strong because I watched as he was buried. I am strong because my sweet baby, my son was buried.
I am strong because I cried. I cried. We all cried.
I am strong because I have the hope that we will see our baby Matteo again, soon.
I am strong because I believe he now won't have to live in a world of sin, pain and suffering, and I am strong because I know I will hold and cuddle him again, and he will be safe in my arms.
I am strong because every day I think about him.
I am strong because every day I want him back.
I am strong because I am a mommy of two beautiful children. I am strong because I am only currently a parent to one of them.
I am strong because of my daughter, although only 3 years old, she's strong too.
I am strong because, although every day I may be sad, I am also happy.
I am strong because I am able to cry and I am strong because I am able to smile.
I am strong because of all the blessings I have been given, including my beautiful sleeping baby.

(Used with permission of Author.)
VBAC, Vaginal birth after Caesarean.

typically happens on birthdays, death days, and anniversaries; at school events; during changes in the seasons; and during the time of the year when the loss occurred. Grief feelings also can be triggered during subsequent pregnancies and after birth.

Resumption of the couple's sexual relationship is an important aspect of recovery but can be very complicated. Many parents are comforted by the belief that their babies were conceived in love, lived in love, and died in love. Their love and intimacy created this child, and parents may believe that they may never experience joy and closeness again. Some couples may have an increased need for sexual activity in an attempt for closeness and healing, whereas others have a decreased desire for sexual intimacy.

Sexuality also brings with it decisions about a future pregnancy. Some couples are eager to have another child, although this child cannot replace the one who died and the grief will continue despite another pregnancy. Other parents have a deep fear of experiencing the pain of loss again, which can make the resumption of sexual activity difficult. These ambivalent feelings are normal, and couples can find themselves moving back and forth between the emotions of exhilaration and fear. The excitement that many other parents experience with a pregnancy is very different for previously bereaved parents. For some, this emotional distress can affect attachment to the new baby.

Couples often mark the progress of the pregnancy in terms of fetal development, waiting anxiously until the number of weeks of the previous loss is passed. In some cases, the fear of repeated loss, especially after a stillbirth, is so great that induction of labour may be considered if the fetus is mature. Support groups are important in helping persons through pregnancies after loss of a fetus or newborn.

Some individuals experience complicated or prolonged grief in the form of depression. Unexplained death has been identified as a causal factor in complicated grief (Garstang et al., 2016). As well, it has been identified that patients who have other children show fewer cases of prolonged grief (Lundroff et al., 2017).

Family Aspects of Grief

Grandparents and Siblings. It is extremely important for the nurse taking care of patients who have experienced a loss to keep in mind that they have an entire family to care for, including grandparents and siblings. Grandparents have hopes and dreams for a grandchild; these have been shattered. The grief of grandparents is often complicated by the fact that they are experiencing intense emotional pain by witnessing and feeling the immense grief of their own child. It is extremely difficult to watch their son or daughter experience unimaginable emotional trauma, with very few ways to comfort them and end their pain. As a result, the grief response may be complicated or delayed for grandparents. On occasion, some grandparents experience immense survivor guilt because they are alive and their grandchild has died.

The siblings of the expected baby also experience a profound loss. Most children have been prepared for having another child in the family, once the pregnancy is confirmed. These children's ages and stages of development must be considered in understanding how they view the event and experience the loss.

Older siblings need to be included in grieving rituals, to the extent that the parents and the child feel comfortable. They may need to see

the baby to realize the loss. Nurses need to have a basic understanding of how children view death and grief in order to reach out to siblings in an appropriate and sensitive manner. Nurses also need to help parents recognize and be sensitive to the grief of siblings, include them in family rituals, and keep the baby alive in the family memory.

Nursing Care

Nursing care of parents experiencing a perinatal loss begins the first time they are faced with the potential loss of their pregnancy or death of their newborn. Assessment is as important for families experiencing a miscarriage or ectopic pregnancy as it is for those experiencing stillbirth or newborn loss. Supportive interventions are important at the time of the loss and after the parents have returned home.

Parents often cannot recall details of their experiences at the time of the child's death, but they may recall vividly a minor event that was perceived as particularly painful or particularly helpful. The interventions provided below are general ideas about what may be helpful to parents. However, care must be individualized for each parent and family. Cultural and spiritual beliefs and practices of individual parents and families must also be considered.

Nurses and organizations are encouraged to facilitate perinatal bereavement training for all involved in perinatal loss (see Additional Resources at the end of the chapter). Nurses may experience compassion fatigue and are encouraged to seek assistance in the form of debriefs, support from colleagues, and seeking professional guidance when needed.

Communicating and Caring Techniques. Parents and extended families look to the interprofessional team for support and understanding during the time of loss. Therapeutic communication and counselling techniques help the mother, partners, and other family members express their feelings and emotions, understand their responses to the loss, and make decisions.

The nurse should listen patiently while people tell their story of loss and grief. It may be necessary to ask questions that help people talk about their grief and the experiences surrounding the loss. However, grief responses in the initial days of crisis make it difficult for individuals to concentrate on what is being asked, think about what a question means, and respond to a question. The use of silence often gives the bereaved person the opportunity to collect their thoughts and respond to questions. The nurse should resist the temptation to give advice or use clichés in offering support.

Nurses need to become comfortable with their own feelings of grief and loss to effectively support and care for the bereaved. It is appropriate to express feelings with the bereaved families and share the moment with them. The nurse might use some of the lines in Box 24.7 in helping the family share and express their grief.

Helping Families Actualize the Loss. When a loss or death occurs, the nurse should be sure that parents have been honestly told about the situation by their primary health care provider or others on the health care team. It is important for their nurse to be with the parents during this time. With early pregnancy loss, it is recommended that the term *miscarriage* be used consistently. With newborn death, caregivers should use the words "dead" and "died," rather than "lost" or "gone" to assist the bereaved in accepting this reality. Encouraging the family to choose a name helps make the baby a member of their family, so that the baby can be remembered in a special way.

BOX 24.7 What to Say and What Not to Say to Bereaved Parents

What to Say

"I'm sad for you."
"How are you doing with all of this?"
"This must be hard for you."
"What can I do for you?"
"I'm sorry."
"I'm here, and I want to listen."

What Not to Say

"God had a purpose for her."
"Be thankful you have another child."
"The living must go on."
"I know how you feel."
"It's God's will."
"You have to keep on going for her sake."
"You're young; you can have others."
"We'll see you back here next year, and you'll be happier."
"Now you have an angel in heaven."
"This happened for the best."
"Better for this to happen now, before you knew the baby."
"There was something wrong with the baby anyway."

! NURSING ALERT

A caution about naming is important to note. Naming is an individual decision that should never be imposed on parents. Beliefs and needs vary widely across individuals, cultures, and religions. Cultural taboos and rules in some religious faiths prohibit the naming of a newborn who has died.

On the basis of vast clinical experience with parents, many professionals believe that seeing the dead fetus or newborn helps parents face the reality of the loss, reduces painful fantasies, and offers an opportunity for continued parenting. Many parents relish the memory of parenting their deceased baby by holding, bathing, and dressing the child. However, parents should never be made to feel that they should see or hold their newborn when this is something they do not want to do. It is good policy for the nurse to first tell them about this option and then give them time to think about it. The nurse can ask a question such as "Some parents have found it helpful to see their baby. Would you like time to consider this?" Later the nurse can return and ask each parent individually what each has decided. Because the need or willingness to see the newborn also may vary between the parents, it is important to determine what each parent really wants.

In preparation for the visit with the baby, parents appreciate explanations about what to expect, so providing a description of how their baby looks is important. For example, babies may have red, peeling skin like a bad sunburn, dark discoloration similar to bruises, moulding of the head that makes the head look soft and swollen, or birth defects. The nurse should make the baby look as normal as possible and remember that parents see their baby with different eyes from those of health care providers. If the baby has been in the morgue, they can be placed

underneath a warmer for 20 to 30 minutes and wrapped in a warm blanket before being brought to the parents. The use of powder and lotion stimulates the parents' senses and can help provide pleasant memories of their baby.

When bringing the newborn to the parents, it is important to treat the baby as one would a live baby. Holding the baby close, touching a hand or cheek, using the baby's name, and talking with the parents about the special features of their baby convey that it is all right for them to do likewise. If a baby has a congenital anomaly, the nurse can focus on aspects of the baby that do not have an abnormality. Nurses can help parents explore the baby's body as they desire. Parents often seek to identify family resemblance. A good question might be: "Who in your family does your baby resemble?"

Some families may like to have the opportunity to bathe and dress their baby. Although the skin may be fragile, parents can still apply lotion with cotton balls; sprinkle powder; tie ribbons; fasten the diaper; and place amulets, medallions, rosaries, or special toys or mementos in their baby's hands or next to their baby. Parents may want to perform other parenting activities, such as combing the baby's hair, dressing the baby in a special outfit, wrapping the baby in a blanket, or placing the baby in a crib.

Parents need to be offered time alone with their baby if they wish. They also need to know when the nurse will return and how to call if they should need anything. If at all possible, the family should be placed in a private room, and the room should have a rocking chair for the parents to sit in when holding their baby. This offers the mother and partner special time together with their baby and with other family members (Figure 24.5). Marking the door to the room with a special card can be helpful in reminding staff that this family has experienced a loss. Many hospitals use a specific picture (often a butterfly) to indicate that the family in the room has experienced a loss. This allows all staff in the hospital to be aware of the needs of the patient.

Sensitivity to parental needs in actualizing the loss and coping with the reality of the death is essential for their healing. Grandparents should be offered the same opportunities to hold, rock, swaddle, and love their grandchildren so that their grief is started in a healthy way.

Helping Parents With Decision Making. At a time when parents are experiencing the great distress of a perinatal loss, and especially if the loss was of a newborn, these parents have many decisions to make. Mothers, partners, and extended families look to the medical and nursing staff for guidance in knowing what decisions they must and can make and in understanding the options related to those decisions. It is a primary responsibility of the nurse to help them and to advocate for them, because decisions made during the time of their loss will provide memories for a lifetime.

One decision might be related to conducting an autopsy. An autopsy can be very important in answering the question "why" if there is a chance that the cause of death can be determined. This information can be helpful in processing grief and perhaps in preventing another loss. Some parents may believe that their baby has been through enough and prefer not to have further information about the cause of death. Some religions prohibit autopsy or limit the choice to instances in which autopsy may help prevent another loss. Parents may need time to make this decision. There is no need to rush them unless there was evidence of contagious disease or maternal infection at the time of death.

Another important decision relates to spiritual rituals that may be helpful and important to parents. Support from clergy is an option that should be offered to all parents. Parents may wish to have their own pastor, priest, rabbi, or spiritual leader contacted, or they may wish to see the hospital's chaplain. They may choose to do neither. Clergy persons may offer the parents the opportunity for baptism, when appropriate. Other rituals that may be important include a blessing, a naming ceremony, anointing, ritual of the sick, memorial service, or prayer.

Fig. 24.5 Laura's family members say a special goodbye. (Courtesy Amy and Ken Turner, Cary, NC.)

One of the major decisions that parents must make is disposition of the body. Parents should be given information about the choices for the final disposition of their baby, regardless of gestational age. However, nurses must be aware of cultural and spiritual beliefs that may dictate the choices of parents, as well as the cost of burial, alternatives to burial, and provincial laws related to burial. In Canada, if a fetus is greater than or equal to 20 weeks of gestational age or is born alive, it is the parents' responsibility to make the final arrangements for their baby, although some parents may want a burial for a fetus that is younger than 20 weeks and this should be facilitated.

LEGAL TIP: Laws Regarding Live Birth

Laws in all provinces govern what constitutes a live birth. In most provinces, a live birth is considered to be any products of conception expelled that show any signs of life. Signs of life are considered to be any muscle irritability, respiratory effort, or heart rate, regardless of gestational age. All nurses should be knowledgeable about the provincial laws regarding what constitutes a live birth and the forms that must be completed and filed in the case of fetal death, stillbirth, or newborn death.

In making final arrangements for their baby, parents may want a special service. They may choose to have a service in the hospital chapel, visitation at a funeral home or their own home, a funeral service, or a graveside service. Parents can make any of these services as special, personal, and memorable as they like.

The timing for actions such as naming the baby, seeing and holding the baby, creating mementos (e.g., pictures and footprint moulds), disposition of the body, and funeral arrangements should never be rushed. In some cases, the mother may be discharged home before these decisions are made. Then the family can think about them in the comfort of their home and contact the hospital in the following days to give their answers.

Helping Families to Acknowledge and Express Feelings. One of the most important goals of the nurse is to validate the experience and feelings of the parents, by encouraging them to tell their stories and by listening with care. Bereaved parents have many questions surrounding the event of their loss, and some questions can leave them feeling guilty. This is particularly true for mothers. Such questions include "What did I do?" "What caused this to happen?" "What do you think I should have, could have done?" Part of the grief process for bereaved parents is figuring out what happened, their role in the loss, why it happened to them, and why it happened to their baby. The nurse should recognize that these questions must be answered by the bereaved themselves; it is part of their healing. For example, a bereaved mother might ask, "Do you think that this was caused by painting the baby's room?" An appropriate response might be, "I understand you need to find an answer for why your baby died, but we really don't know why she died. What are some of the other things you have been thinking about?" Trying to give bereaved parents answers when there are no clear answers or trying to squelch their guilt feelings by telling them they should not feel guilty does not help them process their grief. In reality, many times there are no definite answers to the question of why this terrible thing has happened to them. However, factual information such as data about the frequency of miscarriages in pregnant patients or the fact that there usually is no clear cause of a stillbirth can be helpful.

Feelings of anger, guilt, and sadness can occur immediately but often become more problematic in the early days and months after a loss. When a bereaved person expresses feelings of anger, it can be helpful to identify the feeling by simply saying, "You sound angry," or "You look angry." The nurse's willingness to sit down and listen to these surface feelings of anger can help the bereaved person move past them into the underlying feelings of powerlessness and helplessness in not being able to control the many aspects of the situation.

Normalizing the Grief Process and Facilitating Positive Coping. While helping parents share their feelings of pain, it is critical to help them understand their grief responses and know that they are not alone in these painful responses. Most parents are not prepared for the raw feelings they experience or the fact that these painful, complex feelings and related behavioural reactions continue for many weeks or months. Thus, reassuring them of the normality of their responses and preparing them for the length of their grief is important.

The nurse can help the parent be prepared for the emptiness, loneliness, and yearning; for the feelings of helplessness that can lead to anger, guilt, and fear; and for the disorganization, difficulty making decisions, and sadness and depression that are part of the grief process.

In the initial days after a loss, other useful nursing strategies include follow-up phone calls, referrals to a perinatal grief support group, or providing books, pamphlets, videos, or websites intended for helping parents who have experienced a perinatal loss (see Additional Resources at the end of the chapter).

To help minimize relationship issues that can occur in grieving couples, it is particularly important to help them understand that they may respond and grieve in very different ways. This is called *incongruent grief* (Wilke & Limbo, 2012). For example, one partner may feel depressed and have no energy and be unable to work, while the other partner may cope by going back to work and working long hours. The differences in grieving can lead to serious relationship issues and be a risk factor for complicated bereavement. Remind the couple of the importance of being understanding and patient with each other and seeking professional help as needed.

Nurses can reinforce positive coping efforts and encourage attempts to resume normal activities; reinforce and encourage positive ways to hold onto memories of the pregnancy or baby while letting go; and help the parents organize a plan for daily activities, if needed.

Meeting the Physical Needs of the Bereaved Postpartum Patient. Coping with loss and grief after childbirth can be an overwhelming experience for the patient and their family. One particularly difficult aspect of the loss is the sound of crying babies and the happiness of other families on the unit who have given birth to healthy newborns. The mother should be given the opportunity to decide if they want to remain on the maternity unit or be moved to another hospital unit. They also should be helped to understand the pluses and minuses of each choice. Postpartum care and grief support may not be as good on another hospital unit where the staff are not experienced in postpartum and bereavement care.

The physical needs of a bereaved mother are the same as those of any patient who has given birth. The cruel reality for many bereaved mothers is that their milk can come in with no baby to feed, their afterpains remind them of their emptiness, and gas pains feel as though a fetus is still moving inside. The nurse should ensure that the mother receives appropriate medications to reduce these physical symptoms. Adequate rest, diet, and fluids must be offered to replenish their physical strength. Mothers need postpartum care instructions on discharge.

Creating Memories for Families to Take Home. Parents may want tangible mementos of their baby to help them actualize the loss. Some may want to bring in a previously purchased baby book. Special memory books, cards, and information on grief and mourning are often available to give to parents (Figure 24.6).

The nurse can provide information about the baby's weight, length, and head circumference to the family. Footprints and handprints can be taken and placed with the other information on a special card or in a memory or baby book. If the print does not turn out, the nurse can trace around the baby's hands and feet, although this distorts the actual size. Moulds can also be used to make an imprint of the baby's hand or foot.

Parents often appreciate articles that were in contact with or used in caring for the baby. This might include the tape measure used to measure the baby, baby lotions, combs, clothing, hats, blankets, crib cards,

Fig. 24.6 Memory kit assembled at John C. Lincoln Hospital, Phoenix, AZ. Memory kits may include pictures of the newborn, clothing, death certificate, footprints, ID bands, and ultrasound picture. (Courtesy Julie Perry Nelson.)

and identification bands. The identification band helps the parents remember the size of the baby and personalizes the mementos. The nurse should ask parents if they wish to have these articles. A lock of hair may be another important keepsake. Parents must be asked for permission before cutting a lock of hair, which can be removed from the nape of the neck where it is not noticeable.

For some parents, pictures are the most important memento. Photographs are generally taken whenever there is an identifiable baby and when it is culturally acceptable to the family to take photos. It does not matter how tiny the baby is, what the baby looks like, or how long the baby has been dead. Pictures should include close-ups of the baby's face, hands, and feet and photos of the baby clothed and wrapped in a blanket and unclothed. If there are any congenital anomalies, close-ups of these also should be taken. Flowers, blocks, stuffed animals, or toys can be placed in the background to make the picture more special. Parents may want their pictures taken holding the baby. Keeping a camera nearby and taking pictures when parents are spending special time with their baby can provide special memories. Some parents may have their own camera, video camera, or smartphone and ask the nurse to record them as they bathe, dress, hold, or diaper their baby. An organization called Now I Lay Me Down to Sleep provides a professional photographer to take pictures for families at no cost. Their website can be consulted to determine if there is a photographer within the geographical location.

Documentation. Many hospitals have a checklist that is used in providing care, mobilizing members of the interprofessional health care team, communicating options that the family has chosen, and keeping track of all the details in meeting the needs of bereaved parents. Documentation in the nursing notes of primary concerns, grief responses, health teaching, health care advice, and referrals of the mother or any other family members is essential to ensure continuity and consistency of care.

Providing Sensitive Care at and After Discharge. Leaving the hospital can be a devastating experience for the patient who has had a pregnancy loss, as not carrying a baby in their arms is a very empty and painful experience. Giving the mother a special flower to carry in her arms can be a thoughtful gesture.

The grief of the mother and their family does not end with discharge; it really begins once they return home, attend the funeral, and start to live their lives without their baby. There are numerous models for providing follow-up care to parents after discharge. Such programs include hospital-based bereavement teams who provide support during hospitalization and follow-up contacts and memorial services.

Phone calls from hospital staff after a loss may be helpful to some parents; however, it must be determined which parents do not want them. Follow-up calls let the parents know that someone still thinks and cares about them. The calls are made at predictably difficult times, such as the first week at home, 1 month to 6 weeks later, 4 to 6 months after the loss, and at the anniversary of the death. Families who have experienced a miscarriage, ectopic pregnancy, or death of a preterm baby may appreciate a phone call on the estimated due date. Such calls provide an opportunity for parents to ask questions, share their feelings, seek advice, and receive information to help them process their grief.

A grief conference can be planned when parents return for an appointment with their doctor, nurses, and other health care providers. At the conference, the loss or death of the baby is discussed in detail, parents are given information about the baby's autopsy report and genetic studies, and they have the opportunity to ask questions that have arisen since their baby's death. This is an important time to help parents understand the cause of the loss or accept the fact that the cause will forever be unknown. This meeting also gives health care providers the opportunity to assess how the family is coping with their loss and to offer additional information and education on grief.

Some parents are very interested in finding a perinatal or parent grief support group. Talking with others who have been through similar experiences, sharing memories of the pregnancy and the baby, and gaining an understanding of the normality of the grief process generally have been found to be supportive. Over time, it may be the only place where bereaved parents can talk about the wished-for child and their grief. However, not all parents find such groups helpful.

MATERNAL DEATH

Maternal death can be caused by a variety of complications, including embolism, hypertension, hemorrhage, infection, and cardiomyopathy. In many cases, the death of a mother is sudden and unexpected. Any instance of maternal death is tragic for the family as well as for the nurses and other health professionals who were involved in her care. In Canada it is rare for a patient to die in childbirth; in 2018 the maternal death rate was 8.3 deaths per 100 000 (Statistics Canada, 2019a).

When a patient dies of a complication related to childbearing, the partner and extended family are faced with mourning the death of a partner and mother. The loss and grief are greatly compounded when there is also the death of a fetus or newborn. When the newborn survives, the partner is faced with parenting a baby without a surviving mother. The responsibilities of newborn care can be overwhelming during this time of intense loss and grief.

Because most maternal deaths are unexpected, the grief that follows a maternal death is sudden. This differs from anticipatory grief in which the loss is expected, such as with cancer. The shock and disbelief associated with unplanned grief can be engulfing and debilitating, overwhelming the normal coping abilities and creating difficulties with everyday functioning and decision making.

Nurses and other health care providers working with families who experience maternal loss need to consider the context and the implications of the maternal death for the remaining family members. Young parents may never have experienced a significant personal loss or

tragedy; in many cases, their parents and grandparents are still living. Cultural beliefs and customs surrounding death can influence a family's response to maternal death. The grief response of each family member will vary; grief is an individual response, and the grieving process does not always proceed in a predictable manner.

Families who experience maternal loss are at risk for developing complicated bereavement and altered parenting of the surviving newborn and other children in the family. A referral to social services to help the family mobilize support systems and for counselling can help prevent potential difficulties before they develop and can be beneficial not only at the time of the loss but also in the future. Follow-up care for grieving families is essential as they progress through the stages of grief and adjust to life without the mother.

The emotional toll that a maternal death can take on the nursing and medical staff must also be addressed. Guilt, anger, fear, sadness, and depression are all common responses to a maternal death. The staff may want to participate in a debriefing session in which they can review the situation surrounding the events, their participation in caring for the mother, and their response to the death. Attending memorial or funeral services may benefit staff and family. Follow-up conferences with a social worker or grief counsellor can help staff members work through their grief.

KEY POINTS

- PPH is the most common and most serious type of excessive obstetrical blood loss.
- The etiology of PPH is related to one of the following categories: tone, tissue, trauma, and thrombin.
- Hemorrhagic (hypovolemic) shock is an emergency situation in which the perfusion of body organs may become severely compromised and death may ensue.
- Postpartum infection is a major cause of maternal morbidity and mortality throughout the world.
- Postpartum UTIs are common during the postpartum period.
- Breast infection affects about 1% of patients soon after childbirth.
- Perinatal mood disorders (PMDs) account for most mental health disorders in the postpartum period.
- Suicidal thoughts or attempts are among the most serious symptoms of postpartum psychosis.
- Treatment of PMD requires a combination of medication, education, supportive measures, and psychotherapy.
- Antidepressant medications are the usual treatment for PMD; however, specific precautions are needed for breastfeeding patients.
- An understanding of grief responses and the bereavement process is fundamental in implementation of the nursing process.
- Therapeutic communication and counselling techniques can help families identify their feelings and feel comfortable in expressing their grief.
- Follow-up after discharge is an essential component to providing care to families who have experienced a loss.
- Nurses need to be aware of their own feelings of grief and loss to provide a nonjudgemental environment of care and support for bereaved families.

Physiological Adaptations of the Newborn

Jennifer Marandola

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the physiological adaptations the newborn must make during the period of transition from intrauterine to extrauterine environment.
2. Describe the physiological and behavioural adaptations that are characteristic of the newborn during the transition period.
3. Explain the mechanisms of thermoregulation in the newborn and the potential consequences of hypothermia and hyperthermia.
4. Discuss the sensory and perceptual function of the newborn.
5. Identify signs that the newborn is at risk related to issues with each body system.

The newborn period includes the time from birth through day 28 of life. During this time, the newborn must make many physiological and behavioural adaptations to extrauterine life. Tasks of physiological adjustment are those that involve (1) establishing and maintaining respirations; (2) adjusting to circulatory changes; (3) regulating temperature; (4) ingesting, retaining, and digesting nutrients; (5) eliminating waste; and (6) regulating weight. Behavioural tasks include (1) establishing a regulated behavioural tempo independent of the mother, which involves self-regulating arousal, self-monitoring changes in state, and patterning sleep; (2) processing, storing, and organizing multiple stimuli; and (3) establishing a relationship with caregivers and the environment. The term newborn usually makes these adjustments with little or no difficulty. This chapter describes the physiological and behavioural adaptations required by the newborn for transition to extrauterine life.

TRANSITION TO EXTRAUTERINE LIFE

The major adaptations associated with transition from intrauterine to extrauterine life occur during the first 6 to 8 hours after birth. The predictable series of events during transition are mediated by the sympathetic nervous system and result in changes that involve heart rate, respirations, temperature, and gastrointestinal function. This transition period represents a time of vulnerability for the newborn and warrants careful observation by nurses. To detect disorders in adaptation soon after birth, nurses must be aware of normal features of the transition period.

In their classic work on newborn adaptation to extrauterine life, Desmond et al. (1966) proposed three stages, termed the *transition period*. The stages are still considered valid today.

The first phase of the transition period lasts up to 30 minutes after birth and is called the *first period of reactivity*. The newborn's heart rate increases rapidly to 160 to 180 beats per minute (bpm) but gradually falls by 30 minutes of age to a baseline rate between 100 and 160 bpm. Respirations may be irregular, with variation in the rate between 60 and 80 breaths/min. Fine crackles may be present on **auscultation**; audible grunting, nasal flaring, and retractions of the chest may also be noted, but these should resolve within the first hour of birth. The newborn is alert and may have spontaneous startles, tremors, crying, and movement of the head from side to side. Bowel sounds are audible, and meconium may be passed.

After the first period of reactivity, the newborn either sleeps or has a marked decrease in motor activity. This *period of decreased responsiveness* usually lasts from 60 to 100 minutes. During this time the newborn is pink and respirations may be rapid and shallow (up to 60 breaths/min) but not laboured. Bowel sounds are audible, and peristaltic waves may be noted over the rounded abdomen.

The *second period of reactivity* occurs roughly between 2 and 8 hours after birth and lasts from 10 minutes to several hours. Brief periods of tachycardia and tachypnea occur, associated with increased muscle tone, skin colour changes, and mucus production. Meconium is commonly passed during this phase. Most healthy newborns experience this transition regardless of type of birth. Physiological immaturity prevents this in very preterm newborns.

PHYSIOLOGICAL ADJUSTMENTS

Respiratory System

When the umbilical cord is clamped, the newborn undergoes rapid and complex physiological changes. The most critical and immediate adjustment is the establishment of respirations. Most newborns breathe spontaneously after birth and are able to maintain adequate

oxygenation. Preterm infants often encounter respiratory difficulties related to immaturity of the lungs and gestational age.

Initiation of Breathing. During intrauterine life oxygenation of the fetus occurs through transplacental gas exchange. However, at birth the lungs must be established as the site of gas exchange. In utero, fetal blood was shunted away from the lungs, but when birth occurs the pulmonary vasculature must be fully perfused for this purpose. Clamping the umbilical cord causes a rise in blood pressure (BP), which increases circulation and lung perfusion.

It has been recognized that there is no single trigger for newborn respiratory function. The initiation of respirations in the newborn is the result of a combination of chemical, mechanical, thermal, and sensory factors (Blackburn, 2018).

Chemical factors. The activation of chemoreceptors in the carotid arteries and aorta results from the relative state of hypoxia associated with labour. With each labour contraction there is a temporary decrease in uterine blood flow and transplacental gas exchange, resulting in transient fetal hypoxia and hypercarbia. Although the fetus is able to recover between contractions, there appears to be a cumulative effect that results in progressive decline in P_{O_2}, increased P_{CO_2}, and lowered blood pH. Decreased levels of oxygen and increased levels of carbon dioxide are involved in initiating newborn breathing by stimulating the respiratory centre in the medulla. Another chemical factor may also play a role: it is thought that, as a result of clamping the cord, there is a drop in levels of a prostaglandin that can inhibit respirations.

Mechanical factors. Respirations in the newborn can be stimulated by changes in intrathoracic pressure resulting from compression of the chest during vaginal birth. As the fetus passes through the birth canal, the chest is compressed. With birth this pressure on the chest is released, and the negative intrathoracic pressure helps draw air into the lungs. Crying increases the distribution of air in the lungs and promotes expansion of the alveoli. The positive pressure created by crying helps to keep the alveoli open.

Thermal factors. With birth the newborn enters the extrauterine environment, in which the temperature is significantly lower. Exposure to the profound change in environmental temperature stimulates receptors in the skin, resulting in stimulation of the respiratory centre in the medulla. Cold stress may be important for initializing breathing, but prolonged exposure should be avoided.

Sensory factors. Sensory stimulation occurs in a variety of ways with birth, such as in handling or drying the newborn. The lights, sounds, and smells of the new environment can also be involved in stimulation of the respiratory centre. Pain associated with birth can also be a factor.

At term the lungs hold approximately 20 mL of fluid per kilogram. Air must be substituted for the fluid that filled the fetal respiratory tract. Previously it had been thought that the thoracic squeeze occurring during normal vaginal birth resulted in significant clearance of lung fluid, but now it appears that this event plays a minor role. In the days preceding labour there is reduced production of fetal lung fluid and concomitant decreased alveolar fluid volume. Shortly before the onset of labour there is a catecholamine surge that appears to promote fluid clearance from the lungs, which continues during labour. The movement of lung fluid from the air spaces takes place through active transport into the interstitium, with drainage occurring through the pulmonary circulation and lymphatic system. Retention of lung fluid can interfere with the newborn's ability to maintain adequate oxygenation, especially if other factors (e.g., meconium aspiration, congenital diaphragmatic hernia, esophageal atresia with fistula, choanal atresia, congenital cardiac defect, immature alveoli) that compromise respirations are present. Infants born by Caesarean birth when labour did not occur before birth can experience some lung fluid retention, although it typically clears without deleterious effects on the newborn. These newborns are also more likely to develop **transient tachypnea of the newborn (TTNB)** caused by the lower levels of catecholamines (Fraser, 2015).

The alveoli of the term newborn's lungs are lined with two types of alveolar epithelium, named alveolar type I and type II cells. Type I alveolar cells comprise approximately 95% of the alveolar surface, with type II alveolar cells making up the remaining 5%. The type II cells make and produce surfactant, a group of phospholipids that reduce the alveolar surface tension. Subsequently, with lower surface tension the pressure required to keep the alveoli open with inspiration is reduced, which prevents total alveolar collapse on exhalation, thereby maintaining alveolar stability. The decreased surface tension results in increased lung compliance, helping to establish the functional residual capacity of the lungs (Blackburn, 2018). With absent or decreased surfactant, more pressure must be generated for inspiration, which can soon tire or exhaust preterm or sick term newborns.

Breathing movements that began in utero as intermittent become continuous after birth, although the mechanism for this is not well understood. Once respirations are established, breaths are shallow and irregular, ranging from 30 to 60 breaths/min, with periods of breathing that include pauses in respirations lasting less than 20 seconds. These episodes of periodic breathing occur most often during the active (rapid eye movement [REM]) sleep cycle and decrease in frequency and duration with age. Apneic periods longer than 20 seconds indicate a pathological process and should be evaluated.

! NURSING ALERT

Newborns are by preference nose breathers. The reflex response to nasal obstruction is to open the mouth to maintain an airway. This response is not present in most newborns until 3 weeks after birth; therefore, cyanosis or asphyxia can occur with nasal blockage or stenosis and requires immediate intervention to support adequate ventilation and oxygenation.

In most newborns auscultation of the chest reveals loud, clear breath sounds that seem very near because there is very little chest tissue. Breath sounds should be clear and equal bilaterally. The ribs of the newborn articulate with the spine at a horizontal rather than a downward slope; consequently, the rib cage cannot expand with inspiration as readily as that of an adult. Because newborn respiratory function is largely a matter of diaphragmatic contraction, abdominal breathing is characteristic of newborns. The newborn's chest and abdomen rise simultaneously with inspiration. Characteristics of the respiratory system of the newborn and the effects of these characteristics on respiratory function are listed in Table 25.1.

Signs of Respiratory Distress. Signs of respiratory distress may include nasal flaring, intercostal or subcostal retractions (i.e., drawing in of tissue between the ribs, or below the rib cage), or grunting with respirations. Suprasternal or subclavicular retractions with stridor or gasping most often represent an upper airway obstruction. Seesaw or paradoxical respirations (exaggerated rise in abdomen, with respiration, as chest falls) instead of abdominal respirations are abnormal and should be reported. A respiratory rate less than 30 or greater than 60 breaths/min with the newborn at rest must be carefully evaluated. The respiratory rate can be negatively influenced (slowed, depressed, or absent) by analgesics or anaesthetics administered to the mother during birth. Apneic episodes can be related to events such as rapid increase in body temperature, hypothermia, hypoglycemia, or sepsis that require thorough evaluation. Tachypnea can result from

TABLE 25.1 Characteristics of the Respiratory System of the Newborn

Characteristic	Effect on Function
Immature alveoli; decreased size and number of alveoli	Risk of respiratory insufficiency, inadequate oxygenation and ventilation
Thicker alveolar wall; decreased alveolar surface area	Less efficient gas transport and exchange; poor alveolar compliance
Continued development of alveoli until childhood	Possible opportunity to reduce effects of chronic lung disease
Decreased lung elastic tissue and recoil	Decreased lung compliance requiring higher pressures and more work to expand; increased risk of atelectasis
Reduced diaphragm movement and maximal force potential	Less effective respiratory movement; difficulty generating negative intrathoracic pressures; risk of atelectasis
Tendency to nose breathe; altered position of larynx and epiglottis	Enhanced ability to synchronize swallowing and breathing; risk of airway obstruction; possibly more difficult to intubate
Small compliant airway passages with higher airway resistance; immature reflexes	Risk of airway obstruction and apnea
Increased pulmonary vascular resistance with sensitive pulmonary arterioles	Risk of ductal shunting and hypoxemia with events such as hypoxia, acidosis, hypothermia, hypoglycemia, and hypercarbia
Increased oxygen consumption	Increased respiratory rate and work of breathing; risk of hypoxia; risk of retinopathy of prematurity
Increased intrapulmonary right–left shunting	Increased risk of atelectasis with ineffective ventilation; risk of persistent pulmonary hypertension; lower P_{CO_2}
Immaturity of pulmonary surfactant system in immature newborns	Increased risk of atelectasis and respiratory distress syndrome; increased work of breathing
Immature respiratory control	Irregular respirations with periodic breathing; risk of apnea; inability to rapidly alter depth of respirations

P_{CO_2}, Partial pressure of carbon dioxide.
From Blackburn, S. (2018). *Maternal, fetal, and neonatal physiology: A clinical perspective* (5th ed.). Elsevier, p. 333, Table 10–7, adapted from Blackburn, S. (1992). Alterations in the respiratory system in the neonate: Implications for practice. *Journal of Perinatal & Neonatal Nursing, 6*, 46.

inadequate clearance of lung fluid, or it can be an indication of newborn respiratory distress syndrome (RDS). Tachypnea can be the first sign of respiratory, cardiac, metabolic, or infectious illnesses (Gardner et al., 2021).

Changes in the newborn's colour can indicate respiratory distress. **Acrocyanosis**, the bluish discoloration of hands and feet, is a normal finding in the first 7 to 10 days after birth (Figure 25.1). Transient periods of duskiness while crying are not uncommon immediately after birth; however, central cyanosis is abnormal and signifies hypoxemia. With central cyanosis the lips and mucous membranes are bluish. It can be the result of inadequate delivery of oxygen to the alveoli, poor perfusion of the lungs that inhibits gas exchange, or cardiac dysfunction. Because central cyanosis is a late sign of distress, newborns usually have significant hypoxemia when cyanosis appears.

Fig. 25.1 Newborn with acrocyanosis of upper and lower extremities. (Courtesy Barbara Wilson.)

Newborns who experience mild TTNB often have signs of respiratory distress during the first 1 to 2 hours after birth as they transition to extrauterine life. Tachypnea with rates up to 100 breaths/min can be present along with intermittent grunting, nasal flaring, and mild retractions. Supplemental oxygen or noninvasive ventilator support may be needed. TTNB usually resolves in 24 to 48 hours (Soltau & Carol, 2014).

In newborns with more serious respiratory complications, symptoms of distress are more pronounced and tend to last beyond the first 2 hours after birth. Respiratory rates can exceed 120 breaths/min. Moderate-to-severe retractions, grunting, pallor, and central cyanosis can occur. The respiratory symptoms can be accompanied by hypotension, temperature instability, hypoglycemia, acidosis, and signs of cardiac concerns. Common respiratory complications affecting newborns include RDS, meconium aspiration, pneumonia, and persistent pulmonary hypertension of the newborn (PPHN). Congenital defects such as anomalies of the great vessels, diaphragmatic hernia, or chest wall defects can cause severe respiratory conditions. Blood incompatibilities such as hydrops fetalis can result in respiratory compromise (Gardner et al., 2021) (see Chapters 28 and 29).

Cardiovascular System

The cardiovascular system changes significantly after birth. The newborn's first breaths, combined with increased alveolar capillary distension, inflate the lungs and reduce pulmonary vascular resistance to pulmonary blood flow from the pulmonary arteries. Pulmonary artery

pressure drops, and pressure in the right atrium declines. Increased pulmonary blood flow from the left side of the heart increases pressure in the left atrium, which causes a functional closure of the foramen ovale (see Chapter 47). During the first few days of life, crying may temporarily reverse the flow through the foramen ovale and lead to mild cyanosis. Soon after birth, cardiac output nearly doubles and blood flow increases to the lungs, heart, kidneys, and gastrointestinal tract.

In utero, fetal P_{O_2} is 20–30 mm Hg. After birth, when the P_{O_2} level in the arterial blood approximates 50 mm Hg, the ductus arteriosus constricts in response to increased oxygenation. Circulating hormone prostaglandin (PGE_2) levels also have an important role in closure of the ductus arteriosus. In term newborns it functionally closes within the first 24 hours after birth; permanent closure usually occurs within 3 to 4 weeks, and the ductus arteriosus becomes a ligament. The ductus arteriosus can open in response to low oxygen levels in association with hypoxia, asphyxia, or prematurity. With auscultation of the chest a patent ductus arteriosus can be detected as a heart murmur.

The umbilical vein and arteries constrict rapidly within the first 2 minutes after birth. It is thought that this is related to exposure of the cord to the cooler extrauterine environment and to increased oxygenation as the newborn begins to breathe. With the clamping and severing of the cord, the umbilical arteries, the umbilical vein, and the ductus venosus are functionally closed; they are converted into ligaments within 2 to 3 months. The hypogastric arteries also occlude and become ligaments. Table 25.2 summarizes the cardiovascular changes at birth.

Heart Rate and Sounds. The newborn heart rate averages 110 to 160 bpm at birth, with variations noted during sleep and wake states. The range of the heart rate in the term newborn can be as low as

TABLE 25.2 Cardiovascular Changes at Birth

Prenatal Status	Postbirth Status	Associated Factors
Primary Changes		
Pulmonary Circulation		
High pulmonary vascular resistance, increased pressure in right ventricle and pulmonary arteries	Low pulmonary vascular resistance; decreased pressure in right atrium, ventricle, and pulmonary arteries	Expansion of collapsed fetal lung with air; assume responsibility for adequate gas exchange
Systemic Circulation		
Low pressures in left atrium, ventricle, and aorta	High systemic vascular resistance; increased pressure in left atrium, ventricle, and aorta	Loss of placental blood flow
Secondary Changes		
Umbilical Arteries		
Patent, carrying of blood from hypogastric arteries to placenta	Functionally closed at birth; obliteration by fibrous proliferation possibly taking 2 to 3 months, distal portions becoming lateral vesicoumbilical ligaments, proximal portions remaining open as superior vesicle arteries	Closure preceding that of umbilical vein, probably accomplished by smooth muscle contraction in response to thermal and mechanical stimuli and alteration in oxygen tension Mechanically severed with cord at birth
Umbilical Vein		
Patent, carrying of blood from placenta to ductus venosus and liver	Closed; becoming ligamentum teres hepatis after obliteration	Closure shortly after umbilical arteries; hence blood from placenta possibly entering newborn for short period after birth Mechanically severed with cord at birth
Ductus Venosus		
Patent, connection of umbilical vein to inferior vena cava	Closed; becoming ligamentum venosum after obliteration	Loss of blood flow from umbilical vein
Ductus Arteriosus		
Patent, shunting of blood from pulmonary artery to descending aorta	Functionally closed almost immediately after birth; anatomical obliteration of lumen by fibrous proliferation requiring 1 to 3 months, becoming ligamentum arteriosum	Increased oxygen content of blood in ductus arteriosus creating vasospasm of its muscular wall High systemic resistance increasing aortic pressure; low pulmonary resistance reducing pulmonary arterial pressure
Foramen Ovale		
Formation of a valve opening that allows blood to flow directly to left atrium (shunting of blood from right to left atrium)	Functionally closed at birth; constant apposition gradually leading to fusion and permanent closure within a few months or years in most persons	Increased pressure in left atrium and decreased pressure in right atrium, causing closure of valve over foramen

Data from Blackburn, S. (2018). *Maternal, fetal, and neonatal physiology: A clinical perspective* (5th ed.). Elsevier.

80 to 100 bpm during deep sleep and can increase to 180 bpm or higher when the newborn cries. A heart rate that is either high (more than 160 bpm) or low (fewer than 110 bpm) should be re-evaluated within 30 minutes to 1 hour or when the activity of the newborn changes. Immediately after birth the heart rate can be palpated by grasping the base of the umbilical cord.

The apical impulse (point of maximal impulse [PMI]) in the newborn is at the fourth intercostal space and to the left of the midclavicular line. The PMI is often visible and easily palpable because of the thin chest wall; this is also called *precordial activity*.

Apical pulse rates should be obtained on all newborns. Auscultation should be for a full minute, preferably when asleep. An irregular heart rate in newborns is not uncommon in the first few hours of life. After this time, an irregular heart rate not attributed to changes in activity or respiratory pattern should be further evaluated. Heart sounds during the newborn period are of higher pitch, shorter duration, and greater intensity than during adult life. The first sound (S_1) is typically louder and duller than the second sound (S_2), which is sharp. The third and fourth heart sounds are not auscultated in newborns. Most heart murmurs heard during the newborn and infant periods have no pathological significance, and more than half of the murmurs disappear by 6 months. The presence of a murmur and accompanying signs such as poor feeding, apnea, cyanosis, or pallor is considered abnormal and should be further evaluated. There can be significant cardiac defects without symptoms in the early newborn period, thus ongoing assessment is essential (Sadowski, 2015).

Blood Pressure (BP). Values for newborn BP vary with gestational age and weight. The term newborn's average systolic BP is 60 to 80 mm Hg, and average diastolic BP is 40 to 50 mm Hg. The number of weeks of gestation can be used as a guide for the mean arterial pressure (MAP). While not exact, it is a useful guide; for example, a newborn born at 40 weeks of gestation should have a MAP of at least 40. The BP increases by the second day of life, with minor variations noted during the first month of life. A drop in systolic BP (about 15 mm Hg) in the first hour of life is common. Crying and movement usually cause increases in the systolic BP. The measurement of BP is best accomplished with an oscillometric device while the newborn is at rest. A correctly sized cuff with proper placement must be used for accurate measurement of a newborn's BP.

Unless there is a specific indication, BP is not routinely measured in the healthy newborn. In the presence of cardiovascular symptoms such as tachycardia, murmur, abnormal pulses, poor perfusion, or abnormal precordial activity, four extremity BP and preductal and postductal oxygen saturation levels may be taken. If the systolic pressure is more than 10 mm Hg higher in the upper extremities than in the lower extremities, further diagnostic testing may be needed.

Blood Volume. Blood volume in the newborn is about 80 to 100 mL/kg of body weight. Immediately after birth, the total blood volume averages 300 mL, but this volume can increase by as much as 100 mL, depending on the length of time to cord clamping and cutting. The infant born prematurely has a relatively greater blood volume than the term newborn because the preterm infant has a proportionately greater plasma volume, not a greater red blood cell (RBC) mass.

Delayed clamping of the umbilical cord changes the circulatory dynamics of the newborn. Delayed cord clamping (DCC) expands the blood volume from the so-called *placental transfusion* of blood to the newborn by as much as 100 mL, depending on the length of time to cord clamping and cutting. DCC has been associated with increased blood volume and BP and reduced risk for intraventricular hemorrhage and necrotizing enterocolitis (Perlman et al., 2015). These benefits are most important for preterm infants. Polycythemia that occurs with delayed clamping is usually not harmful, although there can be an increased risk for hyperbilirubinemia that requires phototherapy. The Society of Obstetricians and Gynecologists of Canada (Leduc et al., 2018) and the World Health Organization (2014) recommend that DCC be practised whenever possible. DCC is reasonable for term and preterm newborns who do not need resuscitation.

Signs of Cardiovascular Concerns. Close monitoring of the newborn's vital signs is important for early detection of impending complications. Persistent tachycardia (more than 160 bpm) can be associated with anemia, hypovolemia, hyperthermia, or sepsis. Persistent bradycardia (less than 100 bpm) can be a sign of a congenital heart block, hypoxemia, normal sinus bradycardia, or hypothermia. Unequal or absent pulses, bounding pulses, and decreased or elevated blood pressure can indicate cardiovascular concerns (Verklan, 2015).

The newborn's skin colour can reflect cardiovascular conditions. Pallor in the immediate postbirth period is often symptomatic of underlying issues such as anemia or marked peripheral vasoconstriction as a result of intrapartum asphyxia, difficult assisted birth, or sepsis. Any central or prolonged cyanosis can indicate respiratory or cardiac concerns and requires immediate investigation and evaluation.

Congenital heart defects are the most common type of congenital malformations (see Chapter 47). Although the more serious defects of cyanotic heart defects, such as transposition of the great arteries, tricuspid atresia, and tetralogy of Fallot, are likely to have clinical manifestations such as cyanosis, dyspnea, and hypoxia, others, such as small ventricular septal defects, can be asymptomatic. The prenatal history can provide information regarding risk factors for congenital heart defects, alerting the nurse to watch for symptoms. Maternal illness such as rubella, metabolic disease such as diabetes, and drug ingestion are associated with an increased risk of cardiac defects.

Hematopoietic System

The hematopoietic system of the newborn exhibits certain variations from that of the adult. Levels of RBCs and leukocytes differ, but platelet levels are relatively the same.

Red Blood Cells and Hemoglobin. Because fetal circulation is less efficient at oxygen exchange than the lungs, the fetus needs additional RBCs for transport of oxygen in utero. Therefore, at birth the average levels of RBCs and hemoglobin (fetal hemoglobin is predominant) are higher than those in the adult; these levels fall slowly over the first month. At birth the RBC count ranges from 4.8 to 7.1 $\times$ 10^{12}/L (Blackburn, 2018). The term newborn can have a hemoglobin concentration of 140 to 240 g/L at birth, decreasing gradually to 120 to 200 g/L after the first month of life (Pagana et al., 2019). Hematocrit levels at birth range from 0.51 to 0.56, increase slightly in the first few hours or days as fluid shifts from intravascular to interstitial spaces (Blackburn, 2018), and by 8 weeks are between 0.31 and 0.39 (Pagana et al., 2019). Polycythemia (central venous hematocrit greater than 65%) can occur in term and preterm newborns as a result of DCC, maternal hypertension or diabetes, or intrauterine growth restriction.

The source of the sample is a significant factor in levels of RBCs, hemoglobin, and hematocrit because capillary blood yields higher values than venous blood. The timing of blood sampling is also significant; the slight rise in RBCs after birth is followed by a substantial drop. At birth the newborn's blood contains an average of 70% fetal hemoglobin; however, because of the shorter lifespan of the cells containing fetal hemoglobin the percentage falls rapidly, so that by the age of 6 to 12 months there is only a trace of fetal hemoglobin remaining (Christensen & Ohls, 2016). Iron stores generally are sufficient to

sustain normal RBC production for approximately 4 to 6 months in the term infant, at which time a transient physiological anemia can occur.

Leukocytes. Leukocytosis, with a white blood cell (WBC) count of approximately 18 × 10^9/L (range 9 to 30 × 10^9/L), is normal at birth (Pagana et al., 2019). The number of WBCs increases to 23 to 24 × 10^9/L during the first day after birth. The initial high WBC count of the newborn decreases rapidly, and a stable level of 12 × 10^9/L is normally maintained during the newborn period. Serious infection is not well tolerated by the newborn; leukocytes are slow to recognize foreign protein and to localize and fight infection early in life. Sepsis may be accompanied by a concomitant rise in granulocytes (neutrophilia); however, some newborns may initially be seen with clinical signs of sepsis without a significant elevation in WBCs. In addition, events other than infection—prolonged crying, maternal hypertension, asymptomatic hypoglycemia, hemolytic disease, meconium aspiration syndrome, labour induction with oxytocin, surgery, difficult labour, high altitude, and maternal fever—may cause neutrophilia in the newborn.

Platelets. Platelet count ranges between 150 and 300 × 10^9/L and is essentially the same in newborns as in adults (Pagana et al., 2019). Levels of vitamin K–dependent clotting factors II, VII, IX, and X increase slowly after birth and reach adult levels by 6 months of age (Monagle, 2017).

Blood Groups. The newborn's blood group is genetically determined and established early in fetal life. However, during the newborn period, there is a gradual increase in the strength of the agglutinogens present in the RBC membrane. Cord blood samples may be used to identify the newborn's blood type and Rh status.

Thermogenic System

Next to establishing respiration and adequate circulation, heat regulation is most critical to the newborn's survival. During the first 12 hours after birth the newborn attempts to achieve thermal balance in adjusting to the extrauterine environmental temperature. **Thermoregulation** is the maintenance of balance between heat loss and heat production. Newborns attempt to stabilize their core body temperatures within a narrow range. **Hypothermia** from excessive heat loss is a common and dangerous condition in newborns.

Anatomical and physiological characteristics of newborns place them at risk for heat loss. Newborns have a thin layer of subcutaneous fat. The blood vessels are close to the surface of the skin. Changes in environmental temperature alter the temperature of the blood, thereby influencing temperature regulation centres in the hypothalamus. Newborns have larger body surface–to–body weight (mass) ratios than do children and adults (Blackburn, 2018).

Heat Loss. The body temperature of newborns depends on the heat transfer between the newborn and the external environment. Factors that influence heat loss to the environment include the temperature and humidity of the air, the flow and velocity of the air, and the temperature of surfaces in contact with and around the newborn. The goal of care is to maintain a **neutral thermal environment** for the newborn in which heat balance is maintained. The neutral thermal environment is the ideal environmental temperature that allows the newborn to maintain a normal body temperature to minimize oxygen and glucose consumption. Heat loss in the newborn occurs by four modes (Figure 25.2):

1. **Convection** is the flow of heat from the body surface to cooler ambient air. Because of heat loss by convection, the ambient temperature in the newborn care area should range between 22° and 26°C and newborns in open bassinets are wrapped to protect them from the cold. A cap may be worn to decrease heat loss from the newborn's head.
2. **Radiation** is the loss of heat from the body surface to a cooler solid surface not in direct contact but in relative proximity. To prevent this type of loss, cribs and examining tables are placed away from outside windows and care providers need to avoid exposing the newborn to direct air drafts.
3. **Evaporation** is the loss of heat that occurs when a liquid is converted to a vapour. In the newborn, heat loss by evaporation occurs as a result of vaporization of moisture from the skin. This heat loss is intensified by failing to completely dry the newborn directly after birth or with bathing. The less mature the newborn, the more severe the evaporative heat loss. Evaporative heat loss, as a component of insensible water loss, is the most significant cause of heat loss in the first few days of life.
4. **Conduction** is the loss of heat from the body surface to cooler surfaces in direct contact. The scales used for weighing the newborn should have a protective cover to minimize conductive heat loss.

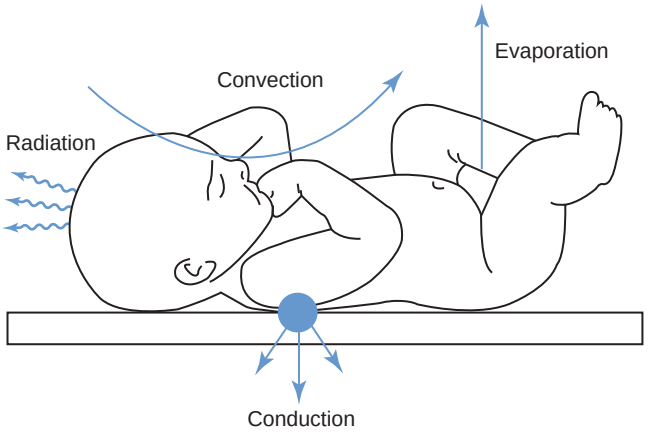

Fig. 25.2 Heat loss in the newborn occurs in four ways: convection, radiation, evaporation, and conduction. (From WHO [1997]. *Safe motherhood: Thermal protection of the newborn, a practical guide*. http://apps.who.int/iris/bitstream/10665/63986/1/WHO_RHT_MSM_97.2.pdf.)

Skin-to-Skin Contact. Loss of heat must be controlled to protect the newborn. Control of such modes of heat loss is the basis of caregiving policies and techniques. One method for promoting maternal–newborn interaction is to place the naked, healthy dried newborn on a parent's bare chest and covered with a warm blanket; a cap may be placed on the newborn's head to help conserve heat. This skin-to-skin contact reduces conductive and radiant heat loss and enhances newborn temperature control and parental–newborn interaction (Figure 25.3). Newborns who are placed skin-to-skin remain warmer than newborns held swaddled in their parent's arms. If the birthing parent is unavailable, then the partner or other significant person in the room could hold the newborn skin-to-skin.

Thermogenesis. In response to cold the newborn attempts to generate heat (**thermogenesis**) by increasing muscle activity. Cold newborns may cry and appear restless. Because of vasoconstriction the skin can feel cool to touch, and acrocyanosis can be present. There is an increase in cellular metabolic activity, primarily in the brain, heart, and liver; this also increases oxygen and glucose consumption.

In an effort to conserve heat, term newborns assume a position of flexion that helps guard against heat loss because it diminishes the

Fig. 25.3 Newborn in skin-to-skin contact with mother. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

amount of body surface exposed to the environment. Newborns also can reduce the loss of internal heat through the body surface by constricting peripheral blood vessels.

Adults are able to produce heat through shivering; however, the shivering mechanism of heat production is rarely operable in the newborn unless there is prolonged cold exposure (Blackburn, 2018). Newborns produce heat through **nonshivering thermogenesis**. This is accomplished primarily by metabolism of **brown fat**, which is unique to the newborn, and secondarily by increased metabolic activity in the brain, heart, and liver. Brown fat is located in superficial deposits in the interscapular region and axillae and in deep deposits at the thoracic inlet, along the vertebral column, and around the kidneys (Figure 25.4). Brown fat has a richer vascular and nerve supply than ordinary fat. Heat produced by intense lipid metabolic activity in brown fat can warm the newborn by increasing heat production as much as 100%. Reserves of brown fat, usually present for several weeks after birth, are rapidly depleted with cold stress. The amount of brown fat reserve increases with the weeks of gestation. A full-term newborn has greater stores than those of a preterm infant.

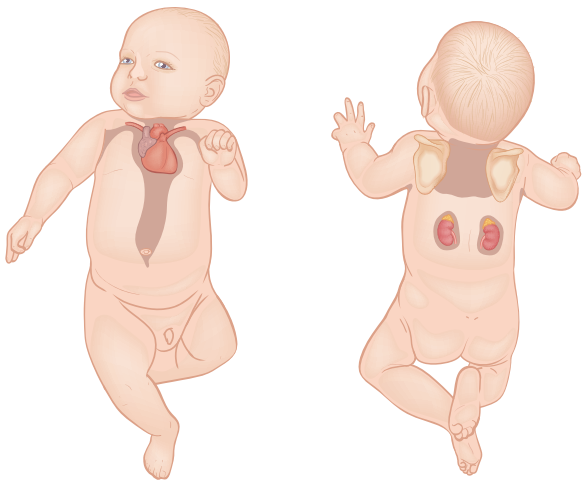

Fig. 25.4 Distribution of brown fat in the newborn.

Hypothermia and Cold Stress. When the newborn's temperature drops, vasoconstriction occurs as a mechanism to conserve heat. The newborn can appear pale and mottled; the skin feels cool, especially on the extremities. If the hypothermia is not corrected, it will progress to cold stress, which imposes metabolic and physiological demands on all newborns, regardless of gestational age and condition. The respiratory rate increases in response to the increased need for oxygen. In the cold-stressed newborn oxygen consumption and energy are diverted from maintaining normal brain and cardiac function and growth to thermogenesis for survival. If the newborn cannot maintain an adequate oxygen tension, vasoconstriction follows and jeopardizes pulmonary perfusion. As a consequence the Po_2 is decreased, and the blood pH drops. These changes can prompt a transient respiratory distress or aggravate existing RDS. Moreover, decreased pulmonary perfusion and oxygen tension can maintain or reopen the right-to-left shunt across the ductus arteriosus.

The basal metabolic rate increases with cold stress. If cold stress is protracted, anaerobic glycolysis occurs, resulting in increased production of acids. Metabolic acidosis develops, and, if an alteration in respiratory function is present, respiratory acidosis also develops (Figure 25.5). Excessive fatty acids can displace the bilirubin from the albumin-binding sites and exacerbate hyperbilirubinemia. Hypoglycemia is another metabolic consequence of cold stress. The process of anaerobic glycolysis uses approximately three to four times the amount of blood glucose, thereby depleting existing stores. If the newborn is sufficiently stressed and low glucose stores are not replaced, hypoglycemia can develop. Hypoglycemia is often asymptomatic in

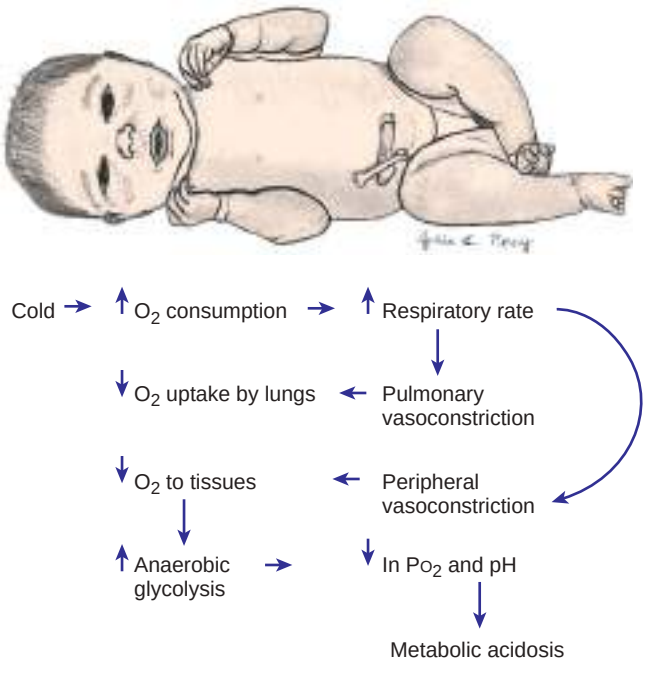

Fig. 25.5 Effects of cold stress. When a newborn is stressed by cold, oxygen consumption increases and pulmonary and peripheral vasoconstriction occur, thereby decreasing oxygen uptake by the lungs and oxygen to the tissues; anaerobic glycolysis increases; and there is a decrease in Po_2 and pH, leading to metabolic acidosis.

the newborn and typically resolves by 72 hours of life (Narvey et al., 2019).

Hyperthermia. Although occurring less frequently than hypothermia, **hyperthermia** can occur and must be corrected. A body temperature greater than 37.5°C (99.5°F) is considered to be abnormally high and is typically caused by excess heat production related to sepsis or a decrease in heat loss. Hyperthermia can result from the inappropriate use of external heat sources such as radiant warmers, phototherapy, sunlight, increased environmental temperature, and use of excessive clothing or blankets (Gardner & Cammack, 2021). The clinical appearance of the newborn who is hyperthermic often indicates the causative mechanism. Newborns who are overheated because of environmental factors such as being swaddled in too many blankets exhibit signs of heat-losing mechanisms: skin vessels dilate, the skin appears flushed, hands and feet are warm to touch, and the newborn assumes a posture of extension. The newborn who is hyperthermic because of sepsis appears stressed: vessels in the skin are constricted, colour is pale, and hands and feet are cool. Hyperthermia develops more rapidly in a newborn than in an adult because of the relatively larger surface area of a newborn. Sweat glands do not function well. Serious overheating of the newborn can cause cerebral damage from dehydration or even heat stroke and death (Gardner & Cammack, 2021).

Renal System

At term, the kidneys occupy a large portion of the posterior abdominal wall. The bladder lies close to the anterior abdominal wall and is an abdominal as well as a pelvic organ. In the newborn, almost all palpable masses in the abdomen are renal in origin.

At birth, a small quantity (approximately 40 mL) of urine is usually present in the bladder of a full-term newborn. Many newborns void at the time of birth, although this is easily missed and may not be recorded. During the first few days term newborns generally excrete 15 to 60 mL/kg; output gradually increases over the first month (Blackburn, 2018). The frequency increases with age of the newborn. At 1 day of age, a minimum of one void is expected. This increases one void per day for the first 5 days. At 1 week of age, about six to eight voidings per day of pale straw-coloured urine are indicative of adequate fluid intake.

! NURSING ALERT

Noting and recording the first voiding are important. A newborn who has not voided by 24 hours should be assessed for adequacy of fluid intake, bladder distension, restlessness, and symptoms of pain. The pediatric health care provider should be notified.

Full-term newborns have limited capacity to concentrate urine; therefore, the specific gravity ranges from 1.001 to 1.020 (Pagana et al., 2019). The ability to concentrate urine fully is attained by about 3 months of age. After the first voiding, the newborn's urine may appear cloudy (because of mucus content) and have a much higher specific gravity. This decreases as fluid intake increases. Normal urine during early infancy is usually straw coloured and almost odourless. Sometimes pink-tinged uric acid crystal stains appear on the diaper; these stains are normal, although they can be misinterpreted as blood. Loss of fluid through urine, feces, lungs, increased metabolic rate, and limited fluid intake results in a 5 to 10% loss of the birth weight. See Chapter 27 for discussion on how to determine weight loss. This weight loss usually occurs over the first 3 to 5 days of life. Excessive weight loss can be related to feeding difficulties or other issues. The newborn should regain the birth weight within 10 to 14 days, depending on the feeding method (breastmilk or formula).

Fluid and Electrolyte Balance. In the term newborn approximately 75% of body weight consists of total body water (extracellular and intracellular). A reduction in extracellular fluid occurs with diuresis during the first few days after birth. The weight loss experienced by most newborns during the first few days after birth is caused primarily by extracellular water loss (Cadnapaphornchai et al., 2021).

The daily fluid requirement for newborns weighing more than 1 500 g is 60 to 80 mL/kg/day during the first 2 days of life, and from 3 to 7 days the requirement is 100 to 150 mL/kg/day, and from 8 to 30 days it is 120 mL/kg/day to 180 mL/kg/day (Dell, 2015).

At birth, the glomerular filtration rate (GFR) of a newborn is significantly lower than in the adult. This results in a decreased ability to remove nitrogenous and other waste products from the blood. The GFR rapidly increases during the 2 to 4 weeks after birth as a result of postnatal physiological changes, including decreased renal vascular resistance, increased renal blood flow, and increased filtration pressure. The GFR gradually rises to adult levels by 2 years of age (Blackburn, 2018; Vogt & Dell, 2015).

Sodium reabsorption is decreased as a result of a lowered sodium- and potassium-activated adenosine triphosphate activity. The decreased ability to excrete excessive sodium results in hypotonic urine, leading to a higher concentration of sodium, phosphates, chloride, and organic acids and a lower concentration of bicarbonate ions. The newborn has a higher renal threshold for glucose than adults.

Tubular reabsorption of glucose in the term newborn is similar to that of an adult. While the renal threshold for glucose is lower, newborns do not typically exhibit glycosuria.

Because of a lower renal threshold for bicarbonate and a limited capacity for reabsorption, the newborn's serum bicarbonate and plasma pH levels are lower. Buffering capacity is decreased. This reduces the newborn's ability to cope with events (e.g., cold stress) that produce acidosis (Blackburn, 2018).

Signs of Renal System Concerns. The renal system has a wide range of functions. Dysfunction resulting from physiological abnormalities can range from the lack of a steady stream of urine to anomalies such as hypospadias and exstrophy of the bladder, which can be identified at birth (see Chapter 49). Enlarged or cystic kidneys can be identified as masses during abdominal palpation. Some kidney anomalies also can be detected by ultrasound examination during pregnancy.

Gastrointestinal System

The full-term newborn is capable of swallowing, digesting, metabolizing, and absorbing proteins and simple carbohydrates, and emulsifying fats. With the exception of pancreatic amylase, the characteristic enzymes and digestive juices are present even in low-birth-weight newborns.

In the adequately hydrated newborn, the mucous membrane of the mouth is moist and pink; the hard and soft palates are intact. The presence of moderate to large amounts of mucus is common in the first few hours after birth. Small whitish areas (Epstein pearls) may be found on the gum margins and at the juncture of the hard and soft palates. The cheeks are full because of well-developed sucking pads. These, like the labial tubercles (sucking calluses) on the upper lip, disappear around the age of 12 months, when the sucking period is over.

Feeding behaviour is related to gestational age and is influenced by neuromuscular maturity, maternal medications during labour and birth, and the type of initial feeding. Feeding requires that the newborn be able to coordinate sucking, swallowing, and breathing. Sucking is a reflex behaviour that begins in utero as early as 15 to 16 weeks. By 28 weeks, some infants can coordinate sucking and swallowing. By 32 to 34 weeks most are able to coordinate sucking, swallowing, and

breathing; this is well developed by 36 to 38 weeks (Blackburn, 2018). Sucking takes place in small bursts of 3 or 4 and up to 8 to 10 sucks at a time, with a brief pause between bursts. The newborn is unable to move food from the lips to the pharynx; therefore, placing the nipple (breast or bottle) well inside the baby's mouth is necessary. Peristaltic activity in the esophagus is uncoordinated in the first few days of life. It quickly becomes a coordinated pattern in healthy full-term newborns, and they swallow easily.

Teeth begin developing in utero, with enamel formation continuing until about 10 years of age. Tooth development is influenced by newborn illnesses and medications, and by illnesses of or medications taken by the mother during pregnancy. The fluoride level in the water supply also influences tooth development. Occasionally a newborn may be born with one or more teeth. These natal teeth have poorly formed roots, and as they loosen they place the newborn at risk of aspiration. Therefore, they are usually extracted.

Intestinal flora, or gut microbiota, are established within the first week after birth; normal intestinal flora help synthesize vitamin K, folate, and biotin. Traditionally it was thought that the fetus grows and develops in a sterile environment. Research on the human microbiome suggests that the pregnant patient and their developing fetus coexist with a variety of commensal and symbiotic microbes that have important influences on the health of both the mother and their infant. Research evidence of microbial presence in amniotic fluid, placenta, and meconium indicates that the fetus is exposed to microbes during pregnancy. The mode of birth (vaginal or Caesarean) seems to play a major role in the microbial colonization of the newborn. Infants born vaginally appear to be initially colonized by the maternal vaginal microbes, whereas infants born by Caesarean are first colonized by maternal skin microbes. This initial colonization plays a major role in establishing intestinal flora; research is ongoing to identify the implications for the child's future health. The microbiome of the newborn is also influenced by diet, antibiotics, and environmental factors (Bäckhed et al., 2015; Mueller et al., 2015; Neu, 2017).

Breastfeeding is important in establishing the intestinal microbiome of the newborn. Human milk contains a variety of microbes that appear to originate in the mother's gastrointestinal tract. Oligosaccharides in human milk may have a prebiotic function that facilitates the growth of beneficial bacteria in the newborn gastrointestinal tract (Neu, 2017).

The capacity of the newborn stomach varies widely, depending on the size of the infant, from less than 10 mL on day 1 to nearly 30 mL on day 3 and expanding to 60 mL on day 7. After birth, the newborn stomach becomes increasingly more compliant and relaxed to accommodate larger volumes. Several factors such as time and volume of feedings or type and temperature of food can affect the emptying time.

The normal intermittent relaxation of the lower esophageal sphincter results in involuntary backflow of stomach contents into the esophagus, known as gastroesophageal reflux (GER). As a result, newborns are prone to regurgitation, "spitting," and vomiting, especially during the first 3 months. GER can be minimized by avoiding overfeeding, burping, and positioning the newborn with the head slightly elevated.

In some infants, GER is severe enough to cause dysphagia, esophagitis, and aspiration. This is known as gastroesophageal reflux disease (GERD). Treatment may include medications to reduce gastric acidity, such as antacids, histamine-blocking agents, or proton-pump inhibitors, and medication to increase gastric motility. In severe cases, surgical treatment may be considered (Hibbs, 2015).

Digestion. The newborn's ability to digest carbohydrates, fats, and proteins is regulated by the presence of certain enzymes. Most of these are functional at birth except for pancreatic amylase and lipase. Amylase is produced by the salivary glands after about 3 months and by the pancreas at about 6 months of age. This enzyme is necessary to convert starch into maltose and occurs in high amounts in colostrum. The other exception is lipase, which is also secreted by the pancreas; it is necessary for the digestion of fat. Thus, the normal newborn is capable of digesting simple carbohydrates and proteins but has a limited ability to digest fats. Mammary lipase in human milk aids in digestion of fats by the newborn.

Lactase levels in newborns are higher than in older infants. This enzyme is necessary for digestion of lactose, the major carbohydrate in human milk and commercial infant formula.

Stools. At birth, the lower intestine is filled with meconium. **Meconium** is formed during fetal life from the amniotic fluid and its constituents, intestinal secretions (including bilirubin), and cells (shed from the mucosa). Meconium is greenish black and viscous and contains occult blood. The first meconium passed is usually sterile, but within hours all meconium passed contains bacteria. Most healthy term newborns pass meconium within 12 to 24 hours of life, and almost all do so by 48 hours. The number of stools passed varies during the first week, being most numerous between the third and sixth days. Progressive changes in the stool pattern indicate a properly functioning gastrointestinal tract (Box 25.1 and Figure 25.6).

Signs of Gastrointestinal Concerns. The time, colour, and character of the newborn's first stool should be noted. Failure to pass meconium can indicate bowel obstruction related to conditions such as malrotation, small or large bowel atresia, an inborn error of metabolism (e.g., cystic fibrosis), or a congenital disorder (e.g., Hirschsprung disease or an imperforate anus). An active rectal "wink" reflex (contraction of the anal sphincter muscle in response to touch) is a sign of good sphincter tone.

Fullness of the abdomen above the umbilicus can be caused by conditions such as hepatomegaly, duodenal atresia, or distension. Abdominal distension at birth usually indicates a serious disorder, such as a ruptured viscus (from abdominal wall defects). Distension that occurs later can be the result of overfeeding or failure to pass stool or signal gastrointestinal disorders. A scaphoid (sunken) abdomen, with bowel

BOX 25.1 Changes in Stooling Patterns of Newborns

Meconium

- Meconium is the newborn's first stool, composed of amniotic fluid and its constituents, intestinal secretions, shed mucosal cells, and possibly blood (ingested maternal blood or minor bleeding of alimentary tract vessels) (see Figure 25.6, *A*).
- Passage of meconium should occur within the first 24 to 48 hours, although it may be delayed up to 7 days in very-low-birth-weight newborns.

Transitional Stools

- Transitional stools usually appear by the third day after initiation of feeding.
- They are greenish brown to yellowish brown, are thin and less sticky than meconium, and may contain some milk curds (see Figure 25.6, *B*).

Milk Stool

- Milk stool usually appears by the fourth day.
- *Breastfed newborns:* Stools are yellow to golden, pasty in consistency, resemble a mixture of mustard and cottage cheese, with an odour similar to sour milk (see Figure 25.6, *C*).
- *Formula-fed newborns*: Stools are pale yellow to light brown, have firmer consistency, with an odour more characteristic of a normal adult stool.

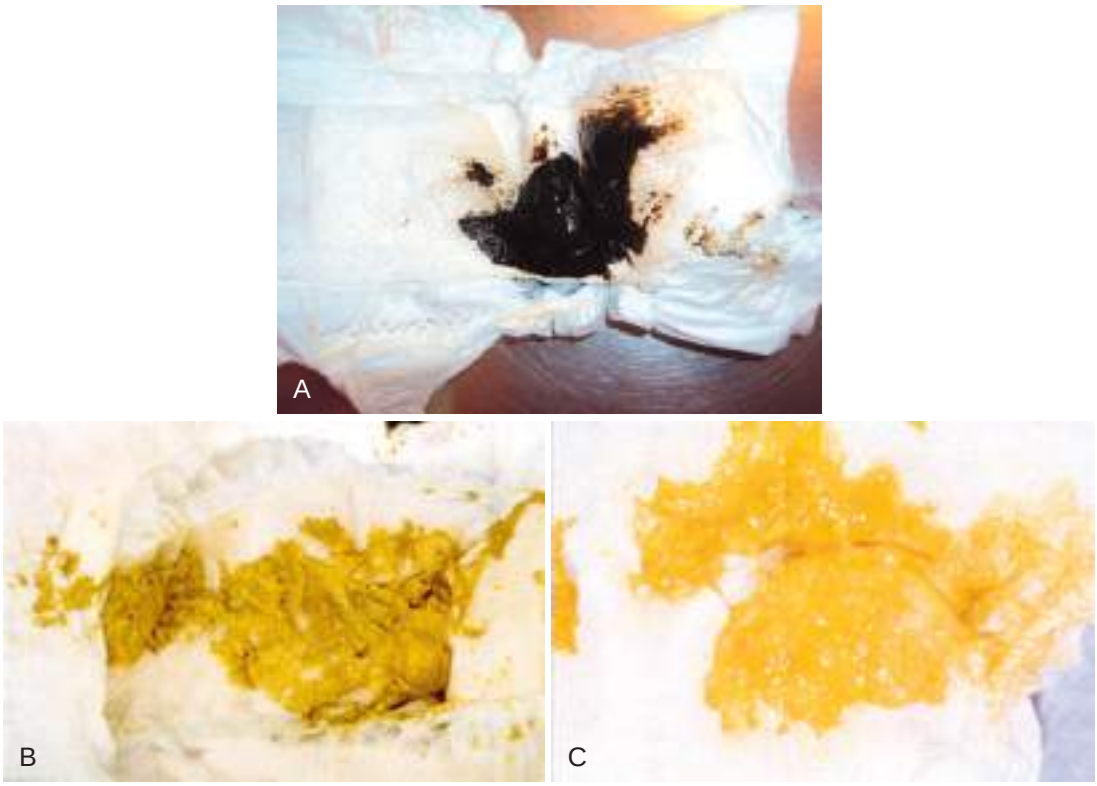

Fig. 25.6 Breastfed newborn stools. **A:** Meconium. **B:** Transition stool. **C:** Milk stool. (*A,* Courtesy Janet Andrews. *B, C,* Courtesy Connie Livingstone.)

sounds heard in the chest and signs of respiratory distress, indicate a diaphragmatic hernia. Fullness below the umbilicus can indicate a distended bladder. Passage of meconium from the vagina or urinary meatus is a sign of a possible fistulous tract from the rectum.

Some newborns are intolerant of certain commercial formulas. If a newborn is allergic or unable to digest a formula, the stools can become very soft with a high water content that is signalled by a distinct water ring around the stool on the diaper. Forceful ejection of stool and a water ring around the stool are signs of diarrhea. Care must be taken to avoid misinterpreting transitional stools for diarrhea. The loss of fluid in diarrhea can rapidly lead to fluid and electrolyte imbalance.

The amount and frequency of regurgitation ("spitting up") after feedings should be documented. Colour change, gagging, and projectile (very forceful) vomiting occur in association with esophageal and tracheoesophageal anomalies (see Chapter 46). Bilious emesis is always considered a serious condition until proven otherwise (volvulus, malrotation).

Hepatic System

The liver and gallbladder are formed by the fourth week of gestation. In the newborn, the liver can be palpated about 1 to 2 cm below the right costal margin because it is enlarged and occupies about 40% of the abdominal cavity. The newborn's liver plays an important role in iron storage, carbohydrate metabolism, conjugation of bilirubin, and coagulation. Although the liver is relatively immature at birth, healthy term newborns do not typically experience complications.

Iron Storage. The fetal liver, which serves as the site for production of hemoglobin after birth, begins storing iron in utero. The newborn's iron store is proportional to total body hemoglobin content and length of gestation. At birth, the term newborn has an iron store sufficient to last 4 to 6 months. Iron stores of preterm and small-for-gestational-age newborns are often lower and are depleted sooner than in healthy term newborns. Although both breast milk and cow's milk contain iron, the bioavailability of iron in breast milk is far superior. Exclusive breastfeeding during the first 6 months is accepted as the nutrition standard for infants as promoted by the World Health Organization as a global public health recommendation. Current opinion suggests that iron supplements are not generally needed for breastfed infants during the first 6 months. Newborns with lower iron stores are at higher risk of iron deficiency, and supplementation with oral iron drops should be prescribed when appropriate. Formula-fed newborns should receive a formula that contains supplemental iron (Health Canada et al., 2015).

Glucose Homeostasis. The liver is responsible for regulation of blood glucose levels. In utero the glucose concentration in the umbilical vein is approximately 70% of the maternal level. At birth the newborn is cut off from its maternal glucose supply and as a result experiences an initial decrease in serum glucose levels. Glucose levels reach a low point between 30 and 90 minutes after birth and then rise gradually. In most healthy term newborns blood glucose levels stabilize at 2.5 to 3.0 mmol/L during the first several hours after birth; by the third day of life, the blood glucose levels should be approximately 4.0 to 6.0 mmol/L.

The initiation of feedings helps to stabilize the newborn's blood glucose levels. Colostrum contains high amounts of glucose, thus also assisting in the stabilization of blood glucose levels in breastfed newborns. In general, blood glucose levels less than 2.2 mmol/L are considered abnormal and may require intervention (see further discussion in Chapter 26, Hypoglycemia). Glucose levels are not routinely assessed in newborns unless there are risk factors or symptoms of hypoglycemia. Risk factors include small or large for gestational

age, preterm, and infant of a diabetic mother. The hypoglycemic newborn can display the classic symptoms of jitteriness, lethargy, apnea, feeding difficulties, or seizures, or the newborn can be asymptomatic. Hypoglycemia in the initial newborn period is most often transient and easily corrected through feeding. Persistent or recurrent hypoglycemia necessitates intravenous glucose therapy and possible pharmacological intervention.

Bilirubin Synthesis and Newborn Jaundice. The liver is responsible for the conjugation of bilirubin, which results from the breakdown of RBCs. When RBCs reach the end of their lifespan, their membranes rupture and hemoglobin is released. The hemoglobin is phagocytosed by macrophages; it then splits into heme and globin. The heme is broken down by the reticuloendothelial cells, converted to bilirubin, and released in an unconjugated form. The unconjugated (indirect) bilirubin is relatively insoluble and almost entirely bound to circulating albumin, a plasma protein. The unbound bilirubin can leave the vascular system and permeate other extravascular tissues (e.g., skin, sclera, and oral mucous membranes). It can also cross the blood–brain barrier and cause neurotoxicity (acute bilirubin encephalopathy or kernicterus).

The unconjugated bilirubin must be conjugated so it becomes soluble and excretable. In the liver the unbound bilirubin is conjugated with glucuronic acid in the presence of the enzyme glucuronyl transferase. The conjugated form of bilirubin (direct bilirubin) is soluble and excreted from liver cells as a constituent of bile. Along with other components of bile, direct bilirubin is excreted into the biliary tract system that carries the bile into the duodenum. Bilirubin is converted to urobilinogen and stercobilinogen within the duodenum through the action of the bacterial flora. Urobilinogen is excreted in urine and feces; stercobilinogen is excreted in the feces (Figure 25.7). The effectiveness

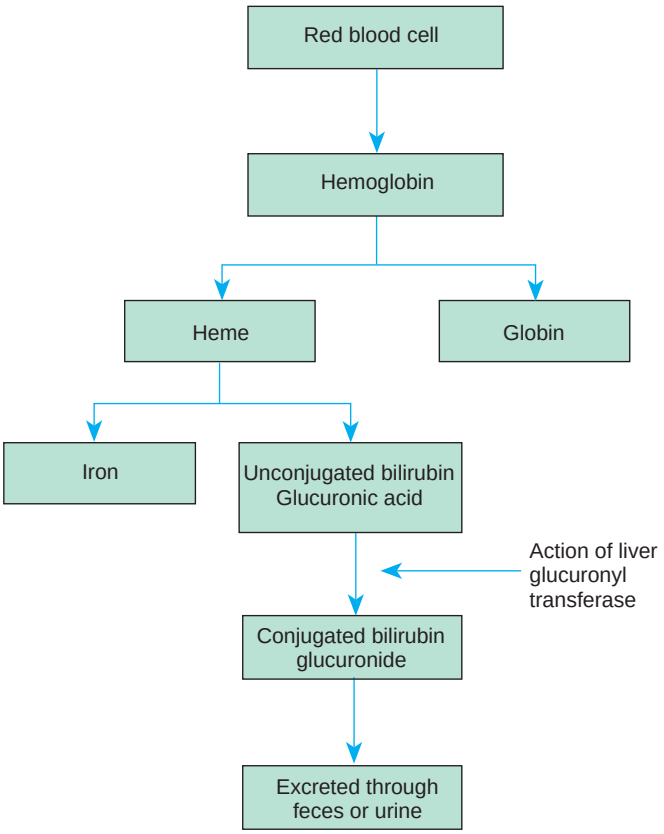

Fig. 25.7 Formation and excretion of bilirubin.

of bilirubin excretion through the feces depends on the stooling pattern of the newborn and the substances in the intestine that break down conjugated bilirubin. In the newborn intestine the enzyme beta-glucuronidase is able to convert conjugated bilirubin into the unconjugated form, which is subsequently reabsorbed by the intestinal mucosa and transported to the liver; this is called *enterohepatic circulation*. Feeding is important in reducing serum bilirubin levels because it stimulates peristalsis and produces more rapid passage of meconium, thus diminishing the amount of reabsorption of unconjugated bilirubin. Feeding also introduces bacteria to aid in the reduction of bilirubin to urobilinogen. Colostrum, a natural laxative, facilitates the passage of meconium.

When levels of unconjugated bilirubin exceed the ability of the liver to conjugate it, plasma levels of bilirubin increase and jaundice appears. **Jaundice**, the visible yellowish colour of the skin and sclera, is likely to appear when bilirubin levels exceed 85 to 102 mcmol/L (Blackburn, 2018). Jaundice is generally noticeable first in the head, especially in the sclera and mucous membranes, and progresses gradually to the thorax, abdomen, and extremities. The degree of jaundice is determined by serum total bilirubin measurements.

The newborn is at risk for hyperbilirubinemia because of distinctive aspects of normal newborn physiology. The higher RBC mass at birth and shorter lifespan of newborn RBCs mean that greater bilirubin synthesis is needed. The ability of the liver to conjugate bilirubin is reduced during the first few days after birth; it can metabolize and excrete only about two thirds of the circulating bilirubin. In addition, there are fewer bilirubin binding sites because newborns have lower serum albumin levels. In the intestines, conjugated bilirubin becomes unconjugated and recirculated through the enterohepatic circulation, which increases serum bilirubin levels (Blackburn, 2018).

Traditionally, newborn jaundice has been categorized as either *physiological* or *pathological* (nonphysiological), depending primarily on the time it appears and on serum bilirubin levels. Controversy surrounds the definitions of normal or physiological ranges of total serum bilirubin. Total serum bilirubin levels in newborns are affected by variables such as length of gestation, age, weight, ethnic background, blood group, nutritional status, mode of feeding, and presence of extravasated blood (e.g., cephalohematoma or severe bruising) (Blackburn, 2018). The time of onset of jaundice is a key factor in evaluating its cause and determining if treatment is needed. Table 25.3 lists the varying causes of neonatal hyperbilirubinemia.

Among the factors that increase the risk of hyperbilirubinemia, prematurity is the most significant one. Prematurity affects liver and brain metabolism and albumin binding sites, placing preterm and late preterm newborns at greater risk for hyperbilirubinemia. Newborns of Asian and Indigenous backgrounds have higher bilirubin levels. Breastfeeding newborns are at greater risk of hyperbilirubinemia (see later discussion).

Although there is no consistent definition for neonatal hyperbilirubinemia, the Canadian Paediatric Society suggests that an unconjugated bilirubin greater than 340 mcmol/L in the first 28 days of life constitutes hyperbilirubinemia (Barrington et al., 2007/2018).

Physiological jaundice. Physiological or nonpathological jaundice occurs in approximately 60% of newborns born at term and 80% of preterm infants. It appears after 24 hours of age and usually resolves without treatment.

Two phases of physiological jaundice have been identified in full-term newborns. In the first phase, bilirubin levels gradually increase to approximately 85 to 100 mcmol/L by 60 to 72 hours of life, then decrease to a plateau of 35 to 50 mcmol/L by the fifth day (Blackburn, 2018). In Asian newborns, levels may reach a peak of 170 to 240 mcmol/L around the third to fifth day of life; the levels

TABLE 25.3 Causes of Neonatal Indirect Hyperbilirubinemia

Basis	Causes
Increased Production of Bilirubin	
Increased hemoglobin destruction	Fetomaternal blood group incompatibility (Rh, ABO) Congenital red blood cell abnormalities Congenital enzyme deficiencies (G6PD, galactosemia) Sepsis Enclosed hemorrhage (cephalohematoma, bruising)
Increased amount of hemoglobin	Polycythemia (maternal–fetal or twin–twin transfusion, SGA) Delayed cord clamping
Increased enterohepatic circulation	Delayed passage of meconium, meconium ileus, or plug Fasting or delayed initiation of feeding Intestinal atresia or stenosis
Altered Hepatic Clearance of Bilirubin	
Alteration in uridine diphosphoglucuronyl transferase production or activity	Immaturity Metabolic or endocrine disorders (e.g., Criglar-Najjar syndrome, hypothyroidism, disorders of amino acid metabolism)
Alteration in hepatic function and perfusion (and thus conjugating ability)	Sepsis (also causes inflammation) Asphyxia, hypoxia, hypothermia, hypoglycemia Medications and hormones
Hepatic obstruction (associated with direct hyperbilirubinemia)	Congenital anomalies (biliary atresia, cystic fibrosis) Biliary stasis (hepatitis, sepsis) Excessive bilirubin load (often seen with severe hemolysis)

G6PD, Glucose-6-phosphate dehydrogenase; *SGA*, small for gestational age.
From Blackburn, S. T. (2018). *Maternal, fetal, and neonatal physiology: A clinical perspective* (5th ed.). Elsevier.

gradually fall to 35 to 50 mcmol/L by the seventh to tenth day. Bilirubin levels maintain a steady plateau state in the second phase without increasing or decreasing until approximately 12 to 14 days, at which time levels decrease to the normal adult value of 17 mcmol/L (Blackburn, 2018). This pattern varies according to ethnicity, method of feeding (breastmilk versus formula), and gestational age. In preterm formula-fed infants, serum bilirubin levels may peak as high as 170 to 200 mcmol/L at 5 to 6 days of life and decrease slowly over a period of 2 to 4 weeks (Kamath-Rayne et al., 2021).

! NURSING ALERT

The appearance of jaundice during the first 24 hours of life or persistence beyond the ages previously delineated usually indicates a potential pathological process that requires investigation.

Pathological jaundice. Although physiological jaundice is usually considered benign, unconjugated bilirubin (indirect) can accumulate to hazardous levels and lead to a pathological condition. Pathological or nonphysiological jaundice is unconjugated hyperbilirubinemia that is either pathological in origin or severe enough to warrant further evaluation and treatment (see Chapter 26). Jaundice is usually considered pathological or nonphysiological if it appears within 24 hours of birth, if total serum bilirubin levels increase by more than 100 mcmcol/L in 24 hours, and if the serum bilirubin level exceeds 256 mcmol/L at any time (Blackburn, 2018; Kamath-Rayne et al., 2021). High levels of unconjugated bilirubin are usually caused by excessive production of bilirubin through hemolysis. Hemolytic disease of the newborn caused by maternal/newborn blood group incompatibility is the most common cause of hyperbilirubinemia. It can also be caused by glucose-6-phosphate dehydrogenase (G6PD) deficiency, a genetic disorder that is more common among Asian and Indigenous populations. Other causes are listed in Table 25.3.

If increased levels of unconjugated bilirubin are left untreated, neurotoxicity can result as bilirubin is transferred into the brain cells. **Acute bilirubin encephalopathy** refers to the acute manifestations of bilirubin toxicity that occur during the first weeks after birth. This can include a range of symptoms, such as lethargy, hypotonia, irritability, seizures, coma, and death. **Kernicterus** refers to the irreversible, long-term consequences of bilirubin toxicity, such as hypotonia, delayed motor skills, hearing loss, cerebral palsy, and gaze abnormalities.

Jaundice related to breastfeeding. Two forms of breastfeeding-related jaundice are recognized: *breastfeeding-associated jaundice* and *breast milk jaundice*. These typically occur in otherwise healthy newborns. Both types can occur in the same newborn and are not easily differentiated (Blackburn, 2018; Kamath-Rayne et al., 2021).

Breastfeeding-associated jaundice (early-onset jaundice) begins at 2 to 5 days of age. Breastfeeding does not cause the jaundice; rather it is a lack of effective breastfeeding that contributes to the hyperbilirubinemia. If the newborn is not feeding effectively, there is less caloric and fluid intake and possible dehydration. Hepatic clearance of bilirubin is reduced. With less intake, there are fewer stools. As a result, bilirubin is reabsorbed from the intestine back into the bloodstream and must be conjugated again so it can be excreted (Blackburn, 2018; Lawrence & Lawrence, 2016).

Breast milk jaundice (late-onset jaundice) usually occurs at 5 to 10 days of age. Newborns are usually feeding well and gaining weight appropriately. Rising levels of bilirubin peak during the second week and gradually diminish. Despite high levels of bilirubin that may persist for 3 to 12 weeks, these infants have no signs of hemolysis or liver dysfunction. The etiology of breast milk jaundice is uncertain. However, it seems to be related to factors in the breast milk (e.g., pregnanediol, fatty acids, and beta-glucuronidase) that either inhibit the conjugation or decrease the excretion of bilirubin (Blackburn, 2018). (See Chapter 27 for a discussion of these conditions in relation to newborn nutrition.)

Coagulation. The liver plays an important role in blood coagulation. Coagulation factors, which are synthesized in the liver, are activated by vitamin K. The lack of intestinal bacteria needed to synthesize vitamin K results in transient blood coagulation deficiency between the second and fifth days of life. The levels of coagulation factors slowly increase to reach adult levels by age 9 months. The administration of vitamin K shortly after birth helps prevent vitamin K deficiency bleeding (VKDB), which can occur suddenly and be catastrophic (Shearer, 2017). Any bleeding issues noted in the newborn should be reported immediately and tests for clotting ordered.

Medication Metabolism. The immaturity of the liver and depressed liver enzyme systems at birth result in slower biotransformation and

elimination of medications. This can result in slower medication clearance, increased serum levels, and longer half-lives (Blackburn, 2018).

Signs of Hepatic System Concerns. Hypoglycemia and hyperbilirubinemia are the most common liver-related conditions experienced by newborns. In most cases, these conditions are transient and require little, if any, treatment. Preterm infants are at increased risk for hepatic system complications because of the immaturity of the liver.

The hematological status of all newborns should be assessed for anemia. For the first week of life, newborns are at risk for bleeding until the coagulation factors are well established. Male newborns who are circumcised prior to discharge from the birthing facility must be monitored carefully for bleeding.

Immune System

Beginning early in gestation, the immune system of the fetus is developing the capacity to respond to foreign antigens. The development of the immune system is necessary to equip the newborn to meet the numerous environmental challenges (e.g., microorganisms) associated with life in the extrauterine world. Compared to adults, the immune response at birth is reduced, leading to increased susceptibility to pathogens.

Newborn levels of circulating immunoglobins are low in comparison to adult levels. Most of the circulating antibodies in the newborn are immunoglobulin G (IgG) antibodies that were transported across the placenta from the maternal circulation. This transfer of antibodies from the mother begins as early as 14 weeks of gestation and is greatest during the third trimester. By term the IgG levels in the cord blood of the newborn are higher than those in maternal blood. The passive immunity afforded the newborn through the placental transfer of IgG usually provides sufficient antimicrobial protection during the first 3 months of life. Production of adult concentrations of IgG is reached by 4 to 6 years of age (Benjamin et al., 2015).

The fetus is capable of producing IgM by the eighth week of gestation, and low levels are present at term (less than 10% of adult levels). IgM is important for immunity to bloodborne infections and is the major Ig synthesized during the first month. By the age of 2 years, IgM reaches adult levels. The production of IgA, IgD, and IgE is much more gradual, and maximal levels are not attained until early childhood (Benjamin et al., 2015).

Natural barrier mechanisms such as the acidity of the stomach and the production of pepsin and trypsin, which maintain sterility of the small intestine, are not fully developed until ages 3 to 4 weeks.

The membrane-protective IgA is missing from the respiratory and urinary tracts, and, unless the newborn is breastfed, it also is absent from the gastrointestinal tract. Breast milk provides the newborn with important immunity. The secretory IgA in human milk acts locally in the intestines to neutralize bacterial and viral pathogens. It may also lessen the risk of allergy and food intolerance through modulation of exposure to foreign milk protein antigens.

Other components of breast milk strengthen the newborn's immune system. Antimicrobial factors such as oligosaccharides, lysozyme, and lactoferrin aid in microbial clearance. Infants who are breastfed have enhanced antibody responses to vaccines. Long-term effects of breast milk on the immune system are demonstrated by lower risk for immune-mediated conditions such as allergies, inflammatory bowel disease, and type I diabetes mellitus (Turfkruyer & Verhasselt, 2015).

The WBCs of the newborn display a delayed response to invading bacteria. Neutrophil levels are low; therefore, their key functions of phagocytosis, chemotaxis, and intracellular killing are limited (Greenberg et al., 2019). The influx of phagocytic cells to areas of inflammation is somewhat slowed, although the ability of these cells to attack and destroy bacteria is equivalent to that of adults. B cells and T cells are present in the newborn, although their function is immature (Benjamin et al., 2015).

The newborn is capable of producing a protective immune response to vaccines, given as early as a few hours after birth. For example, when hepatitis B vaccine is administered at birth to the newborn born to a mother with hepatitis B, there is an excellent immune response. This holds true even if the newborn does not receive additional hepatitis B Ig.

Risk for Infection. All newborns, and preterm newborns especially, are at high risk for infection during the first several months of life. During this period infection is one of the leading causes of morbidity and mortality. The newborn cannot limit the invading pathogen to the portal of entry because of the generalized hypofunctioning of the inflammatory and immune mechanisms.

Early signs of infection must be recognized so that prompt diagnosis and treatment can occur. Temperature instability or hypothermia can be symptomatic of serious infection; newborns do not typically exhibit fever, although hyperthermia can occur (temperature greater than 38°C or 100.4°F). Lethargy, irritability, poor feeding, vomiting or diarrhea, decreased reflexes, decreased body temperature, and pale or mottled skin colour are some of the clinical signs that suggest infection. Respiratory symptoms such as apnea, tachypnea, grunting, or retracting can be associated with infection such as pneumonia (Lott, 2015). The greatest risk factor for newborn infection is prematurity because of immaturity of the immune system. Other risk factors include premature rupture of membranes, chorioamnionitis, maternal fever, antenatal or intrapartal asphyxia, invasive procedures, stress, and congenital anomalies (Lott, 2015). Hand hygiene is key to prevention of serious infections.

Integumentary System

All skin structures are present at birth. The epidermis and dermis are loosely bound and extremely thin. After 35 weeks' gestation the skin is covered by **vernix caseosa** (a cheeselike whitish substance) that is fused with the epidermis and serves as a protective covering. Vernix caseosa is a complex substance that contains sebaceous gland secretions. It has emollient and antimicrobial properties and prevents fluid loss through the skin; it also has antioxidant properties. Removal of the vernix is followed by desquamation of the epidermis in most newborns. There is evidence that leaving residual vernix intact after birth has positive benefits for the newborn's skin, such as decreasing the skin pH, decreasing skin erythema, and improving skin hydration (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 2018; Visscher et al., 2015). The newborn's skin is sensitive and can be easily damaged.

The term newborn has erythematous (red) skin for a few hours after birth, after which it fades to its normal colour. The skin often appears blotchy or mottled, especially over the extremities. The hands and feet appear slightly cyanotic (**acrocyanosis**); this is caused by vasomotor instability and capillary stasis. Acrocyanosis is normal and appears intermittently over the first 7 to 10 days, especially with exposure to cold (see Figure 25.1).

The healthy term newborn usually has a plump appearance because of large amounts of subcutaneous tissue and extracellular water content. Subcutaneous fat accumulated during the last trimester acts as insulation. Fine **lanugo** hair may be noted over the face, shoulders, and back. Edema of the face and **ecchymosis** (bruising) may be noted as a result of face presentation, forceps-assisted birth, or vacuum extraction.

Creases can be found on the palms of the hands. A single palmar crease, is often found in Asian newborns or in newborns with Down syndrome. The soles of the feet should be inspected for the number of creases during the first few hours after birth; as the skin dries, more creases appear. Increasing numbers of creases correlate with a greater maturity rating. Premature newborns have few, if any, creases.

Sweat Glands. Distended, small, white sebaceous glands noticeable on the newborn face are known as **milia**. Although sweat glands are present at birth, term newborns usually do not sweat for the first 24 hours. By day 3, sweating begins on the face and later progresses to the palms. Newborns can sweat as a function of body or environmental temperature; there can also be emotional sweating from crying or pain (Hoath & Narendran, 2015).

Desquamation. Desquamation (peeling) of the skin of the term newborn does not occur until a few days after birth. Large generalized areas of skin desquamation present at birth may be an indication of postmaturity.

Congenital Dermal Melanocytosis. **Congenital dermal melanocytosis (also called *slate grey nevi*)**, bluish black areas of pigmentation, may appear over any part of the exterior surface of the body, including the extremities. This is more commonly noted on the back and buttocks (Figure 25.8). These pigmented areas are most frequently noted in newborns whose ethnic origins are in the Mediterranean area, Latin America, Asia, or Africa (Blackburn, 2018). They fade gradually over months or years.

The presence of congenital dermal melanocytosis in the newborn should be documented carefully in the medical record. These normal skin pigmentations can be mistaken for bruises once the infant is discharged, and this can raise suspicion of physical abuse.

Nevi. **Nevus simplex**, also known as *salmon patches, telangiectatic nevi,* or *"angel kisses,"* are the result of a superficial capillary defect and occur in up to 80% of newborns. They are usually small, flat, and pink and are easily blanched (Figure 25.9, *A*). The most common sites are the upper eyelids, nose, upper lip, and nape of the neck. Salmon patches tend to be symmetrical, with lesions occurring on both eyelids or both sides of midline. They have no clinical significance and require no treatment. Facial lesions usually fade between the first and second years of life, whereas neck lesions can be visible into adulthood (Hoath & Narendran, 2015).

Fig. 25.8 Congenital dermal melanocytosis.

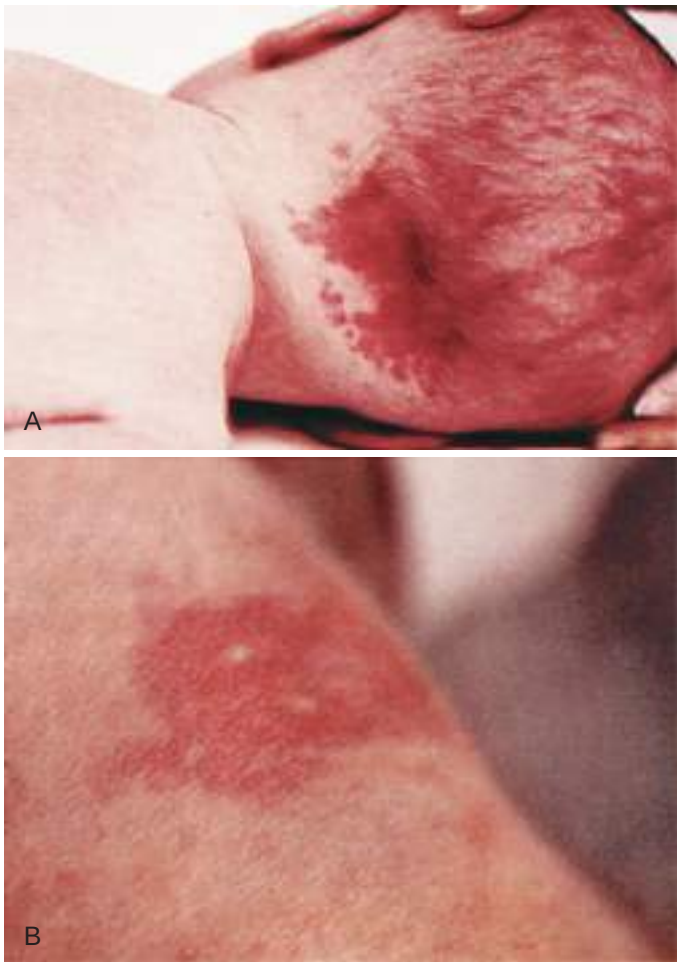

Fig. 25.9 **A:** Telangiectatic nevi. **B:** Erythema toxicum. (Courtesy Mead Johnson & Co., LLC.)

A port-wine stain, or **nevus flammeus**, is usually visible at birth and is composed of a plexus of newly formed capillaries in the papillary layer of the corium. It is red to purple; varies in size, shape, and location; and is not elevated. True port-wine stains do not blanch on pressure or disappear. They are most commonly found on the face and neck (Hoath & Narendran, 2015).

Infantile Hemangioma. Infantile hemangiomas consist of dilated newly formed capillaries occupying the entire dermal and subdermal layers with associated connective tissue hypertrophy. The typical lesion is a raised, sharply demarcated, bright or dark red rough-surfaced swelling that may be present at birth or may appear during the early weeks after birth. Common sites are the scalp, face, back, and anterior chest. These lesions are sometimes called *strawberry hemangiomas,* although experts deem that term inappropriate. Most lesions reach maximum growth in about 6 months and then begin a slow process of involution that can take 5 to 10 years (Martin, 2016).

Erythema Toxicum. **Erythema toxicum**, a transient rash, is also called *erythema neonatorum*, or *newborn rash*. It first appears in term newborns during the first 24 to 72 hours after birth and can last up to 3 weeks of age. It has lesions in different stages: erythematous macules, papules, and small vesicles (see Figure 25.9, *B*). The lesions may appear

suddenly anywhere on the body. The rash is thought to be an inflammatory response. Eosinophils, which help decrease inflammation, are found in the vesicles. Although the appearance is alarming, the rash has no clinical significance and requires no treatment.

Signs of Integumentary Concerns. Close observation of the newborn's skin colour can help in early detection of potential concerns. Any pallor, plethora (deep purplish colour from increased circulating RBCs), petechiae, central cyanosis, or jaundice should be noted and described. The skin should be examined for signs of birth injuries, such as forceps marks and lesions related to fetal monitoring. Bruises or petechiae may be present on the head, neck, and face of a newborn born with a nuchal cord (cord around the neck) or in a newborn who had a face presentation at birth. Bruising can increase the risk of hyperbilirubinemia. Petechiae can be present if increased pressure was applied to an area. Petechiae scattered over the newborn's body should be reported to the pediatric health care provider because their presence can indicate underlying issues such as low platelet count or infection. Unilateral or bilateral periauricular papillomas (skin tags) occur fairly frequently. Their occurrence is usually a family trait and of no consequence.

Reproductive System

Female. An increase in estrogen during pregnancy, followed by a drop after birth, results in a mucoid vaginal discharge and some slight bloody spotting (**pseudomenstruation**). External genitalia (i.e., labia majora and minora) are usually edematous, with increased pigmentation. In term newborns, the labia majora and minora cover the vestibule (Figure 25.10, *A*). In preterm newborns, the clitoris is prominent and the labia majora are small and widely separated. Vaginal or hymenal tags are common findings and have no clinical significance. Vernix caseosa may be present between the labia and should not be forcibly removed during bathing.

If the female was born in the breech position, the labia may be edematous and bruised. The edema and bruising resolve in a few days; no treatment is necessary.

Male. A tight **prepuce** (foreskin) is common in newborns and completely covers the glans (see Figure 25.10, *B*). The urethral opening may be completely covered by the prepuce, which may not be retractable for 3 to 4 years. The position of the urethra should be at the tip of the penis. With **hypospadias**, or **epispadias**, the urethral opening is located in an abnormal position, on or adjacent to the glans, although it can be placed on the penile shaft or perineum. Smegma, a white, cheesy substance, is commonly found under the foreskin. Small, white, firm cysts called *epithelial pearls* may be seen at the tip of the prepuce.

By 28 to 36 weeks of gestation, the testes can be palpated in the inguinal canal and a few rugae appear on the scrotum. At 36 to 40 weeks of gestation, the testes are palpable in the upper scrotum and **rugae** appear on the anterior portion. After 40 weeks, the testes can be palpated in the scrotum and rugae cover the scrotal sac. The post-term newborn has deep rugae and a pendulous scrotum. Undescended testes (cryptorchidism) occur in approximately 4% of term newborn males; in most cases, the testes gradually descend without intervention. The primary risk factors for cryptorchidism are preterm birth and low birth weight (Lee, 2017).

The scrotum is usually more deeply pigmented than the rest of the skin, a difference that is especially apparent in darker-skinned newborns. This pigmentation is a response to maternal estrogen. If the male newborn is born in a breech presentation, the scrotum is edematous and may be bruised (see Figure 26.8). The swelling and discoloration subside within a few days.

Fig. 25.10 External genitalia. **A:** Genitalia in female term newborn. **B:** Genitalia in uncircumcised male newborn. Rugae cover scrotum, indicating term gestation. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

A **hydrocele**, caused by an accumulation of fluid around the testes, may be found. This can be transilluminated with a light and usually decreases in size without treatment.

Swelling of Breast Tissue. Swelling of the breast tissue in term newborns of both sexes is caused by the hyperestrogenism of pregnancy. In a few newborns a thin discharge can be seen. This finding has no clinical significance, requires no treatment, and subsides within a few days as the maternal hormones are eliminated from the newborn's body.

The nipples should be symmetrical on the chest. Breast tissue and areola size increase with gestation. The areola appears slightly elevated at 34 weeks of gestation. By 36 weeks, a breast bud of 1 to 2 mm is palpable; this increases to 12 mm by 42 weeks.

Signs of Reproductive System Concerns. The newborn must be inspected closely for ambiguous genitalia and other abnormalities. Normally, in a female newborn the urethral opening is located behind the clitoris. Any deviation from this can incorrectly suggest that the clitoris is a small penis, which can occur in conditions such as adrenal hyperplasia. Nearly all female newborns are born with hymenal tags; absence of such tags can indicate vaginal agenesis. Fecal discharge from the vagina indicates a rectovaginal fistula. Any of these findings must be reported to the pediatric health care provider for further evaluation.

Hypospadias or epispadias, undescended or maldescended testes, and other abnormalities of the male genitalia must be reported.

Circumcision is contraindicated in the presence of hypospadias or epispadias since the foreskin is used in repair of these anomalies.

Inguinal hernias can be present and become more obvious when the newborn cries. They usually require no treatment because they resolve with time.

Skeletal System

The infant's skeletal system undergoes rapid development during the first year of life. At birth, more cartilage is present than ossified bone.

Because of cephalocaudal (head-to-rump) development, the newborn looks somewhat out of proportion. The head at term is one fourth of the total body length. The arms are slightly longer than the legs. In the newborn, the legs are one third of the total body length but only 15% of the total body weight. As growth proceeds, the midpoint in head-to-toe measurements gradually descends from the level of the umbilicus at birth to the level of the symphysis pubis at maturity.

The face appears small in relation to the skull. The skull appears large and heavy. Cranial size and shape can be distorted by moulding (the shaping of the fetal head through overlapping of the cranial bones to facilitate movement through the birth canal during labour) (Figure 25.11).

Caput Succedaneum. **Caput succedaneum** is a generalized, easily identifiable edematous area of the scalp, most commonly found on the occiput (Figure 25.12, *A*). The sustained pressure of the presenting vertex against the cervix results in compression of local vessels, thereby slowing venous return. The slower venous return causes an increase in tissue fluids within the skin of the scalp, and an edematous swelling develops. This edematous swelling, present at birth, extends across the suture lines of the skull and disappears spontaneously within 3 to 4 days. Newborns who are born with the assistance of vacuum extraction usually have a caput in the area where the cup was applied.

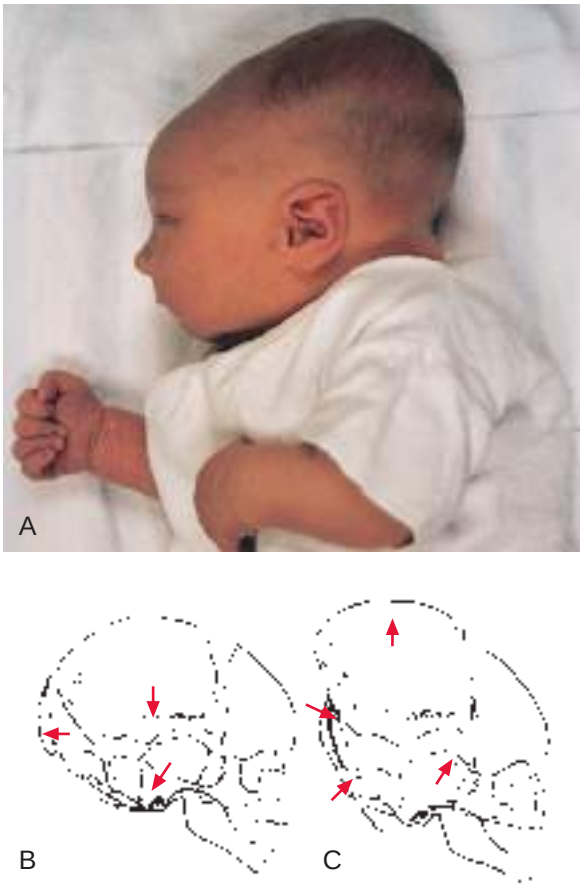

Fig. 25.11 Moulding. **A:** Significant moulding after vaginal birth. **B:** Schematic of bones with no moulding. **C:** Schematic of bones with moulding. (*A*, Courtesy Kim Molloy.)

Cephalohematoma. **Cephalohematoma** is a collection of blood between a skull bone and its periosteum. Thus, a cephalohematoma does not cross a cranial suture line (see Figure 25.12, *B*). A cephalohematoma is firmer and better defined than a caput. Often caput succedaneum and cephalohematoma occur simultaneously.

Bleeding may occur with spontaneous birth from pressure against the maternal bony pelvis. Low forceps birth and difficult forceps rotation and extraction may also cause bleeding. This soft, fluctuating, irreducible fullness does not pulsate or bulge when the newborn cries. It appears several hours or the day after birth and may not become apparent until a caput succedaneum is absorbed. A cephalohematoma is usually largest on the second or third day, by which time the bleeding stops. The fullness of a cephalohematoma spontaneously resolves in 3 to 6 weeks. It is not aspirated because infection may develop if the skin is punctured. As the hematoma resolves, hemolysis of RBCs occurs and jaundice may result. Hyperbilirubinemia and jaundice may occur from a cephalohematoma after the newborn is discharged home.

Subgaleal Hemorrhage. **Subgaleal hemorrhage** is bleeding into the subgaleal compartment (see Figure 25.12, *C*). The subgaleal compartment is a potential space that contains loosely arranged connective tissue; it is located beneath the galea aponeurosis, the tendinous sheath that connects the frontal and occipital muscles and forms the inner surface of the scalp. Subgaleal hemorrhage is commonly associated with difficult operative vaginal birth, especially vacuum extraction. With the vacuum extractor the scalp is pulled away from the bony calvarium; the vessels are torn, and blood collects in the subgaleal space. Blood loss can be severe, resulting in hypovolemic shock, disseminated intravascular coagulation (DIC), and death (Mangurten et al., 2015).

Early detection of the hemorrhage is vital; serial head circumference measurements and inspection of the back of the neck for increasing edema and a firm mass are an essential aspect of assessment of newborns who are born with the assistance of a vacuum extractor. A boggy scalp, pallor, tachycardia, and increasing head circumference may also be early signs of a subgaleal hemorrhage. Computed tomography (CT) or magnetic resonance imaging (MRI) is useful in confirming the diagnosis. Replacement of lost blood and clotting factors is required in acute cases of hemorrhage. Another possible early sign of subgaleal hemorrhage is a forward and lateral positioning of the newborn's ears, because the hematoma extends posteriorly. Monitoring the newborn for changes in level of consciousness and decreases in hematocrit is also key to early recognition and management (Mangurten et al., 2015).

Spine. The bones in the vertebral column of the newborn form two primary curvatures—one in the thoracic region and one in the sacral region. Both are forward, concave curvatures. As the infant gains head control at approximately age 3 months, a secondary curvature appears in the cervical region. The newborn's spine appears straight and can be flexed easily. The newborn can lift the head and turn it from side to side when prone. The vertebrae should appear straight and flat. If a pilonidal dimple is noted, further inspection is required to determine whether a sinus is present. A pilonidal dimple, especially with a sinus and nevus pilosis (hairy nevus), is significant because it can be associated with spina bifida.

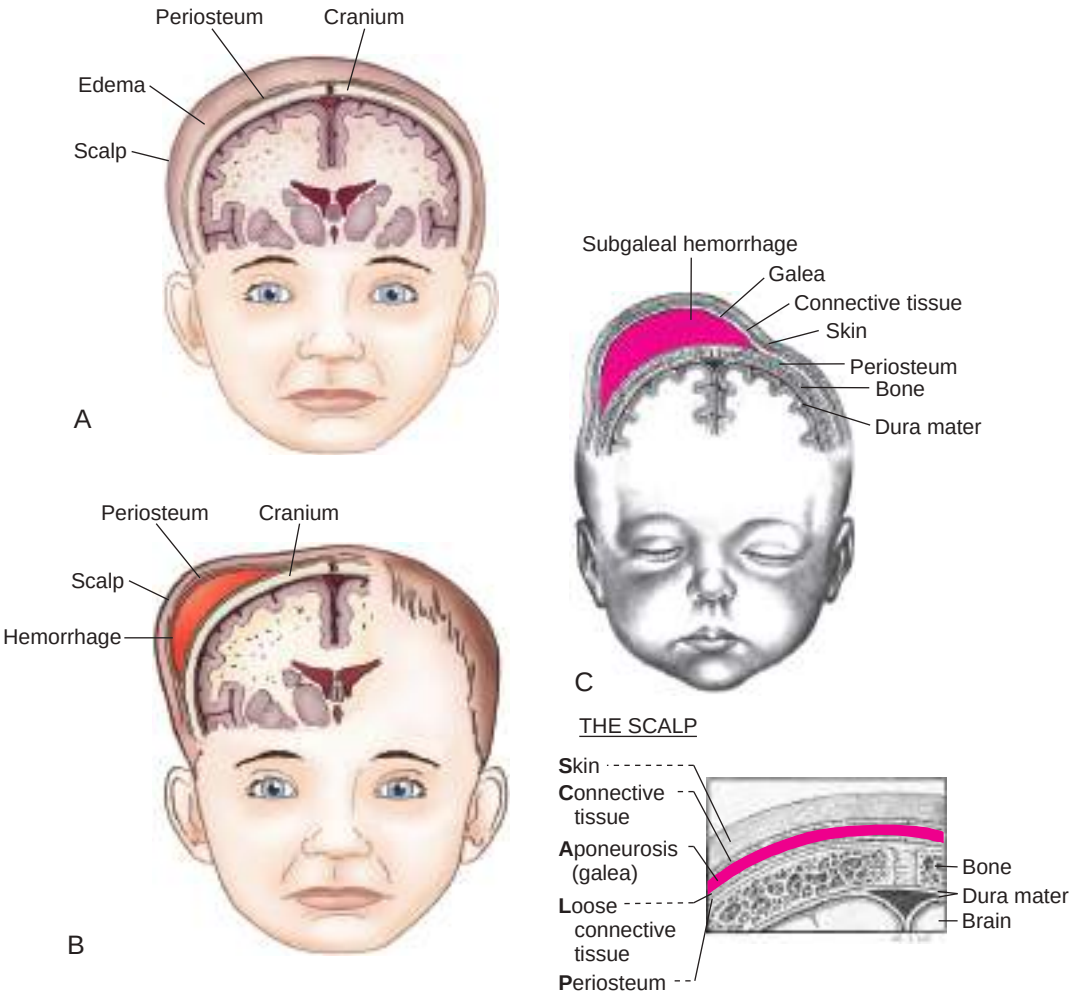

Fig. 25.12 **A:** Caput succedaneum. **B:** Cephalohematoma. **C:** Subgaleal hemorrhage. (*A* and *B* from Seidel, H. M., Stewart, R. W., Ball, J. W., et al. [2006]. *Mosby's guide to physical examination* [6th ed.]. Mosby.)

Extremities. The newborn's extremities should be symmetrical and of equal length. Fingers and toes should be equal in number (five fingers on each hand and five toes on each foot) and should have nails present. Digits may be missing (**oligodactyly**). Extra digits (**polydactyly**) are sometimes found on hands or feet. Fingers or toes may be fused (**syndactyly**). In some newborns, there is a significant separation of the knees when the ankles are held together, resulting in an appearance of bowlegs. At birth, there is no apparent arch to the foot.

The newborn is examined for **developmental dysplasia of the hip (DDH)**. In newborns with DDH the affected hip is unlikely to be dislocated at birth; instead it is easily dislocatable. Postnatal factors determine whether the hip dislocates, subluxates, or remains stable. DDH occurs more often in first-born infants, females, breech presentations (Figure 25.13), and newborns with a family history of DDH (Son-Hing & Thompson, 2015).

Signs of DDH are asymmetrical gluteal and thigh skinfolds, uneven knee levels, a positive Ortolani test, and a positive Barlow test. The hips are inspected for symmetry. Gluteal and thigh skin folds should be equal and symmetrical, and legs should be of equal length (Figure 25.13, *A*). The level of the knees in flexion should be equal (see Figure 25.13, *C*). Hip integrity is assessed by using the Barlow test and the Ortolani manoeuvre. For the Barlow test the examiner places the middle finger over the greater trochanter and the thumb along the midthigh. The hip is flexed to 90 degrees and adducted, followed by gentle downward pushing of the femoral head. If the hip can be dislocated with this manoeuvre, the femoral head moves out of the acetabulum, and the examiner feels a "clunk." The hip is then checked to determine if the femoral head can be returned into the acetabulum using the Ortolani test. As the hip is abducted and upward leverage is applied, a dislocated hip returns to the acetabulum with a clunk that is felt by the examiner (see Figure 25.13, *B* and *D*).

SAFETY ALERT

Only expert examiners (physicians, nurse practitioners) should perform the Barlow test and Ortolani manoeuvre to assess for developmental dysplasia of the hip. An unskilled examiner can cause injury to the newborn.

Signs of Skeletal Concerns. Abnormalities of the skeletal system can be congenital, developmental, drug induced, or the result of intrapartum or postnatal factors. Signs of DDH, additional digits or webbing of digits, and any other abnormality should be documented and reported to the primary health care provider.

A fractured clavicle may occur in macrosomic newborns and in those who had a difficult birth (e.g., shoulder dystocia). Unequal movement of the upper extremities or a crepitant feeling over the clavicular area can indicate fracture.

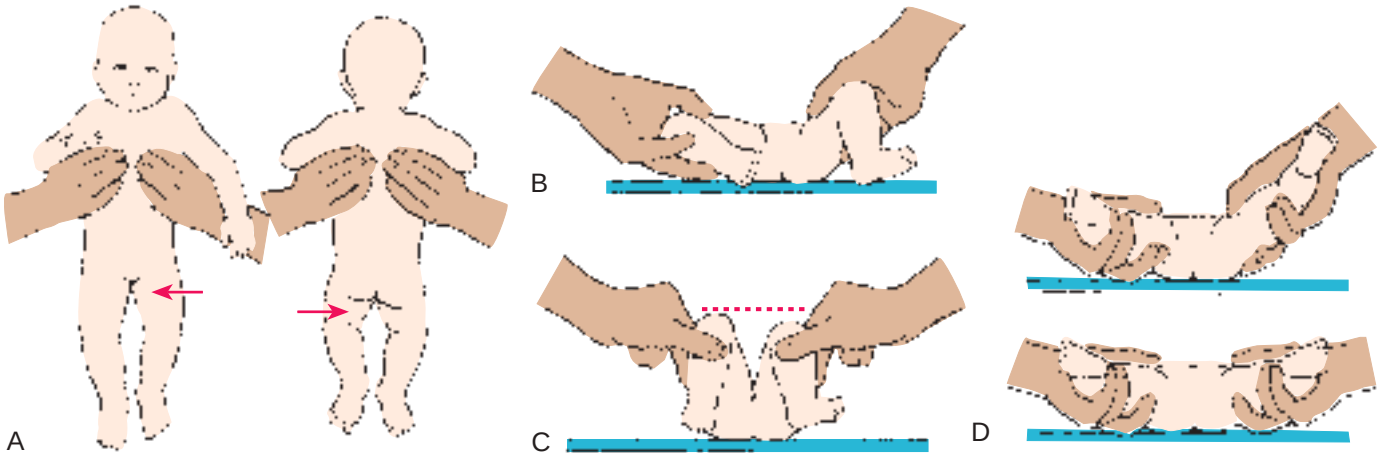

Fig. 25.13 Signs of developmental dysplasia of the hip. **A:** Asymmetry of gluteal and thigh folds with shortening of the thigh (Galeazzi sign). **B:** Limited hip abduction, as seen in flexion (Ortolani test). **C:** Apparent shortening of the femur, as indicated by the level of the knees in flexion (Allis sign). **D:** Ortolani test with femoral head moving in and out of acetabulum (in newborns 1 to 2 months old). (From Hockenberry, M. J., & Wilson, D. [2013]. *Wong's essentials of pediatric nursing* [9th ed.]. Mosby.)

The feet of the newborn can appear to be abnormally positioned. This can indicate a congenital deformity or be related to fetal positioning in utero. For example, clubfoot (talipes equinovarus), a deformity in which the foot turns inward and is fixed in a plantar-flexion position, is a congenital condition that warrants attention. If the foot is turned inward in the plantar-flexion position but can be moved into the normal position, it is likely caused by fetal positioning and should gradually resolve.

Neuromuscular System

The neuromuscular system is almost completely developed at birth. The term newborn is a vital, responsive, and reactive being with a remarkable capacity for social interaction and self-organization.

Growth of the brain after birth follows a predictable pattern of rapid growth during infancy and early childhood; growth becomes more gradual during the remainder of the first decade and minimal during adolescence. The cerebellum ends its growth spurt, which began at about 30 gestational weeks, by the end of the first year.

The brain requires glucose, as a source of energy, and a relatively large supply of oxygen for adequate metabolism. Such requirements signal a need for careful assessment of the newborn's respiratory status. The necessity for glucose requires attentiveness to those newborns who are at risk for hypoglycemia (e.g., newborns of diabetic mothers; newborns who are **macrosomic** or small for gestational age; and newborns experiencing prolonged birth, hypoxia, or preterm birth).

Spontaneous motor activity may be seen as transient tremors of the mouth and chin, especially during crying episodes, and of the extremities, notably the arms and hands. Transient tremors are normal and can be observed in nearly every newborn. These tremors should not be present when the newborn is quiet and should not persist beyond 1 month of age. Persistent tremors or tremors involving the entire body may indicate pathological conditions. Normal tremors, tremors of hypoglycemia, and central nervous system (CNS) disorders need to be differentiated so that corrective care can be instituted as necessary.

To differentiate between tremors or jitteriness and seizure activity, the nurse can consider the following signs (Ditzenberger & Blackburn, 2014):

- Tremors and jitteriness are easily elicited by motions or voice and cease with gentle restraint of the body part, whereas seizure activity continues.
- Seizure activity is associated with ocular changes (eyes deviating or staring) and autonomic changes (apnea, tachycardia, pupil changes, increased salivation); these signs are not associated with jitteriness or tremors.

The posture of the term newborn demonstrates flexion of the arms at the elbows and the legs at the knees. Hips are abducted and partially flexed. Intermittent fisting of the hands is common.

Muscle tone and strength are directly related. The newborn with normal tone and strength exhibits some resistance to passive movement, such as when being pulled to sit or when the arm or leg is extended by the examiner. The hypotonic newborn shows little resistance and can feel like a "rag doll." Hypertonia is evidenced by increased resistance to passive movement.

Newborn Reflexes. The newborn has many primitive reflexes. The times at which these reflexes appear and disappear reflect the maturity and intactness of the developing nervous system. Primary reflexes reflect normal brainstem activity. CNS depression should be suspected if they cannot be elicited or they are persistent beyond a certain age; this suggests damage of cortical functioning. The most common reflexes found in the healthy newborn are described in Table 26.3.

BEHAVIOURAL ADAPTATIONS

The healthy newborn must accomplish behavioural and biological tasks to meet developmental milestones. Behavioural characteristics form the basis of the newborn's social capabilities. Newborns progress through a hierarchy of developmental challenges as they adapt to their environment and caregivers. They must first be able to regulate their physiological or autonomic system, including involuntary physiological functions such as heart rate, respiration, and temperature. The next level is motor organization, in which newborns regulate or control their motor behaviour. This includes controlling random movements, improving muscle tone, and reducing excessive activity. The third level

of behaviour is *state regulation*, which refers to the ability to modulate the state of consciousness. The newborn develops predictable sleep and wake states and is able to react to stress through self-regulation or through communicating with the caregiver by crying and then being consoled. Finally, the infant reaches the fourth level of attention and social interaction. The child is able to attend to visual and auditory stimulation, stay alert for long periods, and engage in social interaction (Brazelton & Nugent, 2011).

This progression in behaviour is the basis for the Brazelton Neonatal Behavioral Assessment Scale (NBAS) (Brazelton & Nugent, 2011). The NBAS is an interactive examination used to assess the infant's response to 28 areas organized according to the clusters in Box 25.2. It is generally used as a research or diagnostic tool and requires special training for use. The NBAS helps the practitioner identify where the infant falls along the continuum of behaviours and determine the type of support needed.

Sleep–Wake States

Healthy newborns differ in their activity levels, feeding patterns, sleeping patterns, and responsiveness. Parents' reactions to their newborns are often determined by these differences. Showing parents the unique characteristics of their newborn can help them develop a more positive perception of the newborn and promote increased interaction between newborn and parent. Newborn responses to environmental stimuli and to their caregivers depend on the newborn's state or state of consciousness.

In the early newborn period infants tend to alternate periods of sleep and wakefulness that resemble their fetal inactivity and activity patterns. Variations in the state of consciousness of newborns are called **sleep–wake states**. The six states form a continuum from deep sleep to extreme irritability (Figure 25.14): two sleep states (deep sleep and light sleep) and four wake states (drowsy, quiet alert, active alert, and crying) (Brazelton & Nugent, 2011). Each state has specific characteristics and state-related behaviours. The optimal state of arousal is the quiet alert state. During this state newborns smile, vocalize, move in synchrony with speech, watch their parents' faces, and respond to people talking to them. They respond to internal and external environmental factors by controlling sensory input and regulating the sleep–wake states; the ability to make smooth transitions between states is called *state modulation*. The ability to regulate sleep–wake states is essential in the newborn's neurobehavioural development. Term newborns are better able than preterm infants to cope with external or internal factors that affect the sleep–wake patterns.

BOX 25.2 Clusters of Neonatal Behaviours in Brazelton Neonatal Behavioural Assessment Scale

- Habituation—Ability to respond to and then inhibit responding to discrete stimulus (e.g., light, rattle, bell, pinprick) while asleep
- Orientation—Quality of alert states and ability to attend to visual and auditory stimuli while alert
- Motor performance—Quality of movement and tone
- Range of state—Measure of general arousal level or arousability of newborn
- Regulation of state—How newborn responds when aroused
- Autonomic stability—Signs of stress (e.g., tremors, startles, skin colour) related to homeostatic (self-regulator) adjustment of the nervous system
- Reflexes—Assessment of several newborn reflexes

From Brazelton, T., & Nugent, J. (2011). *Neonatal behavioural assessment scale* (4th ed.). MacKeith.

Fig. 25.14 Newborn sleep–wake states. **A:** Deep sleep. **B:** Light sleep. **C:** Drowsy. **D:** Quiet alert. **E:** Active alert. **F:** Crying. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

Newborns use purposeful behaviour to maintain the optimal arousal state as follows: (1) actively withdrawing by increasing physical distance, (2) rejecting by pushing away with hands and feet, (3) decreasing sensitivity by falling asleep or breaking eye contact by turning the head, or (4) using signalling behaviours such as fussing and crying. These behaviours permit the newborn to quiet themselves and reinstate readiness to interact.

The first 6 weeks of life involve a steady decrease in the proportion of active REM sleep to total sleep. A steady increase in the proportion of quiet sleep to total sleep also occurs. Periods of wakefulness increase. For the first few weeks the wakeful periods seem dictated by hunger, but soon a need for socializing appears. The newborn sleeps on average approximately 17 hours a day, with periods of wakefulness gradually increasing. By the fourth week of life some infants stay awake from one feeding to the next.

Other Factors Influencing Behaviour of Newborns

Gestational Age. Gestational age and level of CNS maturity affect newborn behaviour. In the preterm newborn with an immature CNS, the entire body responds to a pinprick of the foot, although the response may not be observed by an untrained observer. The more mature newborn withdraws only the foot. CNS immaturity is reflected in reflex development, sleep–wake states, and ability (or lack thereof) to regulate or modulate a smooth transition between different states. Preterm infants have brief periods of alertness but have difficulty maintaining alertness without becoming overstimulated, which leads to autonomic instability unless intervention is implemented. Premature or sick newborns show signs of fatigue or physiological stress sooner than full-term healthy newborns.

Time. The time elapsed since birth affects the behaviour of newborns as they attempt to become organized initially. Time elapsed since the previous feeding and time of day also can influence newborns' responses.

Stimuli. Environmental events and stimuli affect newborns' behavioural responses. The newborn responds to animate and inanimate stimuli. Nurses in neonatal intensive care nurseries have observed that newborns respond to loud noises, bright lights, monitor alarms, and tension in the unit.

Medication. No conclusive evidence exists regarding the effects of maternal analgesia or anaesthesia during labour on newborn behaviour. Researchers who have studied the effects of epidural medications on breastfeeding behaviours have been unable to show a cause-and-effect relationship (Hoyt & Pages-Arroyo, 2015).

Sensory Behaviours

From birth, newborns possess sensory capabilities that indicate a state of readiness for social interaction. Newborns effectively use behavioural responses in establishing their first dialogues. These responses, coupled with the newborns' "baby appearance" (e.g., facial proportions of forehead and eyes larger than the lower part of the face) and their small size and helplessness, evoke feelings of wanting to hold and protect them and to interact with them.

Vision. At birth, the eye is structurally incomplete and the muscles are immature. The process of accommodation is not present at birth but improves over the first 3 months of life. The pupils react to light, the blink reflex is easily stimulated, and the corneal reflex is activated by light touch. Term newborns can see objects as far away as 50 cm. The clearest visual distance is 17 to 20 cm, which is about the distance the newborn's face is from the parent's face as they breastfeed or cuddle. Newborns seem to have a preference for faces and can recognize the mother's face. This facilitates interaction and promotes bonding. They will engage their caregiver with eye contact. Newborns can imitate facial expressions and motions such as protruding the tongue (Gardner & Edward-Goldson, 2021). Newborns prefer complex patterns over nonpatterned stimuli. They prefer black and white, possibly because of the greater contrast. Within 2 to 3 months, they can discriminate colours.

Response to movement is noticeable. If a bright light is shown to newborns (even at 15 minutes of age), they will follow it visually; some will even turn their heads to do so. Because human eyes are bright, shiny objects, newborns will track their parents' eyes. Parents often comment on how exciting this behaviour is. The development of eye-to-eye contact is important for parent–newborn attachment. Children of blind parents and parents who have blind children develop strategies to help assist in developing this relationship.

Hearing. As soon as the amniotic fluid drains from the ears, the newborn's hearing is similar to that of an adult. Loud sounds of about 90 decibels cause the newborn to react with a Moro reflex. Term newborns can hear and differentiate among various sounds. They will turn toward a sound and attempt to locate the source. The newborn recognizes and responds readily to a parent's voice and shows a preference for high-pitched intonation. Newborns respond to rhythmic sounds. They are accustomed to hearing the regular rhythm of the mother's heartbeat, which was a constant sound during intrauterine life. As a result, they respond by relaxing and ceasing to fuss and cry if a regular heartbeat simulator is placed in their cribs; a lullaby can have the same effect. Hearing is integral to bonding and attachment and may be more important than vision (Gardner & Edward-Goldson, 2021).

Routine hearing screening is recommended for all newborns before hospital discharge, although it is not mandatory in all provinces. See Chapter 26 for a discussion about screening of newborn hearing.

Smell. Newborns have a highly developed sense of smell and can detect and discriminate distinct odours. It has been shown that preterm newborns as early as 28 weeks are capable of reacting to odours. They react to strong odours, such as alcohol or vinegar, by turning their heads away but are attracted to sweet smells. Breastfed newborns are able to smell breast milk and can differentiate their mother from other lactating women by the smell (Lawrence & Lawrence, 2016).

Taste. The newborn can distinguish among tastes, and various types of solutions elicit differing facial expressions. A tasteless solution produces no response, a sweet solution elicits eager sucking, a sour solution causes puckering of the lips, and a bitter liquid produces a grimace.

Newborns are particularly oriented toward the use of their mouths, both for meeting their nutritional needs for rapid growth and for releasing tension through sucking. The early development of circumoral sensation, muscle activity, and taste would seem to be preparation for survival in the extrauterine environment.

Touch. The newborn is responsive to touch on all parts of the body. The face (especially the mouth), hands, and soles of the feet appear to be the most sensitive. Reflexes can be elicited by stroking the newborn. The newborn's responses to touch suggest that this sensory system is well prepared to receive and process tactile messages (Gardner & Edward-Goldson, 2021). Touch and motion are essential to normal growth and development, and newborn massage is a way to increase tactile stimulation. However, each newborn is unique, and variations can be seen in responses to touch. Birth trauma or stress and depressant

medications taken by the mother decrease the newborn's sensitivity to touch or painful stimuli. Multiple studies have demonstrated the benefits of skin-to-skin care immediately after birth.

Response to Environmental Stimuli

Temperament. Each newborn has a unique repertoire of behaviours that are influenced by various factors including temperament, sensory threshold, ability to habituate, and consolability. *Temperament* refers to individual variations in the reaction pattern of newborns. Newborns possess individual characteristics that affect selective responses to various stimuli present in the internal and external environments. Some newborns appear to be quiet by nature and can remain still for extended periods. Their movements may be smooth and relaxed most of the time, and they have little difficulty settling down for feeding. Other newborns are more active and seem to be in constant motion; they seem to be excited and interested in exploring the faces and sounds around them. These newborns often need help to settle; containment (swaddling), physical contact, and boundaries surrounding the newborn in the crib can facilitate a quiet alert state (Nugent et al., 2007).

Habituation. *Habituation* is a protective mechanism that allows the newborn to become accustomed to environmental stimuli. Habituation is a psychological and physiological phenomenon in which the response to a constant or repetitive stimulus is decreased. In the term newborn, this can be demonstrated in several ways. Shining a bright light into a newborn's eyes causes a startle or squinting the first two or three times. The third or fourth flash elicits a diminished response, and by the fifth or sixth flash the newborn ceases to respond (Brazelton & Nugent, 2011). The same response pattern holds true for the sounds of a rattle or stroking the bottom of the foot.

The ability to habituate allows the healthy term newborn to select stimuli that promote continued learning about the social world, thus avoiding overload. The intrauterine environment appears to have programmed the newborn to be especially responsive to human voices, soft lights, soft sounds, and sweet tastes.

The newborn quickly learns the sounds in the home environment and is able to sleep in their midst. The selective responses of the newborn indicate cerebral organization capable of memory and making choices. The ability to habituate depends on the state of consciousness, hunger, fatigue, and temperament. These factors also affect consolability, cuddliness, irritability, and crying.

Consolability. Newborns vary in the ability to console themselves or be consoled. In the crying state most newborns initiate one of several ways to reduce their distress. Hand-to-mouth movements with or without sucking and being alert to voices, noises, or visual stimuli are common. Some newborns are consoled only if they are held and rocked (Brazelton & Nugent, 2011).

Cuddliness. Cuddliness is especially important to parents because they often gauge their ability to care for the child by the child's responses to their actions. The degree to which newborns mould into the contours of the person holding them varies. One extreme is the newborn who always resists being held with thrashing and stiffening of the body. This is in contrast to the newborn who immediately relaxes when held and moulds to the body of the person. Less extreme behaviour is demonstrated by newborns who are passive when held and those who gradually mould after being held for a while (Brazelton & Nugent, 2011).

Irritability. Some newborns cry longer and harder than others. For some, the sensory threshold seems low. They are readily upset by unusual noises, hunger, wetness, or new experiences and thus respond intensely. Others with a high sensory threshold require a great deal more stimulation and variation to reach the active, alert state.

Crying. Crying is the language a newborn uses most often to communicate needs. It may signal hunger, discomfort, pain, desire for attention, or fussiness. Newborns may cry in response to environmental stimuli such as cold, being overstimulated, or being held by multiple persons. Responsiveness of the caregiver to the crying creates trust as the newborn learns to associate the caregiver with comfort.

The amount and tone of crying vary based on gestational age, weight, and the reason for the cry (e.g., hunger, pain). A high-pitched cry can be a sign of a neurological disorder. Some mothers state that they learn to distinguish among the cries. The breastfeeding mother's body responds physiologically to newborn crying by stimulating the milk-ejection reflex ("let-down").

The duration of crying also varies greatly in each infant; newborns may cry for as little as 5 minutes or as much as 2 hours or more per day. The amount of crying peaks in the second month and then decreases. There is a diurnal rhythm of crying, with more crying occurring in the evening hours.

Parents need to learn that most crying is normal and a way for the newborn to communicate their needs. Some parents who are exhausted and overwhelmed can become frustrated with a baby who cries excessively. Parents need to be taught to recognize when they have reached their limit and that if this occurs, it is important to put the newborn in a safe place and take a few minutes away from the baby. See further discussion on interpretation of crying in Chapter 26.

KEY POINTS

- By full term, the newborn's various anatomical and physiological systems have reached a level of development and functioning that permits a physical existence apart from the mother.
- The newborn's most critical adaptation to extrauterine life is to establish effective respirations.
- Heat loss in the healthy term newborn may exceed the capacity to produce heat; this can lead to metabolic and respiratory complications that threaten the newborn's well-being.
- Physiological jaundice occurs in 60% of term newborns and 80% of preterm newborns.
- The appearance of jaundice during the first day of life or persistence of jaundice beyond 7 to 10 days may indicate a pathological process that requires further investigation.
- Some reflex behaviours are important for the newborn's survival.
- The healthy newborn has sensory abilities that indicate a state of readiness for social interaction. Sleep–wake states and other factors influence the newborn's behaviour.
- Newborn behaviour progresses from self-regulation of autonomic processes to social interaction.
- Each full-term newborn has a predisposed capacity to handle the multitude of stimuli in the external world.

Nursing Care of the Newborn and Family

Jennifer Marandola

Originating US Chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Explain the purpose and components of the Apgar score.
2. Provide nursing care to assist the newborn to transition to extrauterine life.
3. Describe a systematic approach to assessment of the newborn.
4. Recognize newborn reflexes and differential characteristic responses from abnormal responses.
5. Describe how to perform a gestational-age assessment of a newborn.
6. Compare the characteristics of preterm, late preterm, term, and post-term newborns.
7. Explain the elements of a providing a safe environment for a newborn.
8. Discuss jaundice and phototherapy and the guidelines for teaching parents about this condition and treatment.
9. Explain the purposes and methods of circumcision, the post-operative care of the circumcised newborn, and parent teaching information regarding care of the circumcised or uncircumcised penis.
10. Review the procedures for performing an intramuscular injection, performing a heel stick, collecting urine specimens, and venipuncture.
11. Evaluate pain in the newborn based on physiological changes and behavioural observations and provide pain management strategies.
12. Review anticipatory guidance that nurses provide parents before discharge.

Although most newborns make the necessary biopsychosocial adjustment to extrauterine existence without undue difficulty, their well-being depends on the care they receive from others. This chapter describes the assessment and care of the newborn from immediately after birth until discharge, as well as important anticipatory guidance related to ongoing infant care.

BIRTH THROUGH THE FIRST 2 HOURS

Nursing Care

Care begins immediately after birth and is focused on assessing and stabilizing the newborn's condition if required. The nurse works alongside the primary health care provider to ensure a safe transition. The foundation for providing comprehensive, family–newborn care is awareness of preconception and prenatal history as well as intrapartal events. Recognition of risk factors (Box 26.1) enables the nurse to be more astute in observations and assessments and more likely to identify early signs of complications. This allows for earlier intervention and promotes positive outcomes.

Immediate Care After Birth

The primary goal of care in the first moments after birth is to assist the newborn in their transition to extrauterine life by establishing effective respirations. If the newborn is at term, is crying or breathing, and has good muscle tone, routine care can begin. The newborn is placed prone on the parent's chest, and the nurse assesses the airway. Drying the newborn with rubbing removes moisture to prevent evaporative heat loss and provides tactile stimulation to encourage respiratory effort. The parent and newborn are covered with a warm blanket. It is important to ensure that the blanket allows for the newborn to have an unrestricted ability to lift their thorax and head and that an unobstructed airway is maintained.

The heart rate is quickly assessed by auscultating the left chest with a stethoscope. The heart rate can also be felt through palpation at the base of the umbilical cord, although this has been proven in recent years to be less accurate and underestimates the true heart rate (Weiner & Zaichkin, 2016). The heart rate should be greater than 100 beats per minute (bpm). The newborn's trunk and lips should be pink; acrocyanosis is a normal finding (see Figure 25.1).

BOX 26.1 Assessment of Preconception, Prenatal, and Intrapartum Risk Factors

Preconception

- Age of childbearing person
- Pre-existing medical conditions: Diabetes, hypertension, cardiac disease, anemia, thyroid disorder, renal disease, obesity
- Genetic factors: Family history
- Obstetrical history: Gravidity, parity, number of living children and their ages, history of stillbirth, previous newborn with congenital anomalies, recurrent abortions, use of assisted human reproduction, interpregnancy spacing

Prenatal

- Prenatal care: When started
- Nutrition: Weight gain, diet, obesity, eating disorders
- Health-compromising behaviours: Smoking, alcohol or substance use
- Blood group or Rh sensitization
- Medications: Prescription, over-the-counter, and complementary/alternative medications
- History of infection: Sexually transmitted infections, TORCH infections,* group B streptococci status

Intrapartum

- Length of gestation: Preterm, late preterm, term, or post-term
- First stage of labour: Length, internal electronic fetal monitoring, rupture of membranes (time, presence of meconium), signs of fetal distress, labour complications (bleeding [placental abruption or placenta previa]), maternal analgesia or anaesthesia
- Group B streptococci status: Treatment during labour
- Second stage of labour: Length, vaginal or Caesarean, instrument assisted—forceps or vacuum extractor, complications (e.g., shoulder dystocia, cord prolapse)

*TORCH is the collective name for *t*oxoplasmosis, *o*ther infections (e.g., hepatitis), *r*ubella virus, *c*ytomegalovirus (CMV), and *h*erpes simplex virus (see further discussion in Chapter 29).

Adapted from Hurst, H. M. (2015). Antepartum-intrapartum complications. In T. M. Verklan & M. Walden (Eds.), *Core curriculum for neonatal intensive care nursing* (5th ed.). Saunders.

All newborns require the initial steps of resuscitation, drying, and stimulation after birth. If the newborn does not respond to initial measures or requires more aggressive respiratory or circulatory support, the nurse and other members of the health care team (e.g., attending physician or midwife, pediatrician, neonatal nurse practitioner, respiratory therapist) will perform interventions as outlined in systematic algorithms (Figure 26.1) (Finan et al., 2017).

As soon as possible after birth the nurse must place identically numbered bands on the newborn and mother, and in some hospitals these are put on both parents. As part of routine precautions, with the possibility of transmission of viruses such as hepatitis B virus and human immunodeficiency virus (HIV) via blood and blood-stained amniotic fluid, the nurse should wear gloves when handling the newborn until blood and amniotic fluid are removed by bathing. Gloves should be worn when conducting physical assessments, when in contact with breast milk, during routine diaper changes, and at any time contact with body fluids may be evident.

Apgar Scoring. The *Apgar score* enables a rapid assessment of the newborn's transition to extrauterine existence on the basis of five signs indicating the newborn's physiological state: (1) heart rate, based on **auscultation** with a stethoscope or **palpation** of the umbilical cord; (2) respiratory rate, based on observed movement or auscultation of respiratory efforts; (3) muscle tone, based on degree of flexion and movement of the extremities; (4) reflex irritability, based on response to stimulation; and (5) generalized skin colour, described as pallid, cyanotic, or pink (Table 26.1). Evaluations are made at 1 and 5 minutes after birth and can be done by the nurse or birth attendant. Scores of 0 to 3 indicate severe distress, scores of 4 to 6 indicate moderate difficulty, and scores of 7 to 10 indicate that the newborn is having minimal or no difficulty adjusting to extrauterine life. The Apgar score is reassessed at 10 and 20 minutes if the score is less than 7 at 5 minutes. Apgar scores do not predict future neurological outcome but are useful for describing the newborn's transition to the extrauterine environment. Resuscitation may occur at any point when the newborn is compromised and should not wait until the initial 1-minute Apgar score (Weiner & Zaichkin, 2016). All births require health care providers who are in attendance to be certified in neonatal resuscitation program (NRP). Intervention steps are outlined in the algorithm in Figure 26.1.

Initial Physical Assessment. The nurse will complete a brief physical examination shortly after birth (Box 26.2). The first assessment can often be done while the newborn is skin-to-skin with the parent. If the newborn is vigorous, Apgar scoring and further assessments can be conducted while respecting this intimate time. Skin-to-skin contact enhances the newborn's transition to extrauterine life and initial bonding. Breastfeeding should begin shortly after birth (World Health Organization [WHO], 2019). Should the dyad be separated for stability purposes, the partner may have skin-to-skin contact with the newborn (Figure 26.2). Healthy newborns should remain with their parent(s) throughout the hospital stay, although some newborns who require extra care may be admitted to a nursery.

Early contact between parent and newborn can be important in developing their and their child's future relationships. It also has a positive effect on breastfeeding. Physiological benefits of early skin-to-skin contact include increased oxytocin and prolactin levels in the childbearing person and initiation of suckling activity in the newborn. The process of developing active immunity begins as the newborn ingests flora from the colostrum.

Interventions

Changes can occur rapidly in the compromised newborn immediately after birth. Assessment must be followed by implementation of appropriate care.

Airway Maintenance. Generally, the healthy term newborn born vaginally has little difficulty clearing the airway. Most secretions are moved by gravity and brought by the cough reflex to the oropharynx to be drained or swallowed and suctioning is rarely necessary. The newborn who has difficulty clearing mucus from the airway may initially be placed in a side-lying position (head stabilized, not in Trendelenburg position) until secretions are cleared, and then placed supine. It is important to explain to parents that this is a temporary measure as well as the rationale for the side-lying position: to clear mucus. Parents must be instructed that newborns are normally placed on their backs when sleeping.

The newborn who is choking on secretions should be supported with the head to the side or by initiating the first steps in newborn cardiopulmonary resuscitation (CPR), by tapping between the newborn's shoulders while holding firmly in a slightly downward motion to optimize gravity for the expulsion of mucus. If needed, the mouth is suctioned first to prevent the newborn from inhaling pharyngeal secretions when gasping, as newborns are obligatory nose breathers. The centre of the newborn's mouth should be avoided to prevent

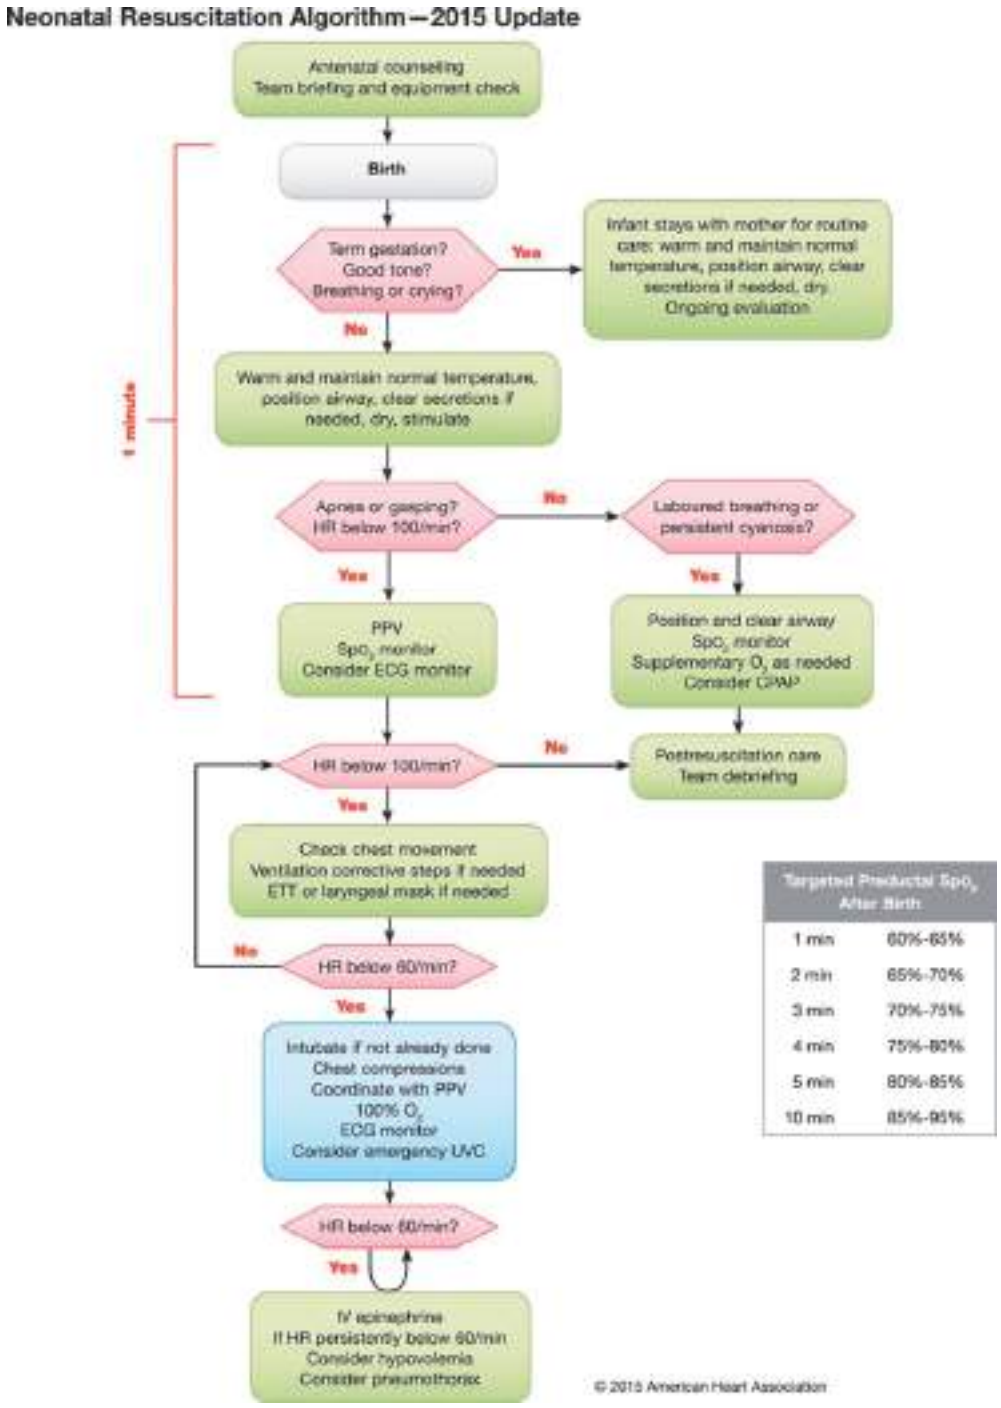

Fig. 26.1 Neonatal resuscitation algorithm. *CPAP,* Continuous positive airway pressure; *ECG,* electrocardiogram; *ETT,* endotracheal tube; *HR,* heart rate; *IV,* intravenous; *PPV,* positive pressure ventilation; *SpO_2,* oxygen saturation; *UVC,* umbilical venous catheter. (Source: Weiner, G., & Zaichkin, J. [2016]. *Textbook of neonatal resuscitation* [7th ed.]. American Academy of Pediatrics.)

stimulation of the gag reflex. The nasal passages are suctioned one nostril at a time. It is important that hospital rooms have suctioning equipment available for use.

The nurse should listen to the newborn's respirations and auscultate lung sounds with a stethoscope to determine whether there are crackles, rhonchi, or inspiratory stridor. Fine crackles may be auscultated for several hours after birth. If air movement is adequate, suctioning is rarely necessary. If mucus is interfering with respiratory effort, mechanical suctioning may be necessary. If the newborn has an obstruction that is not cleared with suctioning, the pediatric care provider should be notified for further investigation to determine whether there is a mechanical defect (e.g., tracheoesophageal fistula, choanal atresia) causing the obstruction.

Deeper suctioning may be necessary to remove mucus from the newborn's nasopharynx or posterior oropharynx; however, this should be performed only after assessment of the risks involved. Prevention of

TABLE 26.1 Apgar Score

Sign	SCORE 0	1	2
Heart rate	Absent	Slow (<100 beats/min)	≥100 beats/min
Respiratory rate	Absent	Slow (hypoventilation), weak cry	Good, crying
Muscle tone	Flaccid	Some flexion of extremities	Well flexed
Reflex irritability	No response	Grimace	Cry or active withdrawal
Colour	Blue, pale	Body pink, extremities blue	Completely pink

vagal stimulation and hypoxia in the newborn is ensured by proper catheter insertion and keeping suctioning to 5 seconds or less. If wall suction is used, the pressure should be adjusted to less than 80 mm Hg. After the catheter is properly placed, suction is created by placing one's thumb over the control as the catheter is carefully rotated and gently withdrawn. This procedure may need to be repeated until the newborn has a clear airway.

Four conditions are essential for maintaining an adequate oxygen supply:

1. A clear airway
2. Effective establishment of respirations
3. Adequate circulation, adequate perfusion, and effective cardiac function
4. Adequate thermoregulation (exposure to cold stress increases oxygen and glucose needs)

Signs of potential complications related to abnormal newborn breathing are listed in Box 26.3.

Fig. 26.2 Father and newborn skin-to-skin. (Courtesy Fraser Health.)

BOX 26.3 Signs of Potential Complications

Abnormal Newborn Breathing

Bradypnea—Respirations (less than 30 breaths/min)
Tachypnea—Respirations (60 breaths/min or more)
Abnormal breath sounds—Crackles (fine crackles may be heard in first few hours after birth), wheezing, rhonchi, expiratory grunting, stridor, diminished or absent air movement
Respiratory distress—Nasal flaring, retractions (substernal or intercostals), stridor, gasping, apnea lasting 20 seconds or longer
Seesaw or paradoxical respirations
Skin colour—Cyanosis, mottling
Pulse oximetry value less than 95%

BOX 26.2 Initial Physical Assessment of Newborn by Body System

General Appearance

- Colour:
  - Pink
  - Acrocyanosis
- Alert
- Active

Neurological System

- Newborn moves all four extremities; flexion, muscle tone appropriate
- Symmetrical features, movement
- Moro, suck, rooting, and grasp reflexes present
- Anterior fontanel soft and flat

Cardiovascular System

- Heart auscultation, regular in rate and rhythm
- No murmurs heard
- Pulses strong, equal bilaterally

Respiratory System

- Lungs auscultated, clear bilaterally with minimal fine crackles shortly after birth
- Respiratory rate less than 60 breaths/min
- Respiratory effort nonlaboured
- Chest expansion symmetrical
- Absence of nasal flaring, grunting, retractions

Skin

- Skin lesions or abrasions documented
- Birthmarks documented
- Caput/moulding
- Other _____

Eyes, Ears, Nose, and Throat

- Eyes clear
- Palates intact
- Nares patent
- Ears in place; correct alignment

Genitourinary System

- Male: Urethral opening at tip of penis, testes descended bilaterally
- Female: Labia minora and majora intact, hymenal tag may be visible

Gastrointestinal System

- Abdomen soft, no visible distension
- Cord attached and clamped
- Anus patent

Maintaining Body Temperature. Effective newborn care includes maintenance of an optimal thermal environment (see Chapter 25, Thermogenic System). Newborns lose heat via evaporation, radiation, conduction, and convection (see Figure 25.2). Cold stress increases the need for oxygen and may deplete glucose stores. The newborn may react to exposure to cold by increasing the respiratory rate and may become cyanotic. The ideal way of promoting warmth and maintaining newborn body temperature is for the newborn to have early skin-to-skin contact with the parents. The naked newborn is placed prone directly on the parent's chest and covered with a warm blanket (see Figure 26.2). Early skin-to-skin contact has distinct short- and long-term benefits, including temperature stabilization, reduced crying, improved breastfeeding initiation and duration, and newborn–maternal attachment (Bramson et al., 2010; Gabriel et al., 2010; Moore et al., 2016). Other interventions to promote warmth include keeping the head well covered and keeping the ambient temperature of the room at 22° to 26°C (72° to 78°F).

Newborns should not be separated from their parents, but if they are, for instance, because of a medical condition, the nurse should place the thoroughly dried newborn under a radiant warmer or in a warm isolette until the body temperature stabilizes. The newborn's skin temperature is used as the point of control when using a warmer with a servocontrolled mechanism. The control panel usually is kept at between 36° and 37°C. This setting should maintain the healthy term newborn's skin temperature at around 36.5° to 37°C. A thermistor probe (automatic sensor) is usually placed on the upper quadrant of the abdomen immediately below the right or left costal margin (never over a bone); a reflector adhesive patch may be used over the probe to provide adequate warming. This probe is designed to detect minor temperature changes resulting from external environmental factors or newborn factors (peripheral vasoconstriction, vasodilation, or increased metabolism) before a dramatic change in core body temperature develops. The servocontroller adjusts the warmer temperature to maintain the newborn's skin temperature within the preset range. The sensor needs to be checked periodically to ensure that it is securely attached to the newborn's skin. The newborn's axillary temperature should be checked every hour (or more often as needed) until their temperature stabilizes. The length of time required to stabilize and maintain body temperature varies; each newborn should be allowed to achieve thermal regulation as necessary, and care should be individualized. See the Evolve website for more information on thermoregulation using a radiant warmer.

During all procedures, heat loss must be avoided or at least minimized for the newborn. The initial bath should be postponed until the newborn's skin temperature is stable and can adjust to heat loss from a bath. For every newborn, the optimal timing of the bath varies and should be individualized according to the newborn's ability to maintain a stable body temperature, which can often take 8 hours or more. In some hospitals, baths are not done until after 24 hours and many newborns are discharged by this time.

Even a healthy term newborn can become hypothermic: birth in a car on the way to the hospital, a cold birthing room, or inadequate drying and wrapping immediately after birth may cause the newborn's temperature to fall below normal range (**hypothermia**). Warming the hypothermic newborn should be done with care, as rapid warming may cause apnea and acidosis in a newborn. The warming process needs to be monitored to progress slowly over a period of 2 to 4 hours.

Eye Prophylaxis. **Ophthalmia neonatorum** is an inflammation of the eyes from gonorrheal or chlamydial infection, contracted by the newborn during passage through the birth canal. Instillation of erythromycin ointment as a prophylactic agent in the eyes

Fig. 26.3 Instillation of medication into eye of newborn. The thumb and forefinger are used to open the eye; medication is placed in the lower conjunctiva from the inner to outer canthus. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

(Figure 26.3) to prevent this condition has been recommended practice and is mandatory by law in most provinces and territories. It may be delayed until 2 hours after birth, to facilitate eye contact and parent–newborn attachment and bonding (see Medication Guide Eye Prophylaxis With Erythromycin Ophthalmic Ointment). Topical antibiotics such as tetracycline and erythromycin, and a 2.5% povidone-iodine solution are not effective in the treatment of chlamydial conjunctivitis.

The Canadian Paediatric Society (CPS), however, does not recommend continuing this practice, based on current evidence (Moore et al., 2015/2016). The CPS (2019) states that ocular prophylaxis with erythromycin has limited or no effect in preventing chlamydia conjunctivitis. Treatment of exposed asymptomatic newborns with a systematic macrolide is not indicated. There has been a national shortage of erythromycin ointment and the CPS has developed recommendations because of this shortage (CPS, 2019):

- If the patient was tested during pregnancy and found to be negative: No further action is necessary, unless the parent is considered to be at high risk of acquiring gonococcus after the test was done.
- If the pregnant patient is at high risk for exposure to gonococcus after the last testing, OR tested positive for gonococcus in pregnancy and was treated but not followed up, OR was not tested in pregnancy: Test the postpartum patient immediately after birth.
  - After the birth, if close follow-up of the newborn can be ensured, the newborn may be discharged while awaiting results.
  - ONLY if close follow-up of the newborn pending test results cannot be assured AND it is NOT possible for the newborn to remain in the hospital while awaiting results, a dose of intramuscular ceftriaxone (50 mg/kg to a maximum of 125 mg) should be given to the newborn before discharge.
- If the pregnant patient tested positive for gonococcus in pregnancy but was not treated, and the baby is asymptomatic: Assume the newborn is infected. Test a conjunctival specimen for gonococcus, and treat the newborn with a single dose of ceftriaxone, pending test results.

Ontario has changed the legislation regarding prophylactic eye ointment to allow parents to opt out of the treatment if a written request is

made to their health care provider and if the parents have made an informed decision and the newborn is not at risk for ophthalmia neonatorum (Ontario Ministry of Health and Long-Term Care, 2018).

MEDICATION GUIDE

Eye Prophylaxis With Erythromycin Ophthalmic Ointment 0.5%

Action
Erythromycin is an antibiotic ointment that is are both bacteriostatic and bactericidal.

Indication
This medication is presently used for the prevention of ophthalmia neonatorum in newborns who have been in contact with gonorrhea and chlamydia when passing through the vaginal canal of an infected parent, although recent research does not support this practice (Moore et al., 2015/2016). It is important to have a discussion with the parents regarding recent evidence and provincial or territorial guidelines.

Newborn Dosage
Apply a 1- to 2-cm ribbon of ointment to the lower conjunctival sac of each eye; the medicines may also be used in drop form.

Adverse Reactions
They may cause chemical conjunctivitis that lasts 24 to 48 hours; vision may be blurred temporarily.

Nursing Considerations
Refer to hospital policy regarding the administration of erythromycin and guidelines related to parental refusal of the medication. Explain treatment to parents. Administer within 2 hours of birth. Wear gloves. Cleanse eyes if necessary, before administration. Open eyes by putting a thumb and finger at the corner of each lid and gently pressing on the periorbital ridges. Squeeze the tube and spread the ointment from the inner canthus of the eye to the outer canthus. Do not touch the tube to the eye. After 1 minute, excess ointment may be wiped off. Observe eyes for irritation.

Vitamin K Prophylaxis. Administration of vitamin K intramuscularly is routine in the newborn period to prevent hemorrhagic disease of the newborn (HDNB). Vitamin K is synthesized by intestinal flora, which are not present at birth. The introduction of bacteria begins with the first feedings; by day 7, healthy newborns are able to produce their own vitamin K (see Medication Guide Vitamin K: Phytonadione).

MEDICATION GUIDE

Vitamin K: Phytonadione

Action
Vitamin K promotes formation of clotting factors (II, VII, IX, and X) in the liver.

Indication
Vitamin K is used for prevention and treatment of hemorrhagic disease in the newborn (HDNB). This is necessary, as the newborn does not have the intestinal flora to produce this vitamin in the first week after birth.

Newborn Dosage
A single intramuscular injection of 1.0 mg of vitamin K for babies weighing greater than or equal to 1 500 g and 0.5 mg for those less than 1 500 g is given within 6 hours after birth and following initial stabilization and appropriate parental–newborn interaction (Ng et al., 2018). The oral vitamin K is not recommended; however, if parents request an alternative route, an oral dose of 2.0 mg vitamin K can be given at the first feeding, to be repeated at 2 to 4 and 6 to 8 weeks of age. Parents should be advised of the importance of the newborn receiving follow-up doses and be cautioned that their newborn remains at increased risk of late HDNB (including the potential for intracranial hemorrhage) with oral dosing (Ng et al., 2018). The parenteral form of vitamin K for oral administration is all that is currently available.

Adverse Reactions
Edema, erythema, and pain at the injection site may occur rarely; hemolysis, jaundice, and hyperbilirubinemia have been reported, particularly in preterm newborns.

Nursing Considerations
If an oral dose is given, ensure that parents know the importance of follow-up and that the newborn is at increased risk for HDNB.

Intramuscular Injection
Selection of the appropriate equipment and site for intramuscular injection is important. In most cases, a 25-gauge, 16-mm (5/8-inch) to 22-mm (7/8-inch) needle is used. Injections must be given in muscles large enough to accommodate the medication, and major nerves and blood vessels must be avoided. The muscles of newborns may not tolerate more than 0.5 mL per intramuscular injection. The preferred injection site for newborns is the vastus lateralis (Figure 26.4). The dorsogluteal muscle is very small, poorly developed, and dangerously close to the sciatic nerve, which occupies a proportionately larger area in newborns than in older children. Therefore, it is not recommended as an injection site in small children. The newborn's deltoid muscle has an inadequate amount of muscle for intramuscular administration. A key factor in preventing and minimizing local reaction to intramuscular injections is adequate deposition of the medication deep within the muscle; therefore, muscle size, needle length, and amount of medication injected should be carefully considered.

The nurse performs hand hygiene prior to putting on nonsterile gloves. The newborn's leg should be stabilized. The nurse cleanses the injection site with an appropriate skin antiseptic and then stabilizes the newborn's muscle between the thumb and forefinger. The needle is inserted into the vastus lateralis at a 90-degree angle. The medication is injected slowly. After the medication is injected, the nurse withdraws the needle quickly and places a dry gauze pad over the site, applying gentle pressure to minimize pain and bleeding.

The nurse must discard the equipment properly. Needles are never recapped but are properly discarded in an appropriate safety container. The name of the medication, date and time, amount, route, and site of injection are documented in the newborn's record. Parents should be encouraged to comfort the newborn during or after the procedure with skin-to-skin contact, cuddling, or breastfeeding.

NURSING ALERT

Vitamin K is never administered via intravenous (IV) route for prevention of HDNB except in some cases of a preterm newborn who has no muscle mass. In such cases, the medication should be diluted and given over 10 to 15 minutes. The preterm newborn should be closely monitored with a cardiorespiratory monitor as rapid bolus administration of vitamin K may cause cardiac arrest.

CARE OF THE NEWBORN FROM 2 HOURS AFTER BIRTH UNTIL DISCHARGE

Nursing Care

In most hospitals one nurse provides care for both the postpartum parent and newborn (couplet). The nurse caring for the parent–newborn

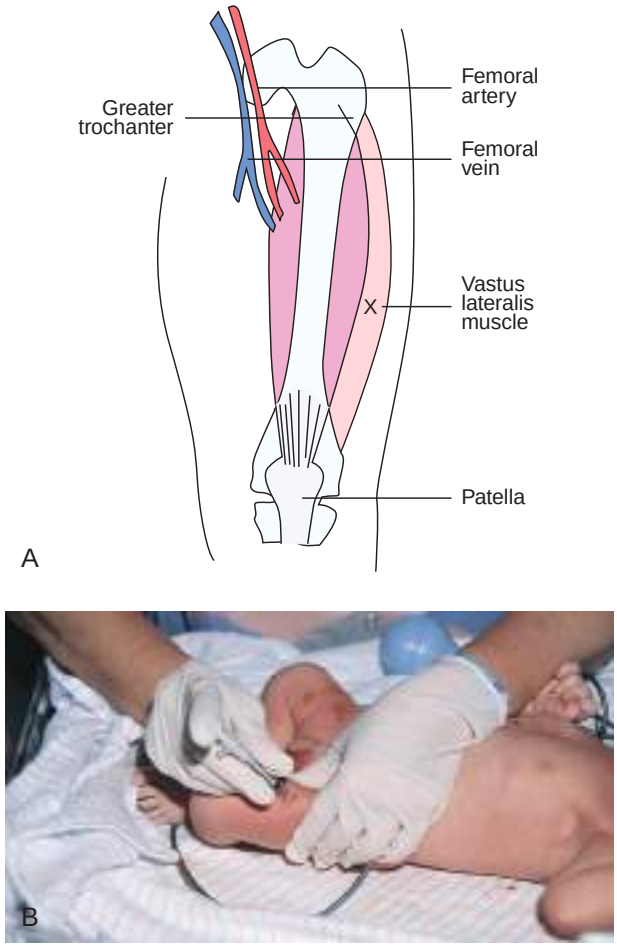

Fig. 26.4 Intramuscular injection. **A:** Acceptable intramuscular injection site (X) for newborn. **B:** Newborn's leg being stabilized for intramuscular injection. The nurse is wearing gloves to give the injection. (*B*, Courtesy Marjorie Pyle, RNC, Lifecircle.)

couplet is responsible for ongoing assessment and care of the newborn. Astute assessment skills and appropriate interventions promote positive outcomes, especially for newborns who experience any complications before going home. Newborn care is family centred, as the nurse provides education and support for the new parents throughout the hospital stay and assists them in preparing for hospital discharge. See Evolve for Nursing Care Plan of Healthy Newborn.

Gestational-Age Assessment. Assessment of **gestational age** is important because perinatal morbidity and mortality rates are related to gestational age and birth weight. A frequently used method of determining gestational age is the New Ballard score, which can be used to measure gestational ages of newborns as young as 20 weeks up to 36 weeks of gestation (Figure 26.5, *A*). It assesses six external physical and six neuromuscular signs. Each sign has a number score, and the cumulative score correlates with a maturity rating (gestational age). See Additional Resources for a video on how to complete the scoring.

The examination of newborns with a gestational age of 26 weeks or less should be performed at a postnatal age of less than 12 hours. For newborns with a gestational age of at least 26 weeks, the examination can be performed up to 96 hours after birth. However, it is recommended that the initial examination be performed within the first 48 hours of life. Neuromuscular adjustments after birth in extremely immature newborns require that a follow-up examination be performed to further validate neuromuscular criteria. Box 26.4 highlights specific manoeuvres used in gestational-age assessment.

Classification of Newborns by Gestational Age and Birth Weight. Classification of newborns at birth by both birth weight and gestational age is a more satisfactory method for predicting mortality risk and providing guidelines for management of the newborn than estimating gestational age or birth weight alone and is the responsibility of the nurse. The newborn's birth weight, length, and head circumference are plotted on standardized graphs that show normal values for gestational age. A normal range of birth weights exists for each gestational week (see Figure 26.5, *B*).

Intrauterine growth curves have been used to classify newborns according to birth weight and gestational age. Canadian data suggest that newborns born to parents of East Asian and South Asian ancestry may be of lower birth weight than those of European descent. Using traditional newborn birth weight curves, some Canadian newborns of East Asian and South Asian ancestry may be misclassified as small for gestational age (SGA), while their birth weight is actually healthy if compared to other East Asian and South Asian newborns (Ray et al., 2009). Nurses should access and use the most current intrauterine growth chart specific to the population being evaluated, especially when considering multiples such as twins. See Additional Resources at the end of the chapter for birth-weight curves that have been developed on the basis of maternal ancestry.

The newborn whose weight is appropriate for gestational age (AGA) (between the tenth and ninetieth percentiles) can be presumed to have grown at a normal rate regardless of the length of gestation—preterm, term, or post-term. The newborn who is large for gestational age (LGA) (above the ninetieth percentile) can be presumed to have grown at an accelerated rate during fetal life; the SGA newborn (below the tenth percentile) can be presumed to have grown at a restricted rate during intrauterine life. Birth weight influences mortality: the lower the birth weight, the higher the mortality rate. The same is true for gestational age: the lower the gestational age, the higher the mortality rate (Gardner & Niermeyer, 2021).

Newborns may also be classified in the following ways according to gestation:

- Preterm or premature—born before completion of 37 weeks of gestation, regardless of birth weight
- Late preterm—born between 34 and 36+6 weeks
- Early term—born between 37 and 38+6 weeks gestation
- Full term—born between the beginning of week 39 and the end of week 40+6 of gestation
- Late term—born in the forty-first week of gestation
- Post-term (postdate)—born after completion of week 42 of gestation
- Postmature—born after completion of week 42 of gestation and showing the effects of progressive placental insufficiency

Early term newborn. "Early term" describes newborns born from 37 0/7 to 38 6/7 weeks of gestation. Compared with full-term newborns, early-term newborns are at increased risk for morbidity and mortality. Early-term birth is associated with higher risk for hypoglycemia, respiratory issues such as respiratory distress syndrome and transient tachypnea of the newborn (TTN), and a greater likelihood of admission to the neonatal intensive care unit (NICU) (Parikh et al., 2014). Nurses and other health care providers need to be aware of the vulnerability of this population of newborns and monitor them closely (Boies et al., 2016; Craighead, 2012).

Late preterm newborn. Much attention has been focused on newborns who are considered "late preterm"; they are often the size and weight of term newborns and may be treated as healthy newborns. Despite their appearance as term newborns, late preterm newborns (born at 34 to 36-6/7 weeks of gestation) are at increased risk for respiratory distress, temperature instability, hypoglycemia, apnea, feeding difficulties, and hyperbilirubinemia (Cooper et al., 2012; Premji, 2019).

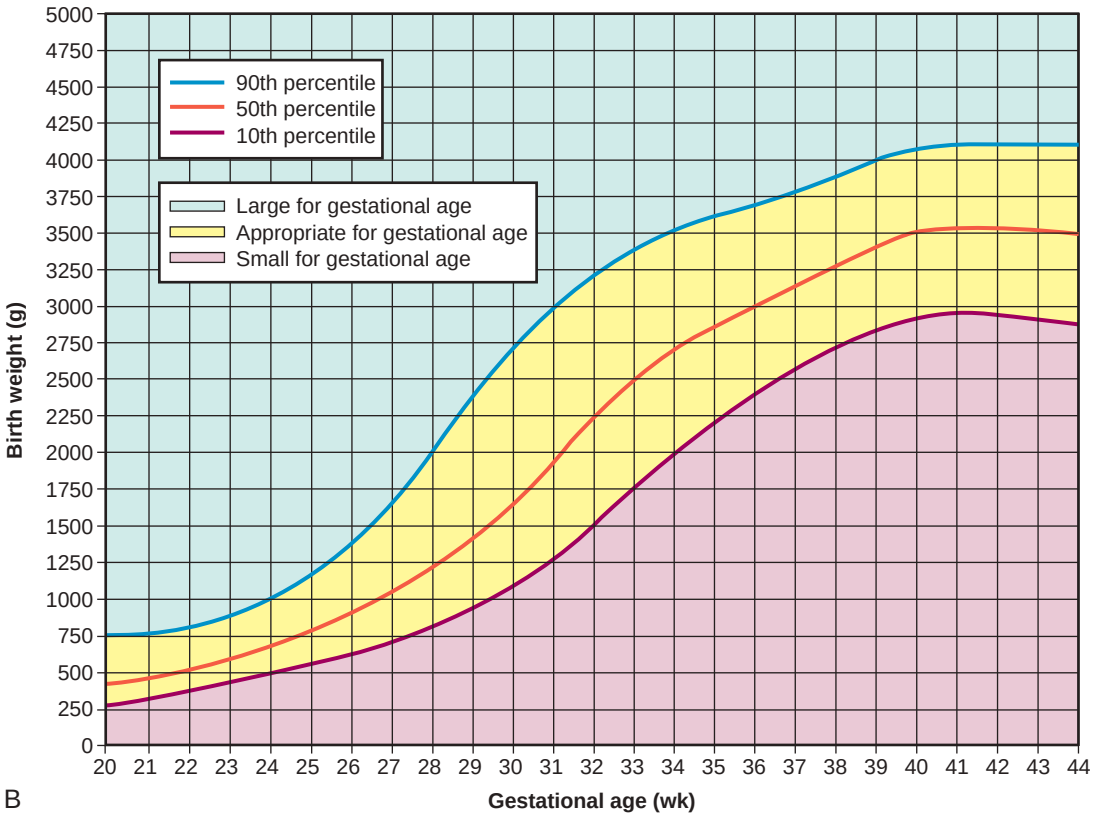
A

Fig. 26.5 Estimation of gestational age. **A:** New Ballard scale for newborn maturity rating. Expanded scale includes extremely preterm newborns and has been refined to improve accuracy in more mature newborns. See Box 26.3 for explanation of assessments of neuromuscular maturity.



(Continued)

Nurses must be cognizant of the risk factors for late preterm newborns and watch for the development of conditions related to the newborn's immaturity (Phillips et al., 2013). The late preterm newborn's care is further addressed in Chapter 28.

Post-term or postmature newborn. Newborns born at 42 weeks of gestation or beyond are considered post-term, regardless of birth weight. Some newborns are appropriate for gestational age but show characteristics of progressive placental insufficiency. These newborns are labelled as postmature and are likely to have little if any vernix caseosa, absence of lanugo, abundant scalp hair, and long fingernails. The skin is often cracked, parchment-like, and peeling. A common finding in postmature newborns is a wasted physical appearance that reflects placental insufficiency. Depletion of subcutaneous fat gives them a thin, elongated appearance. The little vernix caseosa that remains in the skinfolds may be stained deep yellow or green, which is usually an indication of meconium in the amniotic fluid.

There is a significant increase in fetal and newborn mortality in postmature newborns compared with those born at term. They are especially prone to fetal distress associated with placental insufficiency, macrosomia, and meconium aspiration syndrome.

Physical Assessment. Although the initial assessment after birth can reveal significant anomalies, birth injuries, and cardiopulmonary conditions that have immediate implications, a more detailed, thorough physical examination should follow within 12 to 18 hours after birth (see Guidelines Box: Physical Examination of the Newborn and Table 26.2). In some centres a thorough assessment may be carried out by a pediatrician or nurse practitioner; nurses are also expected

A United States national reference for fetal growth. *Obstetrics and Gynecology, 87*[2], 163–168.)

BOX 26.4 Techniques Used in Assessing Gestational Age

Posture
With newborn quiet and in a supine position, observe degree of flexion in arms and legs. Muscle tone and degree of flexion increase with maturity. Full flexion of the arms and legs = score 4.*

Square Window
With thumb supporting back of arm below the wrist, apply gentle pressure with index and third fingers on dorsum of hand without rotating newborn's wrist. Measure angle between base of thumb and forearm. Full flexion (hand lies flat on ventral surface of forearm) = score 4.

Arm Recoil
With newborn supine, fully flex both forearms on upper arms and hold for 5 seconds; pull down on hands to fully extend and rapidly release arms. Observe rapidity and intensity of recoil to a state of flexion. A brisk return to full flexion = score 4.

Popliteal Angle
With newborn supine and pelvis flat on a firm surface, flex lower leg on thigh and then flex thigh on abdomen. While holding knee with thumb and index finger, extend lower leg with index finger of the other hand. Measure degree of angle behind knee (popliteal angle). An angle of less than 90 degrees = score 5.

Scarf Sign
With newborn supine, support head in midline with one hand; use the other hand to pull newborn's arm across the shoulder so that newborn's hand touches shoulder. Determine location of elbow in relation to midline. Elbow does not reach midline = score 4.

Heel to Ear
With newborn supine and pelvis flat on a firm surface, pull foot as far as possible up toward ear on same side. Measure distance of foot from ear and degree of knee flexion (same as popliteal angle). Knees flexed with a popliteal angle of less than 10 degrees = score 4.

*See Figure 26.5 for scale and interpretation of scores.
From Hockenberry, M. J., & Wilson, D. (2015). *Wong's nursing care of newborns and children* (10th ed.). Mosby.

to be able to perform a thorough assessment. The parents' presence during this and other examinations encourages discussion of their concerns and actively involves them in the health care of their newborn from birth. It also gives the nurse an opportunity to observe parental interactions with the newborn. The findings provide a database for nurses to plan appropriate care for newborns and give anticipatory guidance for the parents. Ongoing assessments are made throughout the hospital stay.

TABLE 26.2 Physical Assessment of Newborn

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Posture			
Inspect newborn before disturbing for assessment. Refer to maternal chart for fetal presentation, position, and type of birth (vaginal, Caesarean), since newborn readily assumes in utero position.	Vertex: arms, legs in moderate flexion; fists clenched Resistance to having extremities extended for examination or measurement, crying possible when attempted Cessation of crying when allowed to resume curled-up fetal position (lateral) Normal spontaneous movement bilaterally asynchronous (legs flex and extend in alternating fashion) but equal extension in all extremities	Frank breech: legs straighter and stiff, newborn assuming intrauterine position in repose for a few days Prenatal pressure on limb or shoulder possibly causing temporary facial asymmetry or resistance to extension of extremities	Hypotonia, relaxed posture while awake (preterm or hypoxia in utero, maternal medications, neuromuscular disorder such as spinal muscular atrophy) Hypertonia (chemical dependence, CNS disorder) Limitation of motion in any of extremities
Vital Signs Check heart rate and pulses:			
Thorax (chest):			
Inspection	Visible pulsations in left midclavicular line, fifth intercostal space		
Palpation	Apical pulse, fourth intercostal space, midclavicular region, 110–160 bpm when awake	80–100 bpm (sleeping) to 180 bpm (crying); possibly irregular for brief periods, especially after crying	Tachycardia: persistent, $\geq$160 bpm (RDS, pneumonia, fever) Bradycardia: persistent, $\leq$80 bpm (congenital heart block, maternal lupus)
Auscultation Apex: mitral valve Second interspace, left of sternum: pulmonic valve Second interspace, right of sternum: aortic valve Junction of xiphoid process and sternum: tricuspid valve	Quality: first sound (closure of mitral and tricuspid valves) and second sound (closure of aortic and pulmonic valves) sharp and clear	Murmur, especially over base or at left sternal border in interspace 3–4 (foramen ovale anatomically closing at about 1 year	Murmur (possibly functional) Dysrhythmias: irregular rate Sounds: Distant (pneumopericardium) Poor quality Extra (S_3, S_4) Heart on right side of chest (dextrocardia), often accompanied by reversal of intestines
Peripheral pulses: femoral, brachial, popliteal, posterior tibial	Peripheral pulses equal and strong		Weak or absent peripheral pulses (decreased cardiac output, thrombus, possible coarctation of aorta if weak on left and strong on right) Bounding
Obtain temperature:			
Axillary: method of choice	Axillary: 37°C (98.6°F) Temperature stabilized by 8–10 hr of age	36.5°–37.5°C (97.7°–100°F) Heat loss from evaporation, conduction, convection, radiation (see Figure 25.2)	Subnormal (preterm birth, infection, low environmental temperature, inadequate clothing, dehydration) Increased (infection, high environmental temperature, excessive clothing, proximity to heating unit or in direct sunshine, chemical dependence, diarrhea and dehydration) Temperature not stabilized by 8–10 hr after birth (if mother received magnesium sulphate, newborn less able to conserve heat by vasoconstriction; maternal analgesics possibly reducing thermal stability in newborn)

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Observe and monitor respiratory rate and effort:			
Observe respirations when newborn is at rest. Observe respiratory effort. Count respirations for a full minute. Auscultate breath sounds. Listen for sounds audible without stethoscope.	30–60 breaths/min Tendency to be shallow and irregular in rate, rhythm, and depth when newborn is awake Crackles may be heard after birth. No adventitious sounds audible on inspiration and expiration Breath sounds: bronchial: loud, clear	Short periodic breathing episodes and no evidence of respiratory distress or apnea (>20 seconds); periodic breathing First period (reactivity): 50–60 breaths/min Second period: 50–70 breaths/min Stabilization (1–2 days): 30–60 breaths/min Crackles (fine)	Apneic episodes: >20 sec (preterm newborn: rapid warming or cooling of newborn; CNS or blood glucose instability) Bradypnea: <30 breaths/min (maternal narcosis from analgesics or anaesthetics, birth trauma) Tachypnea: >60 breaths/min (RDS, transient tachypnea of the newborn, congenital diaphragmatic hernia) Breath sounds: Crackles (coarse), rhonchi, wheezing Expiratory grunt (narrowing of bronchi) Distress evidenced by nasal flaring, grunting, retractions, laboured breathing Stridor (upper airway occlusion)
Obtain blood pressure (BP) (usually not done in healthy term newborn):			
Check oscillometric monitor BP cuff: BP cuff width affects readings; use appropriately sized cuff and palpate brachial, popliteal, or posterior tibial pulse (depending on measurement site).	60–80/40–50 mm Hg (approximate ranges) At birth: Systolic: 60–80 mm Hg Diastolic: 40–50 mm Hg At 2 weeks: Systolic: 68–80 mm Hg Diastolic: 40–60 mm Hg	Variation with change in activity level: awake, crying, sleeping	Difference between upper and lower extremity pressures (coarctation of aorta) Hypotension (sepsis, hypovolemia) Hypertension (coarctation of aorta, renal involvement, thrombus)
Weight*			
Put protective liner cloth or paper in place and adjust scale to 0 g. Protect newborn from heat loss.	Female: 3 400 g Male: 3 500 g Regaining of birth weight within first 2 weeks	2 500–4 000 g Acceptable weight loss: 10% or less in first 3–5 days Second baby often weighs more than first (on average)	Weight ≤2 500 g (preterm, small for gestational age, rubella syndrome) Weight ≥4 000 g (large for gestational age, maternal diabetes, heredity—normal for these parents) Weight loss 10–15% (growth failure, dehydration); assess breastfeeding

Weighing the newborn. The baby is placed prone on the scale, which is covered with a blanket to protect against cross-infection and heat loss. (Courtesy Lisa Keenan-Lindsay.)

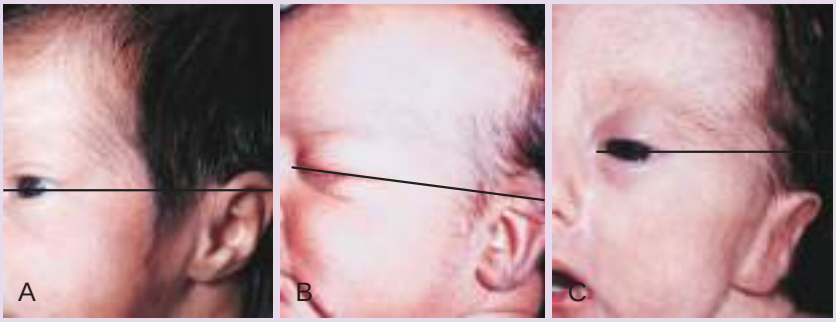
TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS: Average Findings	NORMAL FINDINGS: Normal Variations	Deviations From Normal Range—Possible Concerns (Etiology)
Length*			
Measure length from top of head to heel. Measuring is difficult in term newborns because of moulding and incomplete extension of knees. Ideally this should be done using a length board.	45–55 cm		<45 cm or >55 cm (chromosomal abnormality, heredity—normal for these parents); some syndromes result in shorter-than-average limb length (skeletal dysplasias, achondroplasia)
			
Length, crown to heel. To determine total length, include length of legs. (Courtesy Marjorie Pyle, RNC, Lifecircle.)			
Head Circumference*			
Measure head at greatest diameter: occipitofrontal circumference May need to remeasure on second or third day after resolution of moulding and caput succedaneum	33–35 cm Circumference of head and chest approximately the same for first 1 or 2 days after birth; chest circumference rarely measured on routine basis	32–36.8 cm	Microcephaly: head ≤32 cm (maternal rubella, toxoplasmosis, cytomegalovirus, Zika virus, fused cranial sutures [craniosynostosis]) Hydrocephaly: sutures widely separated, circumference ≥4 cm more than chest circumference (infection) Increased intracranial pressure (hemorrhage, space-occupying lesion)
			
Circumference of head. (Courtesy Marjorie Pyle, RNC, Lifecircle.)			
Skin			
Check colour. Inspect and palpate: Inspect semi-naked newborn in well-lit, warm area without drafts; natural daylight is best. Inspect newborn when quiet and alert.	Generally pink Varying with ethnic origin; skin pigmentation beginning to deepen right after birth in basal layer of epidermis Acrocyanosis common after birth	Mottling Harlequin sign Plethora Telangiectatic nevi nevus simplex) (see Figure 25.9, *A*) Erythema toxicum/ neonatorum ("newborn rash") (see Figure 25.9, *B*) Milia Petechiae over presenting part Ecchymoses from forceps in vertex	Dark red (preterm, polycythemia) Grey (hypotension, poor perfusion) Pallor (cardiovascular issue, CNS damage, blood dyscrasia, blood loss, twin-to-twin transfusion, infection) Cyanosis (hypothermia, infection, hypoglycemia, cardiopulmonary diseases, neurological, or respiratory malformations) Generalized petechiae (clotting factor deficiency, infection)

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
		births or over buttocks, genitalia, and legs in breech births	Generalized ecchymoses (hemorrhagic disease)
Observe for jaundice.	None at birth	Physiological jaundice in up to 60% of term newborns in first week of life	Jaundice within first 24 hour (pathological jaundice) (increased hemolysis, Rh isoimmunization, ABO incompatibility)
Observe for birthmarks or bruises: Inspect and palpate for location, size, distribution, characteristics, and colour, if obstructing airway or oral cavity.		Congenital dermal melanocytosis (slate grey nevi) (see Figure 25.8) in newborns of African, Asian, or other ethnicities with darker-coloured skin	Hemangiomas Nevus flammeus: port-wine stain Nevus vasculosus: strawberry hemangioma
Check skin condition: Inspect and palpate for intactness, smoothness, texture, edema, pressure points if ill or immobilized.	Eyelid edema (result of eye prophylaxis) Opacity: few large blood vessels visible indistinctly over abdomen	Possibly puffy Slightly thick; superficial cracking, peeling, especially of hands, feet No visible blood vessels, a few large vessels clearly visible over abdomen Some fingernail scratches	Edema on hands, feet; pitting over tibia; periorbital (overhydration; hydrops) Texture thin, smooth, or of medium thickness; rash or superficial peeling visible (preterm, post-term) Numerous vessels very visible over abdomen (preterm) Texture thick, parchment-like; cracking, peeling (post-term) Skin tags, webbing Papules, pustules, vesicles, ulcers, maceration (impetigo, candidiasis, herpes, diaper rash)
Gently pinch skin between thumb and forefinger over abdomen and inner thigh to check for turgor.	After pinch is released, skin returns to original state immediately	Dehydration: loss of weight is best indicator	Loose, wrinkled skin (prematurity, postmaturity, dehydration: fold of skin persisting after release of pinch) Tense, tight, shiny skin (edema, extreme cold, shock, infection)
Note presence of subcutaneous fat deposits (adipose pads) over cheeks and buttocks.		Variation in amount of subcutaneous fat	Lack of subcutaneous fat, prominence of clavicle or ribs (preterm, malnutrition)
Observe for vernix caseosa: Observe colour, amount, and odour before bath or removing clothing.	Whitish, cheesy, odourless	Usually more found in creases, folds	Absent or minimal (post-term) Abundant (preterm) Green colour (possible in utero release of meconium or presence of bilirubin) Odour (possible intrauterine infection)
Assess lanugo: Inspect for fine, downy hair, amount and distribution.	Over shoulders, pinnae of ears, forehead	Variation in amount	Absent (postmature) Abundant (preterm, especially if lanugo abundant, long, and thick over back)
Head			
Palpate head.		Caput succedaneum, possibly showing some ecchymosis (see Figure 25.12, *A*) Cephalohematoma (see Figure 25.12, *B*)	Subgaleal hemorrhage
Inspect shape and size.	Making up one fourth of body length Moulding (see Figure 25.11)	Slight asymmetry from intrauterine position Lack of moulding (preterm, breech presentation, Caesarean birth)	Severe moulding (birth trauma) Indentation (fracture from trauma)
Palpate, inspect, and note status of fontanels (open vs. closed).	Anterior fontanel 5-cm diamond, increasing as moulding resolves	Variation in fontanel size with degree of moulding	Fontanels: Full, bulging (tumour, hemorrhage, infection)



Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
	Posterior fontanel triangle, smaller than anterior	Difficulty in feeling fontanels possible because of moulding	Large, flat, soft (malnutrition, hydrocephaly, delayed bone age, hypothyroidism) Depressed (dehydration)
Palpate sutures.	Palpable and separated sutures	Possible overlap of sutures with moulding	Sutures: Widely spaced (hydrocephaly) Premature closure (fused) (craniosynostosis)
Inspect pattern, distribution, and amount of hair; feel texture.	Silky, single strands lying flat; growth pattern toward face and neck	Variation in amount	Fine, woolly (preterm) Unusual swirls, patterns, or hairline; or coarse, brittle (endocrine or genetic disorders)
Eyes Check placement on face.	Eyes and space between eyes each one-third the distance from outer (left) to outer (right) canthus	Epicanthal folds (upward sloping): characteristic in some ethnicities	Epicanthal folds when present with other signs (chromosomal disorders such as Down, cri-du-chat syndromes)
			
	In pseudostrabismus, inner epicanthal folds cause the eyes to appear misaligned; however, corneal light reflexes are perfectly symmetrical. Eyes are symmetrical in size and shape and are well placed.		
Check for symmetry in size and shape.	Symmetrical in size, shape		
Check eyelids for size, movement, and blink.	Blink reflex	Edema if eye prophylaxis ointment instilled	
Assess for discharge.	None No tears	Occasional presence of some tears	Discharge: purulent (infection) Chemical conjunctivitis from eye medication is common—requires no treatment
Evaluate eyeballs for presence, size, and shape.	Both present and of equal size, both round, firm	Subconjunctival hemorrhage	Agenesis or absence of one or both eyeballs Lens opacity or absence of red reflex (congenital cataracts, possibly from rubella, retinoblastoma [cat's eye reflex]) Lesions: coloboma, absence of part of iris (congenital) Pink colour of iris (albinism) Jaundiced sclera (hyperbilirubinemia)

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Check pupils.	Present, equal in size, reactive to light Pediatric health care provider will evaluate red reflex.		Pupils: unequal, constricted, dilated, fixed (intracranial pressure, medications, tumour)
Evaluate eyeball movement.	Random, jerky, uneven, focus possible briefly, following to midline	Transient strabismus or nystagmus until third or fourth month	Persistent strabismus Doll's eyes (increased intracranial pressure) Sunset (increased intracranial pressure)
Assess eyebrows: amount of hair, pattern.	Distinct (not connected in midline)		Connection in midline (Cornelia de Lange syndrome)
Nose			
Observe shape, placement, patency, and configuration.	Midline Some mucus but no drainage Preferential nose breather Sneezing to clear nose	Slight deformity (flat or deviated to one side) from passage through birth canal	Copious drainage (rarely, congenital syphilis) Blockage—membranous or bone with cyanosis at rest and return of pink colour with crying (choanal atresia) Malformed (congenital syphilis, chromosomal disorder) Flaring of nares (respiratory distress)
Ears			
Observe size, placement on head, amount of cartilage, open auditory canal.	Correct placement: line drawn through inner and outer canthi of eyes reaching to top notch of ears (at junction with scalp) Well-formed, firm cartilage	Size: small, large, floppy Darwin's tubercle (nodule on posterior helix)	Agenesis Lack of cartilage (preterm) Low placement (chromosomal disorder, cognitive impairment, kidney disorder) Preauricular tag or sinus Size: possibly overly prominent or protruding ears
 Placement of ears on the head in relation to a line drawn from the inner to outer canthus of the eye. **A:** Normal position. **B:** Abnormally angled ear. **C:** True low-set ear. (Courtesy Mead Johnson Nutritionals, Evansville, IN.)			
Assess hearing.	Responds to voice and other sounds	State (e.g., alert, asleep) influencing response	Lack of response to loud noise should not imply deafness.
Ensure newborn hearing screening is completed to identify deficits (in some provinces) (see Figure 26.15).	Both ears pass.		One or both ears fail.
Face			
Observe overall appearance and symmetry of face.	Rounded and symmetrical; influenced by birth type or any moulding	Positional deformities associated with intrauterine positioning, cranial moulding	Asymmetrical facial features may be accompanied by other characteristics, such as low-set ears, absence of outer ear, or other structural disorders (hereditary, chromosomal aberration).

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Mouth			
Inspect and palpate. Assess buccal mucosa: Dry or moist Pink Status intact Assess lips for colour, configuration, and movement.	Symmetry of lip movement	Transient circumoral cyanosis	Gross anomalies in placement, size, shape (cleft lip or palate, gums) Cyanosis, circumoral pallor (respiratory distress, hypothermia) Asymmetry in movement of lips (seventh cranial nerve paralysis)
Check gums.	Pink gums	Inclusion cysts (Epstein pearls—Bohn nodules, whitish, hard nodules on gums or roof of mouth)	Teeth: predeciduous or deciduous (hereditary)
Assess tongue for colour, mobility, movement, and size.	Tongue not protruding; freely movable; symmetrical in shape, movement Sucking pads inside cheeks	Short lingual frenulum (ankyloglossia- tongue-tie)	Macroglossia (preterm, chromosomal disorder) Thrush: white plaques on cheeks or tongue that bleed if touched (*Candida albicans*)
Assess palate (soft, hard): Arch Uvula	Soft and hard palates intact Uvula in midline	Anatomical groove in palate to accommodate nipple, disappearance by 3–4 yr of age Epstein pearls	Cleft hard or soft palate
Assess chin.	Distinct chin		Micrognathia—recessed chin with prominent overbite (Pierre Robin sequence or other syndrome)
Evaluate saliva for amount and character.	Mouth moist, pink		Excessive salivation and choking or turning blue (esophageal atresia, tracheoesophageal fistula)
Check reflexes: Rooting, sucking, extrusion (see Table 26.3)	Reflexes present	Reflex response dependent on state of wakefulness and hunger	Absent (preterm)
Neck			
Inspect and palpate for movement, flexibility, masses, and bruising.	Short, thick, surrounded by skin folds; no webbing		Webbing (Turner syndrome)
Check sternocleidomastoid muscles, movement and position of head.	Head held in midline (sternocleidomastoid muscles equal), no masses Freedom of movement from side to side and flexion and extension; no movement of chin past shoulder	Transient positional deformity apparent when newborn is at rest; passive movement of head possible	Restricted movement, holding of head at angle (torticollis [wryneck], opisthotonos) Absence of head control (preterm birth, Down syndrome, hypotonia [spinal muscular atrophy])
Assess trachea for position and thyroid gland.	Thyroid not palpable		Mass (enlarged thyroid, cystic hygroma) Distended veins (cardiopulmonary disorder) Skin tags
Chest			
Inspect and palpate: Shape	Almost circular, barrel shaped	Tip of sternum possibly prominent	Bulging of chest, unequal movement (pneumothorax, pneumomediastinum) Malformation (funnel chest—pectus excavatum)
Observe respiratory movements.	Symmetrical chest movements, chest and abdominal movements synchronized during respirations	Occasional retractions, especially when crying	Retractions with or without respiratory distress (preterm, RDS) Paradoxical breathing
Evaluate clavicles.	Clavicles intact		Fracture of clavicle (trauma); crepitus
Assess ribs.	Rib cage symmetrical, intact; moves with respirations		Poor development of rib cage and musculature (preterm)

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Assess nipples for size, placement, and number.	Nipples prominent, well formed, symmetrically placed		Nipples: Supernumerary, along nipple line Malpositioned or widely spaced
Check breast tissue.	Breast nodule: approximately 6 mm in term newborn	Breast nodule: 3–10 mm Thin discharge from breast	Lack of breast tissue (preterm) Sounds: bowel sounds may be heard in diaphragmatic hernia (see Abdomen, below)
Abdomen			
Inspect and palpate umbilical cord.	Two arteries, one vein Whitish grey Definite demarcation between cord and skin; no intestinal structures within cord Dry around base, drying Odourless Cord clamp may be in place	Reducible umbilical hernia	One artery (renal anomaly) Meconium stained (intrauterine distress) Bleeding or oozing around cord (hemorrhagic disease) Redness or drainage around cord (infection, possible persistence of urachus) Hernia: herniation of abdominal contents through cord opening (e.g., omphalocele); defect covered with thin, friable membrane, possibly extensive
Inspect size of abdomen and palpate contour.	Rounded, prominent, dome shaped because abdominal musculature not fully developed Liver possibly palpable 1–2 cm below right costal margin No other masses palpable No distension Few visible veins on abdominal surface	Some diastasis recti (separation) of abdominal musculature	Gastroschisis: herniation of abdominal contents to the side or above the cord; contents not covered by membranous tissue and may include liver Distension at birth (ruptured viscus, genitourinary masses or malformations: hydronephrosis, teratomas, abdominal tumours): Mild (overfeeding, high gastrointestinal tract obstruction) Marked (lower gastrointestinal tract obstruction, anorectal malformation, anal stenosis), often with bilious emesis Intermittent or transient (overfeeding) Partial intestinal obstruction (stenosis of bowel) Visible peristalsis (obstruction) Malrotation of bowel or adhesions Sepsis (infection)
Auscultate bowel sounds and note number, amount, and character of stools.	Sounds present within minutes after birth in healthy term newborn Meconium stool passing within 24–48 hour after birth		Scaphoid, with bowel sounds in chest and severe respiratory distress (congenital diaphragmatic hernia)
Assess colour.		Linea nigra possibly apparent and caused by hormone influence during pregnancy	
Observe movement with respiration.	Respirations primarily diaphragmatic, abdominal and chest movement synchronous		Decreased or absent abdominal movement with breathing (phrenic nerve palsy, congenital diaphragmatic hernia)

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS: Average Findings	NORMAL FINDINGS: Normal Variations	Deviations From Normal Range—Possible Concerns (Etiology)
Genitalia			
Female (see Figure 25.10, A)			
Inspect and palpate: General appearance		Increased pigmentation caused by pregnancy hormones	Ambiguous genitalia—wide variation (small phallus not well distinguished from enlarged clitoris)
Clitoris	Usually edematous		Virilized female—extremely large clitoris (congenital adrenal hyperplasia)
Labia majora	Usually edematous, covering labia minora in term newborns	Edema and ecchymosis after breech birth Some vernix caseosa between labia possible	
Labia minora	Possible protrusion over labia majora		Enlarged clitoris with urinary meatus on tip, absent scrotum, micropenis, fused labia Stenosed meatus Labia majora widely separated and labia minora prominent (preterm)
Discharge	Smegma	Blood-tinged discharge from pseudomenstruation caused by pregnancy hormones	Fecal discharge (fistula)
Vagina	Open orifice Mucoid discharge Hymenal/vaginal tag		Absence of vaginal orifice
Urinary meatus	Beneath clitoris, difficult to see		Bladder exstrophy (bladder outside abdominal cavity and turned inside out)
Assess urination.	Voiding 1 void per day for each day of life until fifth day and then 4 to 6 wet diapers. After day 7 frequent urination	Rust-stained urine (uric acid crystals)	No void within first 24 hr (renal agenesis; Potter syndrome)
Male (see Figure 25.10, B)			
Inspect and palpate: General appearance		Increased size and pigmentation caused by pregnancy hormones Wide variation in size of genitalia	Ambiguous genitalia Micropenis
Penis: Urinary meatus appearance Prepuce (foreskin)—do not forcibly retract foreskin if uncircumcised	Foreskin covers glans (if uncircumcised), meatus at tip of penis	Prepuce removed if circumcised	Urinary meatus not on tip of glans penis (hypospadias, epispadias, foreskin may be retracted or absent); chordee (ventral curvature) Round meatal opening
Scrotum: Rugae (wrinkles)	Large, edematous, pendulous in term newborn; covered with rugae	Scrotal edema and ecchymosis if breech birth Hydrocele, small, noncommunicating	Scrotum smooth and testes undescended (preterm, cryptorchidism) Bifid scrotum Hydrocele Inguinal hernia
Testes Check reflexes: Cremasteric	Palpable on each side Testes retracted, especially when newborn is chilled	Bulge palpable in inguinal canal	Undescended (preterm)
Assess urination.	Voiding within 24 hour, stream adequate, amount adequate Voiding 1 void per day for each day of life until fifth day and then 4 to 6 wet diapers. After day 7 frequent urination	Rust-stained urine (uric acid crystals)	No void in first 24 hr Renal agenesis: Potter syndrome

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Extremities			
Make a general check. Inspect and palpate: Degree of flexion Range of motion Symmetry of motion Muscle tone	Assuming of position maintained in utero Attitude of general flexion Full range of motion, spontaneous movements	Transient positional deformities	Limited motion (malformations) Poor muscle tone (preterm, maternal medications, CNS anomalies)
Check arms and hands. Inspect and palpate: Colour Intactness Appropriate placement	Longer than legs in newborn period Contours and movements symmetrical	Slight tremors sometimes apparent Some acrocyanosis	Asymmetry of movement (fracture or crepitus, brachial nerve trauma, malformations) Asymmetry of contour (malformations, fracture) Amelia or phocomelia (teratogens) Palmar creases Simian line with short, in-curved little fingers (Down syndrome)
Count number of fingers.	Five on each hand Fist often clenched with thumb under fingers		Webbing of fingers: syndactyly Absence or excess of fingers Strong, rigid flexion; persistent fists; positioning of fists in front of mouth constantly (CNS disorder) Yellowed nail beds (meconium staining)
Evaluate joints: Shoulder Elbow Wrist Fingers	Full range of motion, symmetrical contour		Increased tonicity, clonus, prolonged tremors (CNS disorder)
Check palmar and plantar grasp reflexes (see Table 26.3)			
Observe legs and feet. Inspect and palpate: Colour Intactness Length in relation to arms and body and to each other	Appearance of bowing because lateral muscles more developed than medial muscles	Feet appearing to turn in but can be easily rotated externally, positional defects tending to correct while newborn is crying Acrocyanosis	Amelia, phocomelia (chromosomal defect, teratogenic effect) Clubfoot Temperature of one leg differing from that of the other (circulatory deficiency, CNS disorder) Webbing, syndactyly (chromosomal defect) Absence or excess of digits (chromosomal defect, familial trait) Femoral fracture (difficult breech birth) Developmental dysplasia of the hip (DDH)
Count number of toes	Five toes on each foot		
Femur Head of femur as legs are flexed and abducted, placement in acetabulum (see Figure 25.13)	Intact femur		
Major gluteal folds	Major gluteal folds even		Gluteal folds uneven: DDH
Soles of feet	Soles well lined (or wrinkled) over two thirds of foot in term newborns Plantar fat pad giving flat-footed effect		Soles of feet: Few creases (preterm) Covered with creases (post-term) Congenital clubfoot
Evaluate joints: Hip Knee Ankle Toes	Full range of motion, symmetrical contour		Hypermobility of joints (Down syndrome)
Check reflexes (see Table 26.3)			Asymmetrical movement (trauma, CNS disorder)

Continued

TABLE 26.2 Physical Assessment of Newborn—cont'd

Area Assessed and Appraisal Procedure	NORMAL FINDINGS		Deviations From Normal Range—Possible Concerns (Etiology)
	Average Findings	Normal Variations	
Back			
Assess anatomy. Inspect and palpate: Spine, shoulders, scapulae, iliac crests	Spine straight and easily flexed Newborn able to raise and support head momentarily when prone Shoulders, scapulae, and iliac crests lining up in same plane	Temporary minor positional deformities; correction with passive manipulation	Limitation of movement (fusion or deformity of vertebra) Meningocele, myelomeningocele (spina bifida cystica)
Base of spine—pilonidal dimple or sinus			Pigmented nevus with tuft of hair, located anywhere along the spine, often associated with spina bifida occulta Sinus (opening to spinal cord)
Check reflexes (spinal related):		May not be apparent in first few days but is usually present in 5–6 days	If transverse lesion is present, no response below lesion; absence of response: CNS abnormality or CNS depression
Test trunk incurvation reflex (see Table 26.3)	Trunk flexed and pelvis swings to stimulated side		
Test magnet reflex.	Lower limbs extend as pressure applied to feet with legs in semiflexed position	Weak or exaggerated response with breech presentation	Absence suggestive of CNS damage or malformation
Anus			
Inspect and palpate: Placement Patency	One anus with good sphincter tone Passage of meconium within 24 hour after birth = patent	Passage of meconium within 48 hour after birth	Imperforate anus without fistula Rectal atresia and stenosis Absence of anal opening; drainage of fecal material from vagina in female or urinary meatus in male (rectal fistula) or along perineal raphe (midline area between base of penis and anus) (anorectal malformation)
Test for sphincter response (active "wink" reflex). Observe for the following: Abdominal distension Passage of meconium from anal opening Fecal drainage from perineum, penis, vagina	Anal "wink" present, anal opening patent		
Stools			
Observe frequency, colour, and consistency.	Meconium followed by transitional and soft yellow stool (see Figure 25.6)		No stool (obstruction), dehydration Frequent watery stools (infection, phototherapy)

bpm, Beats per minute; *CNS*, central nervous system; *RDS*, respiratory distress syndrome.
*Weight, length, and head circumference should all be close to the same percentile for any child.

TABLE 26.3 Assessment of Newborn Reflexes

Reflex	Eliciting the Reflex	Characteristic Response	Comments
Sucking and rooting	Touch newborn's lip, cheek, or corner of mouth with nipple or finger.	Newborn turns head toward stimulus and opens mouth.	Response is difficult if not impossible to elicit after newborn has been fed. Parental guidance: Avoid trying to turn head toward breast or nipple; allow newborn to root; response disappears after 3–4* mo but may persist up to 1 yr. A weak or absent response can indicate prematurity or neurological deficit.
Swallowing	Feed newborn; swallowing usually follows sucking and obtaining fluids.	Swallowing is usually coordinated with sucking and breathing and usually occurs without gagging, coughing, apnea, or vomiting.	If response is weak or absent, this may indicate preterm birth, effects of maternal analgesics, or illness that needs investigation. Sucking, swallowing, and breathing are often uncoordinated in a preterm newborn.
Palmar grasp	Place finger in palm of hand.	Newborn's fingers curl around examiner's fingers.	Palmar response lessens by 3–4 mo; parents enjoy this contact with newborn.
Plantar grasp	Place finger at base of toes.	Toes curl downward.	Plantar response lessens by 8 mo.

TABLE 26.3 Assessment of Newborn Reflexes—cont'd

Reflex	Eliciting the Reflex	Characteristic Response	Comments
			
		Plantar grasp reflex. (From Zitelli, B. J., & Davis, H. W. [2007]. *Atlas of pediatric physical diagnosis* [5th ed.]. Mosby.)	
Extrusion	Touch or depress tip of tongue.	Newborn forces tongue outward.	Response disappears by about 4–5 mo.
Glabellar (Myerson)	Tap over forehead, bridge of nose, or maxilla of newborn whose eyes are open.	Newborn blinks for first four or five taps.	Continued blinking with repeated taps is consistent with extrapyramidal signs.
Tonic neck or "fencing"	With newborn in a supine neutral position, turn head quickly to one side.	With newborn facing left side, arm and leg on that side extend; the opposite arm and leg flex (turn head to right, and extremities assume opposite postures).	Responses in leg are more consistent. Complete response disappears by 3–4 mo; incomplete response may be seen until 3-4 yr. After 6 wk, persistent response is a sign of an abnormality.
			
		Classic pose in tonic neck reflex. (Courtesy Marjorie Pyle, RNC, Lifecircle.)	
Moro (or startle)	Hold newborn in semisitting position, allowing head and trunk to fall backward (with support). Place newborn supine on flat surface; make a loud, abrupt noise.	Symmetrical abduction and extension of arms are seen; fingers fan out and form a *C* with thumb and forefinger; slight tremor may be noted; arms are adducted in embracing motion and return to relaxed flexion and movement. A cry may accompany or follow motor movement. Legs may follow similar pattern of response. Preterm newborns do not complete "embrace";	Response is present at birth; complete response may be seen until 8 wk; body jerk only is seen between 8 and 18 wk; response is absent by 6 mo if neurological maturation is not delayed; response may be incomplete if newborn is in deep sleep state; give parental guidance about normal response. Asymmetrical response may connote injury to brachial plexus, clavicle, or humerus.

TABLE 26.3 Assessment of Newborn Reflexes—cont'd

Reflex	Eliciting the Reflex	Characteristic Response	Comments
		instead, their arms fall backward because of weakness.	Persistent response after 6 mo indicates possible neurological abnormality.

Moro reflex. (Courtesy Paul Vincent Kuntz, Texas Children's Hospital.)

Stepping or "walking"	Hold newborn vertically under arms or on trunk, allowing one foot to touch table surface.	Newborn will simulate walking, alternating flexion and extension of feet; term newborns walk on soles of their feet, and preterm newborns walk on their toes.	Response is normally present for 3–4 wk.

Stepping reflex. (From Dickason, E. J., Silverman, B. L., & Kaplan, J. A. [1998]. *Maternal–newborn nursing care* [3rd ed.]. Mosby.)

Crawling	Place newborn on abdomen.	Newborn makes crawling movements with arms and legs.	Response should disappear at about 6 wk of age.

Crawling reflex. (Courtesy Paul Vincent Kuntz, Texas Children's Hospital.)

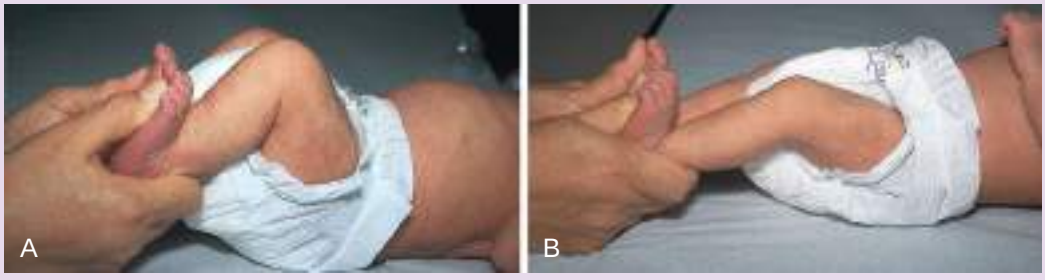
TABLE 26.3 Assessment of Newborn Reflexes—cont'd

Reflex	Eliciting the Reflex	Characteristic Response	Comments
Deep tendon	Use finger instead of percussion hammer to elicit patellar, or knee jerk, reflex; newborn must be relaxed.	Reflex jerk is present; even with newborn relaxed, nonselective overall reaction may occur.	It is usually more difficult to elicit upper extremity reflexes than lower extremity reflexes.
Crossed extension	With newborn in supine position, examiner extends one leg of newborn and presses down knee. Stimulation of sole of foot of fixated limb should cause free leg to flex, adduct, and extend as if attempting to push away stimulating agent.	Opposite leg flexes, adducts, and then extends.	This reflex should be present during newborn period.

Crossed extension reflex. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

Babinski (plantar)	On sole of foot, beginning at heel, stroke upward along lateral aspect of sole, then move finger across ball of foot.	All toes hyperextend, with dorsiflexion of big toe—recorded as a positive sign.	Absence requires neurological evaluation, should disappear after 1 yr of age. Response depends on newborn's general muscle tone, maturity, and condition.



Babinski reflex. **A:** Direction of stroke. **B:** Dorsiflexion of big toe. **C:** Fanning of toes. (From Hockenberry, M. J., & Wilson, D. [2013]. *Wong's nursing care of newborns and children* [9th ed.]. Mosby.)

Pull-to-sit (traction response); postural tone	Pull newborn up by wrists from supine position with head in midline.	Head lags until newborn is in upright position; then head is held in same plane with chest and shoulder momentarily before falling forward; newborn attempts to right head.	Response depends on general muscle tone and maturity and condition of newborn.
Truncal incurvation (Galant)	Place newborn prone on flat surface; run finger down back about 4–5 cm lateral to spine, first on one side and then down the other.	Trunk is flexed and pelvis is swung toward stimulated side.	Response disappears by fourth wk. Response varies but should be obtainable in all newborns, including preterm ones. Absence suggests general depression of central nervous system. With transverse lesions of cord, no response below the level of lesion is present.

Continued

TABLE 26.3 Assessment of Newborn Reflexes—cont'd

Reflex	Eliciting the Reflex	Characteristic Response	Comments
	 Trunk incurvation reflex. (Courtesy Marjorie Pyle, RNC, Lifecircle.)		
Magnet	Place newborn in supine position, partially flex both lower extremities, and apply light pressure with fingers to soles of feet (Figure A). Normally, while examiner's fingers maintain contact with soles of feet, lower limbs extend.	Both lower limbs should extend against examiner's pressure (Figure B).	Absence suggests damage to central nervous system. Weak reflex may be seen after breech presentation without extended legs or may indicate sciatic nerve stretch syndrome. Breech presentation with extended legs may evoke exaggerated response.
	 Magnet reflex. (Courtesy Michael S. Clement, MD.)		
Additional newborn responses: yawn, stretch, burp, hiccup, sneeze	These are spontaneous behaviours.	They may be slightly depressed temporarily because of maternal analgesia or anaesthesia, fetal hypoxia, or infection.	Parental guidance: Most of these behaviours are pleasurable to parents. Parents need to be assured that behaviours are normal. Sneeze is usually a response to mucus in nose and not an indicator of a cold (upper respiratory tract infection). No treatment is needed for hiccups; sucking may help. In the preterm newborn, these are signs of neurodevelopmental immaturity and physiological stress.

*All durations for persistence of reflexes are based on time elapsed after 40 weeks of gestation; that is, if newborn was born at 36 weeks of gestation, add 1 month to all time limits given.

GUIDELINES

Physical Examination of the Newborn

Provide a normothermic and nonstimulating examination area.
Check that equipment and supplies are working properly and are accessible.
Undress only the body area to be examined, to prevent heat loss.
Proceed in an orderly sequence (usually head to toe), with the following exceptions:
- Perform all procedures that require quiet first, such as observing position, skin colour, tone, and condition.
- Next auscultate the lungs, heart, and abdomen.
- Perform more disturbing procedures, such as taking temperature and testing reflexes, last.
- Measure head circumference and length as a baseline for further comparison as needed.

Proceed quickly to avoid stressing the newborn.
Comfort the newborn during and after examination; involve parents in the following:
- Talking softly to the newborn
- Holding the newborn's hands against the chest
- Holding the newborn
- Placing the baby skin-to-skin

General appearance. The newborn's maturity level can be gauged by assessment of general appearance. Features to assess in the general survey include posture, activity, any overt signs of anomalies that may cause initial distress, presence of bruising or other consequences of birth, and state of alertness. The normal resting position of the newborn is one of general flexion (Figure 26.6).

Vital signs. The newborn may need to be held and comforted during assessment. If the newborn is inconsolable, consider placing the newborn in skin-to-skin contact with a parent and returning shortly afterward to complete assessment. The temperature, heart rate, and respiratory rate are always obtained. BP is not routinely assessed unless cardiac issues are suspected. Before taking the temperature, the examiner may determine the apical heart rate and respiratory rate while the newborn is quiet and at rest. If the newborn is crying while assessing the vital signs, the use of a gloved finger or pacifier to suck on might be considered but only if approved by the parents. The parents should be involved in this procedure. An irregular, very slow, or very fast heart rate may indicate a need for further evaluation of circulatory status, including BP measurement.

The axillary temperature is a safe, accurate measurement of temperature. Electronic thermometers have expedited this task and provide a reading within 1 minute. In 2017, Health Canada conducted a safety review of infrared thermometers for both tympanic and temporal artery routes and concluded that, given new information in literature and clinical guidelines, these routes for temperature assessment were appropriate for use in children under 2 years old in the community (Health Canada, 2017). Taking a newborn's temperature may cause the newborn to cry and struggle against the placement of the thermometer in the axilla. The normal axillary temperature ranges from 36.5° to 37.5°C (97.7° to 99.5°F).

Fig. 26.6 Newborn in position of flexion in prone position while awake. (From Hockenberry, M. J., et al. [2007]. *Wong's nursing care of infants and children* [8th ed., p. 274]. Mosby.)

SAFETY ALERT

Rectal temperatures should not be done on a newborn because of the risk for perforation and vagal stimulation.

The respiratory rate varies with the state of alertness and activity after birth. Respirations are abdominal and can be counted by observing or by lightly feeling the rise and fall of the abdomen while listening to air entry. Newborn respirations are shallow and irregular. It is important to count the respirations for a full minute to obtain an accurate count as there can be episodes of periodic breathing during which respirations may cease for up to 20 seconds and then resume again. The examiner should also observe for symmetry of chest movement. The average respiratory rate is between 30 and 60 breaths/min or may be higher than 60 breaths/min if the newborn is very active or crying.

An apical pulse rate should be obtained on all newborns. Auscultation should be for a full minute, preferably when the newborn is asleep or in a quiet alert state. The heart rate may range from 110 to 160 bpm. It is common to detect brief irregularities in the heart rate. Heart rate varies with the newborn's behavioural state. Bradycardia is a heart rate less than 100 bpm. However, a term newborn in deep sleep may have a heart rate in the 80s or 90s; the rate should increase when the newborn awakens. Tachycardia is defined as a sustained heart rate exceeding 160 bpm. It is not unusual for a crying newborn to have a heart rate greater than 160; the heart rate should decrease when the crying ceases (Gardner & Niermeyer, 2021). Brachial and femoral pulses should be assessed for equality and strength.

If BP is measured, an oscillometric monitor calibrated for newborn pressures is preferred. An appropriate-sized cuff (width-to-arm or calf ratio of 0.45 to 0.70, or approximately ½ to ¾) is essential for accuracy. Newborn BP usually is highest immediately after birth and falls to a minimum by 3 hours after birth. It then begins to rise steadily and reaches a plateau between 4 and 6 days after birth. This measurement is usually equal to that of the immediate post-birth BP. The blood pressure (BP) varies with the newborn's activity; accurate measurement is best obtained while the newborn is at rest. BP also varies with gestational age and chronological age. Systolic pressure in a term newborn averages 60 to 80 mm Hg; diastolic pressure averages 40 to 50 mm Hg. The mean arterial pressure (MAP) should approximate the newborn's week of gestation. According to agency protocol, four extremity BPs may be assessed routinely or only when a murmur is auscultated. If the upper extremity pressures are more than 10 mm Hg greater than those in the lower extremities, the newborn may have a cardiac defect such as coarctation of the aorta (Gardner & Niermeyer, 2021). Peripheral pulses are also palpated as part of the assessment in any newborn with a heart murmur. Pulse oximetry is completed for congenital heart disease screening (see discussion below in Critical Congenital Heart Disease).

Baseline measurements of physical growth. Baseline measurements are taken and recorded to help assess the progress and determine the growth patterns of the newborn. These may be recorded on growth charts. The following measurements are made when the newborn is assessed.

Weight. The newborn is usually weighed in the first few hours after birth. Care must be taken to ensure that the scales are balanced. The

totally unclothed newborn is placed in the centre of the scale, which is usually covered with a disposable pad or cloth to prevent heat loss via conduction and prevent cross-infection. The nurse should place one hand over (but not touching) the newborn to prevent the newborn from falling off the scale. Most newborns need to be weighed only at birth and at discharge, although newborns who are SGA or who are not feeding well may require daily weighing. This should be done at the same time every day during the hospital stay. Birth weight of a term newborn typically ranges from 2 500 to 4 000 g.

Head circumference and length. The head is measured at the widest part, which is the occipitofrontal diameter. The tape measure is placed around the head just above the newborn's eyebrows. The term newborn's head circumference ranges from 32 to 36.8 cm (12.6 to 14.5 in).

The length may be difficult to obtain because of the flexed posture of the newborn. The examiner places the newborn on a flat surface and extends the leg until the knee is flat against the surface. Placing the head against a perpendicular surface and extending the leg may assist with this measurement. In the term newborn, head-to-heel length ranges from 45 to 55 cm (17.7 to 21.7 in) (see Chapter 33, Length).

Neurological assessment. The physical assessment includes a neurological assessment of newborn reflexes (Table 26.3). This assessment provides useful information about the newborn's nervous system and state of neurological maturation. Many reflex behaviours (e.g., sucking and rooting) are important for proper development. Other reflexes such as gagging and sneezing act as primitive safety mechanisms. The assessment needs to be carried out as early as possible because abnormal signs present in the early newborn period may require further investigation before the newborn is discharged home.

Common Newborn Concerns

Birth Injuries. Birth trauma includes any physical injury sustained by a newborn during labour and birth. Although most injuries are minor and resolve during the newborn period without treatment, some types of trauma require intervention; a few are serious enough to be fatal. See Chapter 29 for more information on birth injuries.

Retinal and **subconjunctival hemorrhages** result from rupture of capillaries caused by increased pressure during birth. The hemorrhages clear within 5 days after birth and usually present no further issues. Parents need explanation about them and reassurance that these injuries are harmless.

Erythema, ecchymoses, petechiae, abrasions, lacerations, or edema of buttocks and extremities may be present. Localized discoloration can appear over a presenting part as a result of forceps or vacuum-assisted birth. Ecchymoses and edema can appear anywhere on the body. *Petechiae*, or pinpoint hemorrhagic areas, acquired during birth may extend over the upper trunk and face. These lesions are benign if they disappear within 2 or 3 days of birth and no new lesions appear. Ecchymoses and petechiae may be signs of a more serious disorder, such as thrombocytopenic purpura. To differentiate hemorrhagic areas from a skin rash or discoloration, the nurse can apply pressure to the skin with two fingers. Petechiae and ecchymoses do not blanch because extravasated blood remains within the tissues, whereas skin rashes and discolorations do blanch. For further discussion regarding birthmarks see Chapter 25, Integumentary System.

Trauma can occur to the presenting part during labour and birth. Caput succedaneum and cephalhematoma are normal and are discussed in Chapter 25 (see Figure 25.12). Forceps injury and bruising from the vacuum cup occur at the site of application of the instruments. A forceps injury commonly produces a linear mark across both sides of the face in the shape of the blades of the forceps, with skin integrity rarely being compromised. These injuries usually resolve spontaneously within several days with no specific therapy. If small abrasions are evident the area should be kept clean to minimize the risk of infection. A topical ointment may be ordered by the primary health care provider to optimize healing. With increased use of the vacuum extractor, the incidence of these lesions has been significantly reduced.

Fig. 26.7 Marked bruising on the entire face of a newborn born vaginally after face presentation. Less severe ecchymoses were present on the extremities. Phototherapy was required for treatment of jaundice resulting from breakdown of accumulated blood. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn.* Hoffmann-La Roche. Used with permission of F. Hoffmann-La Roche Ltd.)

Fig. 26.8 Swelling of genitalia and bruising of the buttocks after a breech birth. (From O'Doherty, N. [1986]. *Neonatology: Micro atlas of the newborn.* Hoffmann-La Roche. Used with permission of F. Hoffmann-La Roche Ltd.)

Bruises over the face may be the result of face presentation (Figure 26.7). In a breech presentation, bruising and swelling may be seen over the buttocks or genitalia (Figure 26.8). The skin over the entire head may be ecchymotic and covered with petechiae caused by a tight nuchal cord or a precipitous birth. If the hemorrhagic areas

do not disappear spontaneously in 2 days or if the newborn's condition changes, the primary health care provider should be notified.

Accidental lacerations can be inflicted with a scalpel during a Caesarean birth. These cuts may occur on any part of the body but are most often found on the scalp, buttocks, and thighs. Usually they are superficial and only need to be kept clean. If skin closure is needed, an adhesive substance or strips may be applied. Rarely are sutures needed.

Physiological Conditions.

Hyperbilirubinemia. Hyperbilirubinemia in the newborn, also referred to as *neonatal jaundice*, occurs in approximately 60% of all full-term newborns by the second through fifth day of life (Barrington et al., 2007/2018). In most cases it is *physiological jaundice*, which causes increased levels of bilirubin as a result of the diminished ability to conjugate and excrete an excess of bilirubin in the blood of the newborn; physiological jaundice is usually self-limiting, requires no treatment, and resolves in a few days. Physiological jaundice or neonatal hyperbilirubinemia occurs in 80% of preterm newborns. The incidence of physiological jaundice is increased in darker-skinned newborns. It must be differentiated from pathological jaundice, or hyperbilirubinemia, which is associated with higher levels of unconjugated bilirubin. Pathological jaundice can appear in the first 24 hours and often requires phototherapy to resolve. (See Chapter 25, Bilirubin Synthesis and Newborn Jaundice for further discussion on pathophysiology of hyperbilirubinemia.) See Clinical Reasoning Case Study: Home Assessment of Physiological Jaundice.

CLINICAL REASONING CASE STUDY

Home Assessment of Physiological Jaundice

Minh and Viet have been home with their newborn son for 2 days now. As Bao was born early at 35+5 weeks gestation, they were required to stay an extra day in the hospital for further evaluation. During the postpartum home visit, the public health nurse notices that Bao appears very lethargic and has a slight yellow tinge in his eyes. Viet reveals that Bao reminds him of their first son, who had to be readmitted to the hospital for phototherapy. Viet is breastfeeding Bao.

1. Evidence—What risk factors for physiological jaundice are present?
2. Assessment—What further information does the nurse need to gather to complete the assessment of the baby Bao?
3. What priorities for nursing care can be drawn at this time?
4. Interprofessional care—Describe the roles and responsibilities of members of the interprofessional health care team who may be involved in care management of this mother and her newborn.
5. What other factors need to be considered when planning follow-up for baby Bao and his mother Minh?

Every newborn should be assessed for jaundice; this can be easily done when vital signs are assessed. Jaundice is generally first noticed in the head, especially the sclera and mucous membranes, and then progresses gradually to the thorax, abdomen, and extremities. Visual assessment of jaundice alone does not provide an accurate assessment of the level of serum bilirubin, especially in dark-skinned newborns; only 50% of babies with a total serum bilirubin (TSB) concentration greater than 128 mcmol/L appear jaundiced (Barrington et al., 2007/2018). To differentiate cutaneous jaundice from normal skin colour, the nurse applies pressure with a finger over a bony area (e.g., the nose, forehead, sternum) for several seconds to empty all the capillaries in that spot. If jaundice is present, the blanched area will look yellow before the capillaries refill and further assessment will be required. The conjunctival sacs and buccal mucosa are also assessed. Assessing for jaundice in natural light is recommended because artificial lighting and the reflection from walls can distort the actual skin colour.

Fig. 26.9 Transcutaneous monitoring of bilirubin with a transcutaneous bilirubinometry (TcB) monitor. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

Noninvasive monitoring of bilirubin via cutaneous reflectance measurements (transcutaneous bilirubinometry [TcB]) allows for repetitive estimations of bilirubin; however, there are limitations to the use of TcB monitors (Figure 26.9). They are more accurate at lower TSB levels, are not accurate once phototherapy is initiated, and may be unreliable with changes in skin colour and thickness. TcB monitors may be used to screen clinically significant jaundice (Barrington et al., 2007/2018). The CPS recommends monitoring healthy newborns at 35 weeks of gestation or greater before discharge from the hospital using hour-specific serum bilirubin levels to determine the newborn's risk for development of hyperbilirubinemia requiring medical treatment or closer screening (Barrington et al., 2007/2018; Provincial Council for Maternal & Child Health [PCMCH] & Ministry of Health and Long-Term Care, 2017). Use of a nomogram (Figure 26.10) with three levels (high, intermediate, or low risk) of rising TSB values assists in determination of newborns that might need further evaluation after discharge. Universal bilirubin screening based on hour-specific TSB may be done at the same time as the routine newborn metabolic screening (Barrington et al., 2007/2018).

Adequate feeding is essential in preventing hyperbilirubinemia. Newborns should breastfeed early (within 1 hour after birth) and often. Colostrum acts as a laxative to promote stooling, which helps rid the body of bilirubin. Formula-fed newborns should be fed after birth when their physiological status has stabilized and thereafter on demand, at least every 3 to 4 hours.

Newborns should be assessed for risk factors for severe hyperbilirubinemia. Factors that place newborns at high risk include gestational age of 35 to 38 weeks; exclusive breastfeeding not being well established and excessive weight loss; having a sibling who had neonatal hyperbilirubinemia; visible bruising, cephalohematoma, a positive Coombs' test (also known as a direct antibody test [DAT]), or other known hemolytic disease; glucose-6-phosphate dehydrogenase (G6PD) deficiency (diagnosed at birth); ethnic background (East Asian); asphyxia (Apgar 0–3 beyond 5 minutes and cord pH less than 7); acidosis (pH less than 7 beyond initial cord sample); albumin less than 30 g/L; sepsis being currently treated; temperature instability; and significant lethargy or poor feeding (Barrington et al., 2007/2018; PCMCH & Ministry of Health and Long-Term Care, 2017). It is recommended that healthy newborns (35 weeks or greater) receive assessment of bilirubin at 24 hours of life.

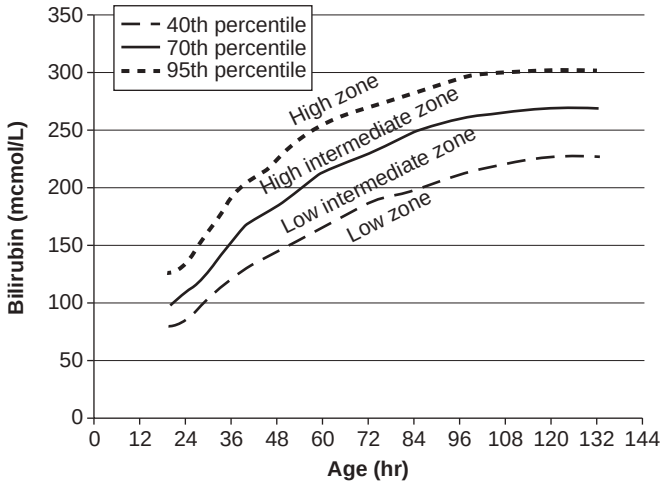


Fig. 26.10 Nomogram for evaluation of screening total serum bilirubin (TSB) concentration in term and late preterm newborns, according to the TSB concentration obtained at a known postnatal age in hours. (From Barrington, K. J., Sankaran, K., & Canadian Paediatric Society. [2007/2018]. Guidelines for detection, management and prevention of hyperbilirubinemia in term and late term newborn infants [35 or more weeks gestation]. *Paediatrics & Child Health, 12*[Suppl B], 1B–12B. Figure reproduced and adapted with permission from *Pediatrics, 114*, 297–316. Copyright © 2004 by the AAP.)

If intervention is not required, further follow-up will depend on individual risk factors. If a newborn is discharged before 24 hours of age, the newborn needs further assessment within 24 hours by someone experienced in newborn care and with access to testing (Barrington et al., 2007/2018). Close follow-up of newborns at risk for severe hyperbilirubinemia is essential; parents should be educated about the symptoms and encouraged to follow postdischarge recommendations.

If a newborn is jaundiced in the first 24 hours of life, a TcB or TSB level should be measured and results interpreted on the basis of the newborn's age in hours according to the hour-specific nomogram for newborns born at 35 weeks of gestation or later. Repeat testing is based on the risk level (low, intermediate, or high), the age of the newborn, and the progression of jaundice.

Pathological jaundice is that level of serum bilirubin which, if left untreated, can result in sensorineural hearing loss, mild cognitive delays, and kernicterus, which is the deposition of bilirubin in the brain. **Kernicterus** describes the yellow staining of the brain cells that may result in bilirubin encephalopathy. The damage to the brain occurs when the serum concentration reaches toxic levels, regardless of cause. The key to prevention of this complication is universal screening between 24 and 72 hours.

Therapy for hyperbilirubinemia. The best therapy for hyperbilirubinemia is prevention. Because bilirubin is excreted in meconium, prevention can be facilitated by early and frequent feeding, which stimulates passage of meconium. However, despite early passage of meconium, some term newborns may have trouble conjugating the increased amount of bilirubin derived from disintegrating fetal red blood cells (RBCs). As a result, the serum levels of unconjugated bilirubin may rise beyond normal limits, causing hyperbilirubinemia. The goal of treatment of hyperbilirubinemia is to help reduce the newborn's serum levels of unconjugated bilirubin. There are two ways to reduce unconjugated bilirubin levels: **phototherapy** and **exchange blood transfusion**.

Phototherapy. The purpose of phototherapy is to reduce the level of circulating unconjugated bilirubin or to keep it from increasing. Phototherapy uses light energy to change the shape and structure of unconjugated bilirubin and convert it to molecules that can be excreted. The dose and effectiveness of phototherapy are affected by the source of light. Phototherapy units vary in the spectrum of light they deliver and in the filters that are used. The most effective therapy is achieved with special blue fluorescent tubes or a specially designed light-emitting diode (LED). Phototherapy lights do not emit significant ultraviolet radiation; the small amount that is emitted does not cause erythema. Most of the ultraviolet light is absorbed by the glass wall of the fluorescent tube and by the plastic cover of the light (Kamath-Rayne et al., 2021). Phototherapy is usually effective for treatment of hyperbilirubinemia that has not reached levels associated with acute bilirubin encephalopathy or kernicterus.

The effectiveness of phototherapy is related to the distance between the light and the newborn and on the area of skin that is exposed. During phototherapy using a lamp, the newborn wearing only a diaper is placed under a bank of lights approximately 45 to 50 cm from the light source. Newborn should be placed supine for maximum exposure to the light source. Phototherapy can be used for the newborn in an isolette (Figure 26.11) or in an open crib. The distance varies according to unit protocol and type of light used. The lamp's energy output should be monitored routinely with a photometer during treatment to ensure efficacy of therapy.

If phototherapy is effective, the bilirubin level should begin to decrease within 4 to 6 hours after phototherapy is initiated and within 24 hours it should decrease by 30 to 40% (Kamath-Rayne et al., 2021). Phototherapy is used until the newborn's serum bilirubin level decreases to within an acceptable range. The decision to discontinue therapy is based on the observation of a definite downward trend in bilirubin values.

SAFETY ALERT

When a phototherapy lamp is used, the newborn's eyes must be protected by an opaque mask to prevent retinal damage (Figure 26.12). The eye shield should cover the eyes completely but not occlude the nares. Before the mask is applied, the newborn's eyes should be closed gently to prevent excoriation of the corneas. The mask should be removed periodically and during newborn feedings so that the eyes can be assessed and cleansed with water and the parents can have visual contact with the newborn (Kamath-Rayne et al., 2021).

Phototherapy may cause changes in the newborn's temperature, depending partially on the bed used: bassinet, isolette, or radiant warmer. The newborn's temperature should be closely monitored at least every 2 hours. Phototherapy lights can increase the rate of insensible water loss, which contributes to fluid loss and dehydration.

Fig. 26.11 Newborn under phototherapy lights. (iStock.com/stockstudioX)

Fig. 26.12 Newborn with eyes covered while receiving phototherapy. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

Fig. 26.13 A mother can put her newborn skin-to-skin without interrupting phototherapy when a fibre-optic blanket is used. (Courtesy Mother and Childcare, Phillips Healthcare.)

Therefore, it is important that the newborn be adequately hydrated. The healthy newborn is kept hydrated through breastfeeding, pasteurized donor milk, or infant formula; there is no advantage or benefit to administering oral glucose or plain water because these do not promote excretion of bilirubin in stools and may in fact perpetuate enterohepatic circulation, thus delaying bilirubin excretion.

It is important to closely monitor urinary output as an indicator of hydration status while the newborn is receiving phototherapy. Urine output can be decreased or unaltered; the urine can have a dark gold or brown appearance.

The number and consistency of stools should also be monitored. Bilirubin breakdown increases gastric motility, which results in loose stools that can cause skin excoriation and breakdown. The newborn's buttocks must be cleaned after each stool to maintain skin integrity. A fine maculopapular rash may appear during phototherapy, but this is transient.

SAFETY ALERT

No ointments, creams, or lotions should be applied to the newborn's skin during phototherapy because they can absorb heat and cause burns.

Additional systems used for phototherapy include a bassinet system that provides special blue light above and beneath the newborn. Another phototherapy device is a fibre-optic blanket that is connected to a light source (Figure 26.13). The blanket is flexible and can be placed around the newborn's torso or underneath the newborn in the bassinet. There are also bilirubin beds with LED lights in a pad that covers the surface of the bassinet. The LED lights do not produce heat and can be used with radiant warmers. These devices are usually less effective when used alone than with conventional phototherapy lights. They can be very useful in combination with overhead phototherapy lights. In certain instances, the newborn's bilirubin levels increase rapidly and intensive phototherapy is required; this situation involves the use of a combination of conventional lights and fibre-optic blankets to maximize bilirubin reduction. Although fibre-optic lights do not produce heat as conventional lights do, staff should ensure that a covering pad is placed between the newborn's skin and the fibre-optic device to prevent skin burns, especially in preterm newborns. The newborn can remain in the hospital room in an open crib or in the parent's arms during treatment. The use of eye patches depends on whether the devices are used alone or in combination with phototherapy lights.

The use of home phototherapy should be reserved for healthy term newborns with bilirubin levels in the "optional phototherapy" range according to the nomogram. The concern is that home phototherapy units do not provide the same level of irradiance or body surface coverage as phototherapy devices used in the hospital.

Exchange transfusion. When phototherapy is not effective in reducing serum bilirubin levels or in treating severe hyperbilirubinemia such as in hemolytic disease, exchange transfusion may be needed. This procedure is done in an intensive care setting and can reduce bilirubin levels by 45 to 85%. A portion of the newborn's blood is replaced with donor blood (Kamath-Rayne et al., 2021). This invasive procedure is not done frequently, although it may be necessary in the very preterm newborn or newborns with other medical conditions causing the hyperbilirubinemia (see discussion in Chapter 29).

Follow-up. Serum levels of bilirubin in the newborn continue to rise until the fifth day of life. Many parents leave the hospital within 24 hours of birth, and some as early as 6 hours after birth. Therefore, parents must receive education regarding jaundice and its treatment. They should have written instructions for assessing the newborn's condition and the name of a contact person to whom they should report their findings and concerns.

Close follow-up is needed for newborns who have been treated for hyperbilirubinemia. Repeat testing of serum bilirubin levels and follow-up visits with the pediatric health care provider are expected.

Hypoglycemia. **Hypoglycemia** in a term newborn is defined as a blood glucose concentration less than that needed to support adequate neurological, organ, and tissue function; however, there is a lack of consensus regarding the precise level at which this concentration occurs.

At birth, the maternal source of glucose is cut off with the clamping of the umbilical cord. Most healthy term newborns experience a transient decrease in glucose levels to as low as 1.7 mmol/L during the first 1 to 2 hours after birth, with a subsequent mobilization of free fatty acids and ketones to help maintain adequate glucose levels (Blackburn, 2018). Newborns who are asphyxiated or have other

physiological stress may experience hypoglycemia as a result of a decreased glycogen supply, inadequate gluconeogenesis, or overutilization of glycogen stored during fetal life. There is concern about neurological injury as a result of severe or prolonged hypoglycemia, especially in combination with ischemia (Rozance et al., 2021).

There is no need to routinely assess glucose levels of healthy term newborns (Aziz et al., 2004/2018). Breastfeeding early and often helps these newborns maintain adequate glucose levels.

Glucose levels should be measured in newborns at 34 weeks of gestation or more if risk factors or clinical manifestations of hypoglycemia are present. In newborns who are at risk for altered metabolism as a result of maternal illness factors (diabetes, gestational hypertension) or newborn factors (perinatal hypoxia, infection, hypothermia, **polycythemia**, congenital malformations, hyperinsulinism, SGA, LGA, fetal hydrops), close observation and monitoring of blood glucose levels within 2 hours of birth, after an initial feeding, are recommended. The frequency of glucose testing is determined by the risk factors for each individual newborn. Newborns of diabetic mothers should undergo glucose screening before feedings for at least the first 12 hours after birth; further testing is done if glucose levels are less than 2.6 mmol/L. However, preterm and SGA newborns may be vulnerable up to 36 hours of age so should be screened until 36 hours of age if feeding is established and blood glucose is maintained at 2.6 mmol/L or higher (Aziz et al., 2004/2018). Early and frequent breastfeeding and skin-to-skin contact with the parent for as long as possible after birth promote thermoregulation and stabilization of glucose levels (Wight et al., 2014).

The CPS recommendations state that asymptomatic, at-risk babies should receive at least one effective feeding before a blood glucose check at 2 hours of age and should be encouraged to feed regularly thereafter. Blood glucose of less than 2.8 requires follow-up, but if breastfeeding is effective, supplementation with a sugar source is not required. At-risk babies who have persistent blood glucose levels of less than 2.6 mmol/L despite subsequent feeding or symptomatic newborns should also be considered for IV dextrose therapy (Aziz et al., 2004/2018). It is also important to review organization policies regarding hypoglycemia protocols.

Hypoglycemia in the low-risk term newborn is usually eliminated by feeding the newborn a source of carbohydrate (i.e., preferably human milk) or giving dextrose gel, and placing the newborn skin-to-skin with a parent. Occasionally, IV administration of glucose is required for newborns with persistently high insulin levels or in those with depleted stores of glycogen.

Glucose testing should be done in any newborn with clinical signs of hypoglycemia. The clinical signs can be transient or recurrent and include jitteriness, lethargy, poor feeding, abnormal cry, hypotonia, temperature instability (hypothermia), respiratory distress, apnea, and seizures (Rozance et al., 2021). It is important to remember that hypoglycemia can be present in the absence of clinical manifestations.

! NURSING ALERT

Late preterm newborns are at increased risk for hypoglycemia. They have decreased glycogen stores and lack hepatic enzymes for gluconeogenesis and glycogenolysis. Their hormonal regulation and insulin secretion are immature. The increased risk of cold stress and feeding difficulties adds to the risk for hypoglycemia (Premji, 2019).

Hypocalcemia. Hypocalcemia in newborns is defined as serum calcium levels less than 2 mmol/L in the term newborn and slightly lower (1.75 mmol/L) in the preterm newborn. Hypocalcemia is common in critically ill newborns but also can occur in newborns of mothers with diabetes or in those who experienced perinatal asphyxia or trauma and in low-birth-weight and preterm newborns. Newborns born to mothers treated with anticonvulsants during pregnancy are also at risk (Halbardier, 2015). Early-onset hypocalcemia usually occurs within the first 24 to 48 hours after birth. Signs of hypocalcemia include jitteriness, tremors, twitching, high-pitched cry, irritability, apnea, and laryngospasm, although some newborns may be asymptomatic. Jitteriness is a symptom of both hypoglycemia and hypocalcemia; therefore, hypocalcemia must be considered if the therapy for hypoglycemia proves ineffective.

In most instances, early-onset hypocalcemia is self-limiting and resolves within 1 to 3 days. Treatment usually includes early feeding of an appropriate source of calcium, such as fortified human milk or a preterm formula (Nyp et al., 2021). In some cases (e.g., the medically unstable, extremely low-birth-weight newborn) administration of IV elemental calcium and phosphorus may be necessary.

Laboratory and Screening Tests

Because newborns experience many transitional events in the first 28 days of life, laboratory samples are often gathered to determine adequate physiological adaptation and to identify disorders that may adversely affect the child's life beyond the newborn period. Most laboratory tests for newborn screening may be obtained from the newborn with a heel puncture, also known as a heel stick. Tests that may be performed include bilirubin levels, blood glucose, newborn metabolic screening tests (e.g., PKU, hypothyroidism [T_4], sickle cell disease, and galactosemia), and drug serum levels. Box 26.5 lists standard laboratory values in a term newborn.

Universal Newborn Screening. Newborn screening (NBS) is an important public health program aimed at early detection of metabolic diseases that result in severe health conditions if not treated early. As many as 40 conditions may be screened. Earlier identification of these conditions may prevent further developmental delays and morbidities in affected children. The majority of disorders included in NBS are not symptomatic at birth.

While all provinces and territories have programs for NBS, the number of conditions screened for varies by province. The core disorders that are screened for include hemoglobinopathies (e.g., sickle cell disease), inborn errors of metabolism (e.g., PKU, galactosemia), and severe combined immunodeficiency. Although NBS is considered the standard of care, it is important that prior to the test a discussion is held with the parents, informing them of the importance of NBS, as parents have the right to refuse such screening. Information about which tests

BOX 26.5 Standard Laboratory Values in a Term Newborn

Hemoglobin	140–240 g/L
Hematocrit	0.37–0.48
Glucose	1.7–3.3 mmol/L
Leukocytes (white blood cells)	9–30 × 10^9/L
Bilirubin, total serum	1.7-180 mcmol/L
Blood Gases	
Arterial	pH 7.32–7.49
	P_{CO_2} 26–41 mm Hg
	P_{O_2} 60–70 mm Hg
	HCO_3 16-24 mmol/L

P_{CO_2}, Partial pressure of carbon dioxide; P_{O_2}, partial pressure of oxygen. Data from Pagana, K., Pagana, T., & Pike-MacDonald, S. (2019). *Mosby's Canadian manual of diagnostic and laboratory tests* (2nd Canadian ed.). Elsevier.

are performed in each province can be obtained from provincial and territorial health departments, as these vary across the country.

Blood samples are obtained from newborns using a heel stick; blood is collected on a special filter paper and sent to a designated provincial/territorial laboratory for analysis (Figure 26.14). NBS is done between 24 and 48 hours of age, although if a newborn is discharged prior to 24 hours it is recommended that the blood work be done before discharge and then again within 2 weeks (Perinatal Services BC, 2018).

Nurses can provide education for parents regarding the purpose of the screening, the procedure for blood sampling, when to expect results, and the importance of follow-up.

Newborn Hearing Screening. Hearing loss is one of the most common congenital disorders, with approximately 3 in 1 000 newborns born profoundly deaf and another 3 in 1 000 having serious hearing impairment (CPS, 2020b). In Canada, newborn hearing screening has been an established routine practice in most provinces, but not all. This screening offers a potentially critical sequelae of tests to establish that the newborn is able to hear and will be aware of the early engagement in sound and language. If testing points to a hearing impairment, interventions can be implemented early to mitigate the potential for complex social barriers (Patel et al., 2011/2018). Through early hearing detection and intervention programs, the outcome for newborns who are deaf or hearing impaired can be maximized.

Using noninvasive technology, newborn hearing screening provides information about the pathways from the external ear to the cerebral cortex. Two tests commonly are used to assess hearing function in the newborn: initial screening is done with the evoked otoacoustic emissions (EOAE) test, and the auditory brainstem response (ABR) test is used as follow-up if the initial screening is abnormal. Neither test is definitive in diagnosing hearing impairment; they are used to determine whether further, more accurate hearing testing is needed through audiological evaluation. For the EOAE test, a soft rubber earpiece that makes a soft clicking noise is placed in the newborn's outer ear (Figure 26.15, *A*). A healthy ear will "echo" the click sound back to a microphone inside the earpiece that is in the newborn's ear. The ABR test is performed by attaching sensors to the newborn's forehead and behind each ear. An earphone is placed in the newborn's outer ear and sends a series of quiet sounds into the sleeping newborn's ear (Figure 26.15, *B*). The sensors measure the responses of the newborn's acoustic nerve. The responses are recorded and stored in a computer.

Newborns who do not pass the initial screening test should have the hearing screening test repeated as part of follow-up care. If the newborn

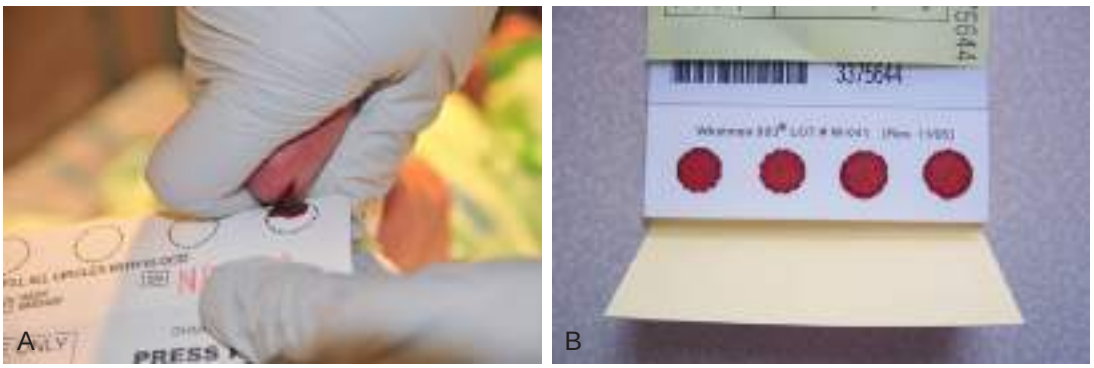

Fig. 26.14 **A,** Nurse obtaining blood sample from newborn's heel for universal screening. Sample is applied to filter paper. **B**, All circles on the filter paper must be filled in completely. (Courtesy Cheryl Briggs, RNC, Annapolis, MD.)

Fig. 26.15 Newborn hearing screening. **A:** Evoked otoacoustic emissions (EOAE) test. **B:** Auditory brain response (ABR) test. (*A*, Courtesy Julie and Darren Nelson. *B*, Courtesy Dee Lowdermilk.)

still does not pass the test, a comprehensive audiological evaluation should be done by 3 months of age.

Screening for Critical Congenital Heart Disease (CCHD).

Congenital heart disease (CHD) is the most common congenital malformation, with a prevalence of 12/1 000 live births in Canada. Approximately one quarter of these newborns have CCHD, defined as more severe and often duct-dependent lesions that require intervention early in life for optimal outcome (Narvey et al., 2017). Optimum screening should include prenatal ultrasound, physical examination, and pulse oximetry screening. The noninvasive screening test is performed using pulse oximetry to measure oxygen saturation for the purpose of detecting hypoxemia. Pulse oximetry testing can detect some critical congenital heart defects that present with hypoxemia in the absence of other physical symptoms. Hypoxemia can be the first sign that a congenital heart defect is present, and other symptoms can develop once the newborn has been discharged. Screening is performed at 24 to 36 hours of age. Oxygen saturation is measured in the right hand and one foot. A "passing" result is oxygen saturation of greater than or equal to 95% in the right hand or either foot, with a less than 3% absolute difference between the upper and lower extremity readings. Repeated screens are recommended for "borderline" results with oxygen saturation between 90 and 94% or less than 3% difference between extremities. An oxygen saturation less than 90% in either extremity requires immediate health care provider intervention (Narvey et al., 2017). This noninvasive test can be performed in less than 5 minutes. It is estimated that implementation of pulse oximetry screening could detect an additional 136 CCHD cases per year before the appearance of symptoms (Narvey et al., 2017).

Collection of Specimens.

Ongoing evaluation and screening of a newborn often requires obtaining blood by heel stick or venipuncture or the collection of a urine specimen. Laboratory tests may be ordered routinely (e.g., NBS) or for a specific purpose as directed by the health care provider.

Heel stick. Some blood specimens may be drawn by laboratory technicians. However, nurses generally have established a relationship with the family and are able to perform heel sticks at the bedside to obtain blood for glucose monitoring or NBS or other tests.

! NURSING ALERT

Blood samples should be collected in a manner that minimizes pain and trauma to the newborn and maximizes the accuracy of test results. If a laboratory technician is collecting the specimen, the nurse assists as needed to maximize safety and newborn comfort. It is recommended that the parent have skin-to-skin contact with the newborn prior to and during the heel prick to minimize newborn pain during the procedure (Johnston et al., 2017).

It is often helpful to warm the heel before the sample is taken; application of heat for 5 to 10 minutes helps dilate the blood vessels in the area. A cloth soaked with warm water (not hot) and wrapped loosely around the foot provides effective warming (Figure 26.16, *A*). Disposable heel warmers are available from a variety of companies; they should be used with care to prevent burns. Nurses should wear gloves when collecting any specimen. The nurse cleanses the area with an appropriate skin antiseptic, allows the area to dry, restrains the newborn's foot with a free hand, and then punctures the site. A spring-loaded automatic puncture device causes less pain and requires fewer punctures than a manual lance blade; therefore, manual lance blades should not be used on newborns. It is important that the heel is not "milked" to obtain the blood specimen.

The most serious complication of newborn heel stick is necrotizing osteochondritis from lancet penetration of the bone. To prevent this, the penetration should be made at the outer aspect of the heel and should be no deeper than 2.4 mm. To identify the appropriate puncture site, the nurse should draw an imaginary line running from between the fourth and fifth toes and parallel to the lateral aspect of the foot to the heel where the puncture is made; a second line can be drawn from the great toe to the medial aspect of the heel (see Figure 26.16, *B*). Repeated trauma to the walking surface of the heel can cause fibrosis and scarring that may lead to difficulties with walking later in life.

After the specimen has been collected, pressure is applied with a dry gauze square. No further skin cleanser should be applied because this will cause the site to continue to bleed. The site is then covered with an adhesive bandage. The nurse needs to ensure proper disposal of equipment used, review the laboratory requisition for correct identification, and check the specimen for adequate labelling and routing.

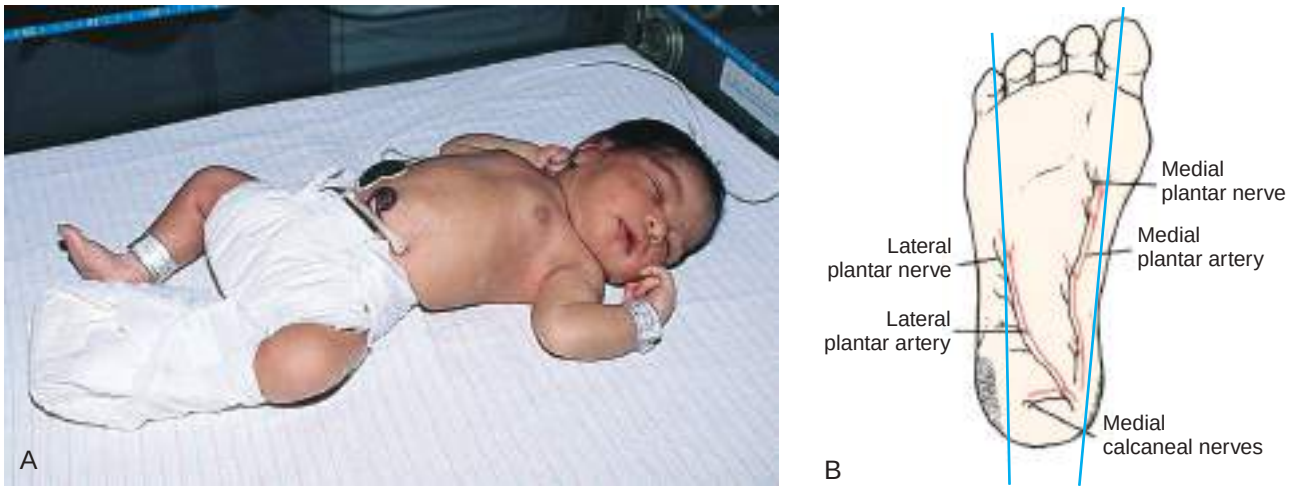

Fig. 26.16 Heel stick. **A:** Newborn with foot wrapped for warmth to increase blood flow to extremity before heel stick. **B:** Heel stick sites (shaded areas) on newborn's foot for obtaining samples of capillary blood. (*A*, Courtesy Marjorie Pyle, RNC, Lifecircle.)

A heel stick is traumatic for the newborn and causes pain. Nurses should ensure that they use effective newborn pain prevention programs utilizing all nonpharmacological and pharmacological methods aimed at prevention of potentially hurtful routine procedures (Barrington et al., 2007/2017) (see Management of Pain in the Newborn, later in the chapter). This will help to reassure the newborn and to promote feelings of safety. Parental reassurance is essential before, during, and after routine procedures.

Venipuncture. Occasionally, laboratory tests are ordered that require larger samples of blood than can be collected with a heel stick. Venous blood samples can be drawn from antecubital, saphenous, superficial wrist, and, rarely, scalp veins. When venipuncture is required, positioning of the needle is extremely important. A 23- or 25-gauge butterfly needle or hypodermic needle with a syringe is used (Figure 26.17). Patience is required during the procedure because the blood return in small veins is slow; consequently, the small needle must remain in place longer than a larger needle. A tourniquet is optional but can help increase blood flow with venipuncture. The newborn is carefully held during the procedure to prevent injury (see Chapter 34). Pain relief is also a key component to nursing care in any venipuncture procedure.

If venipuncture or arterial puncture is performed for blood gas studies, crying, fear, and agitation will affect the values; therefore, every effort must be made to keep the newborn quiet during the procedure. Pressure must be maintained over an arterial or femoral vein puncture with a dry gauze square for 3 to 5 minutes to prevent bleeding from the site.

For an hour after any venipuncture, the nurse should observe the newborn frequently for evidence of bleeding or hematoma formation at the puncture site. The newborn should be cuddled and comforted when the procedure is completed and appropriate pain management measures taken. The nurse needs to assess and document the newborn's tolerance of the procedure.

Urine specimen. Analysis of urine is a valuable laboratory tool for newborn assessment; the way in which the specimen is collected can influence the results. The urine sample should be fresh and analyzed within 1 hour of collection. A urine collection bag is often used to obtain a specimen (see Chapter 44 for more information about the procedure for collecting a urine specimen from a newborn).

Interventions

Protective Environment. The provision of a protective environment is basic to the care of the newborn. Hospital personnel develop their own policies and procedures for protecting newborns under their care. Prescribed standards cover areas such as environmental factors, measures to control infection, and safety factors.

Fig. 26.17 Venipuncture using a butterfly needle. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

Current health care trends and the focus on nonseparation of parents and babies have prompted most hospitals to abandon having a separate newborn nursery. In the dyad model of care, the newborn stays in the parent's room, which reduces the need for a separate nursery.

Environmental factors. Environmental factors include provision of adequate lighting, elimination of potential fire hazards, safety of electrical appliances, adequate ventilation, and controlled temperature (i.e., warm and free of drafts) and humidity.

Measures to control infection. Measures to control infection include adequate floor space for positioning bassinets at least 90 cm apart in all directions if in a newborn nursery, hand hygiene facilities, and areas for cleaning and storing equipment and supplies. Only those personnel directly involved in the care of parents and newborns are allowed in these areas, thereby reducing opportunities for the introduction of pathogenic organisms.

! NURSING ALERT

Proper hand hygiene is essential to preventing the spread of health care–associated infections (HAI). Personnel should wash their hands with soap and water or use an alcohol-based hand rub in accordance with hospital infection control policies. Hand hygiene should be performed before and after touching the newborn, before an invasive procedure or medication administration, after contact with potentially contaminated objects (e.g., computer keyboards, telephone, countertop surfaces), and after removing sterile or nonsterile gloves (WHO, 2009).

Health care workers must wear gloves when handling the newborn before blood and amniotic fluid have been removed from the newborn's skin, when drawing blood (e.g., heel stick), when caring for a fresh wound (e.g., circumcision), when assisting with breastfeeding, and during diaper changes.

Visitors and health care providers, including nurses, physicians, parents, siblings, and grandparents, are expected to wash their hands before having contact with newborns or equipment. Individuals with infectious conditions, including upper respiratory tract or gastrointestinal tract infections and infectious skin conditions, should be excluded from contact with newborns or must take special precautions when working with newborns.

Safety factors. Personnel caring for newborns must be clearly identified by photo identification, and parents must be educated about measures to prevent abduction from the parent's room (i.e., be certain they know the identity of anyone who cares for the newborn and never release the newborn to anyone who is not wearing the appropriate identification). Other safety measures include placing matching identification bracelets on newborns and their parents and using identification bands with radiofrequency transmitters that set off an alarm if the bracelet is removed or if a certain threshold is crossed (doorway to exit building or floor). Nurses and new parents must work together to ensure the safety of newborns in the hospital environment.

Prevention of newborn falls. Newborns are at risk of injury as a result of falling. Even falls occurring from low-level surfaces such as beds or chairs can result in head injury that could include skull fracture. Most falls occurring in hospital settings appear to occur when the parent falls asleep while holding the newborn in bed or reclining chair, although some occur during transportation of the newborn. Risk factors in the parent for newborn falls include sleep deprivation,

Caesarean birth, pain medication with sedatives, and leaving the newborn unattended.

Nurses have developed programs to prevent and manage falls, emphasizing sensitization of hospital staff, parent education, assessing for falls risks, fall management algorithms, and implementing hospital policies (Ainsworth et al., 2016; Miner, 2019).

SAFETY ALERT

Nurses play a critical role in newborn fall prevention. Parental exhaustion levels should be part of routine nursing assessments. Education provided to parents should include placing the newborn in a supine position for sleeping in a cot or bassinet and the potential risk associated with bed-sharing. Newborns should always be transported via newborn cot and not carried outside of the hospital room in the parent's arms. Educating parents using a nonjudgemental approach may increase the likelihood that a parent will report a newborn fall (Ainsworth et al., 2016).

Immunizations. In some provinces the hepatitis B vaccine is given at birth, whereas in others it is given before the child is a preteen. If not routinely given at birth, hepatitis B vaccination is recommended for newborns at highest risk of contracting hepatitis B. This includes newborns born to a parent with hepatitis B or whose hepatitis B status is unknown or if another family member who lives in the home has hepatitis B. If the newborn is born to an infected mother or to a mother who is a chronic carrier, hepatitis B vaccine and hepatitis B immune globulin (HBIG) should be given within 12 hours of birth (see Medication Guides). The Public Health Agency of Canada website has the vaccination schedule for different provinces (see Additional Resources at the end of the chapter).

MEDICATION GUIDE

*Hepatitis B Vaccine (Recombivax HB, Engerix-B)**

Action
Hepatitis B vaccine induces protective anti–hepatitis B antibodies in 95 to 99% of healthy newborns who receive the recommended three doses. The duration of protection of the vaccine is unknown.

Indication
Hepatitis B vaccine provides immunization against infection caused by all known subtypes of hepatitis B virus.

Newborn Dosage
The usual dosage is Recombivax HB 5 mcg/0.5 mL or Engerix-B 10 mcg/0.5 mL at birth, 1 month, and 6 months. (See also Immunizations, Chapter 35.)

Adverse Reactions
Common adverse reactions are rash, fever, erythema, swelling, and pain at injection site.

Nursing Considerations
- Parental consent must be obtained before administration.
- Follow proper procedure for administration of intramuscular (IM) injection (see Figure 26.4). If the newborn also needs hepatitis B immune globulin (HBIG), use separate sites for the two injections.
- For newborns born to hepatitis B surface antigen (HBsAg)–positive mothers: administer HepB vaccine and HBIG within 12 hours after birth.
- Document immunization administration on a vaccination card for parent(s) to have a record.

*Note: The combination vaccines containing hepatitis B are not recommended for the birth (first) dose.

MEDICATION GUIDE

Hepatitis B Immune Globulin

Action
Hepatitis B immunoglobulin (HBIG) provides a high titre of antibody to hepatitis B surface antigen (HBsAg).

Indication
The HBIG vaccine provides prophylaxis against infection in newborns born to HBsAg-positive mothers.

Newborn Dosage
Administer one 0.5-mL dose intramuscularly within 12 hours of birth.

Adverse Reactions
Hypersensitivity may occur.

Nursing Considerations
- Administer within 12 hours of birth.
- Follow proper procedure for administration of intramuscular injection.
- The HBIG vaccine may be given at the same time as hepatitis B vaccine, but at a different site.
- Document immunization administration on a vaccination card for parent(s) to have a record.

Circumcision. Circumcision is the removal of all or part of the foreskin (prepuce) of the penis. Usually it is performed during the first week of life but is sometimes done at a later time for preterm or ill newborns or for religious or cultural reasons. It is often performed in the community after discharge in physician offices or clinics. The most recent reported rate of newborn male circumcision (NMC) in Canada was in 2007 and was 32%; the rates are highest in Alberta (44%) and Ontario (43%) and below 10% in Northwest Territories and Nova Scotia (Public Health Agency of Canada [PHAC], 2009; Sorokan et al., 2015/2018). Circumcision is considered an elective procedure; all provincial health insurance plans have removed nontherapeutic NMC from the schedule of procedures covered under provincial health care plans. This factor, and possibly a wider movement to holistic health, has led to a decline in the rate of NMC in Canada.

The CPS policy statement regarding NMC states that NMC may have some health benefits, including prevention of urinary tract infection in male newborns younger than 1 year, reduced risk for penile cancer, and reduced risk for heterosexual acquisition of sexually transmitted infections (STIs), particularly HIV (Sorokan et al., 2015/2018). Despite the scientific evidence of potential medical benefits of circumcision for some boys in high-risk populations, the CPS has stated that the data are not sufficient to recommend routine circumcision. The WHO (2016) recognizes male circumcision as an important intervention in reducing the risk for heterosexually acquired HIV in men.

Circumcision is a matter of personal parental choice. Parents usually decide to have their newborn circumcised on the basis of one or more of the following factors: religious conviction, tradition, culture, social norms, or perceived hygiene benefits although this is not true as hygiene with an uncircumcised penis is not a concern. Parents need to make an informed choice regarding newborn circumcision based on the most current evidence and recommendations. Health care providers and nurses who care for childbearing families can help parents make an informed choice about newborn circumcision by providing factual, unbiased, evidence-informed information that includes a discussion about the benefits and risks of the procedure (see Community Focus box: Newborn Circumcision). For parents who

decide not to have their newborn son circumcised they need to be taught to clean the penis with soap and water and to not retract the foreskin until it is easily done, often not until the child is 3 or 4 years old and sometimes not until the child is an adolescent.

COMMUNITY FOCUS

Newborn Circumcision

Prepare a poster presentation to provide parents information on newborn circumcision. Because circumcision is considered an optional surgical procedure, it may not be performed until after the newborn is discharged home. Include in your display the advantages and disadvantages of circumcision, as well as the care of the uncircumcised penis in newborns and young children.

Procedure. Circumcision involves removal of the **prepuce** (foreskin) of the glans. The procedure is not usually done immediately after birth because of the danger of cold stress and decreased clotting factors, but it may be performed in some hospitals before the newborn's discharge. The circumcision of a Jewish boy is performed on the eighth day after birth and is often done at home in a ceremony called a *bris*. The timing is logical from a physiological standpoint because clotting factors drop somewhat immediately after birth and do not return to prebirth levels until the end of the first week.

Feedings may be withheld up to 2 to 3 hours before the circumcision to prevent vomiting and aspiration, although some practitioners allow newborns to breastfeed until the time they are taken for the procedure. To prepare the newborn for the circumcision, he is positioned on a plastic restraint form (Figure 26.18) and the penis is cleansed with soap and water or other prep solution such as povidone-iodine. The newborn is draped to provide warmth and a sterile field, and the sterile equipment is readied for use.

Newborn circumcision is usually performed using the Gomco (Yellen) or Mogen clamp or the PlastiBell device. The technique is usually based on health care provider training and preference. The procedure takes only a few minutes to perform. Use of the Gomco or Mogen clamp involves surgical removal of the foreskin. The clamp technique minimizes blood loss (Figure 26.19). With the PlastiBell technique, the plastic bell is first fitted over the glans, a suture is tied around the rim of the bell, and excess foreskin is cut away. The plastic rim remains in place for about a week; it falls off after healing has taken place, usually within 5 to 7 days (Figure 26.20).

Procedural pain management. Circumcision is painful. The pain is manifested by both physiological and behavioural changes in the newborn (see discussion on newborn pain that follows). Three types of anaesthetics are used in newborns undergoing circumcision: ring block, dorsal penile nerve block (DPNB), and topical anaesthetic such as eutectic mixture of lidocaine and prilocaine (EMLA) (prilocaine-lidocaine). Nonpharmacological methods such as concentrated oral sucrose, non-nutritive sucking, and swaddling may be used to enhance pain management. Pain during circumcision is most effectively managed using a combination of pharmacological and nonpharmacological measures (Bellieni et al., 2013).

A DPNB consists of subcutaneous injections of buffered lidocaine at the 2 o'clock and 10 o'clock positions on the dorsum of the penis.

Fig. 26.18 Proper positioning of newborn in Circumstraint. (Courtesy Paul Vincent Kuntz, Texas Children's Hospital.)

Fig. 26.19 Circumcision with Gomco (Yellen) clamp. After hemostasis occurs, the foreskin (over the metal dome) is cut away. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

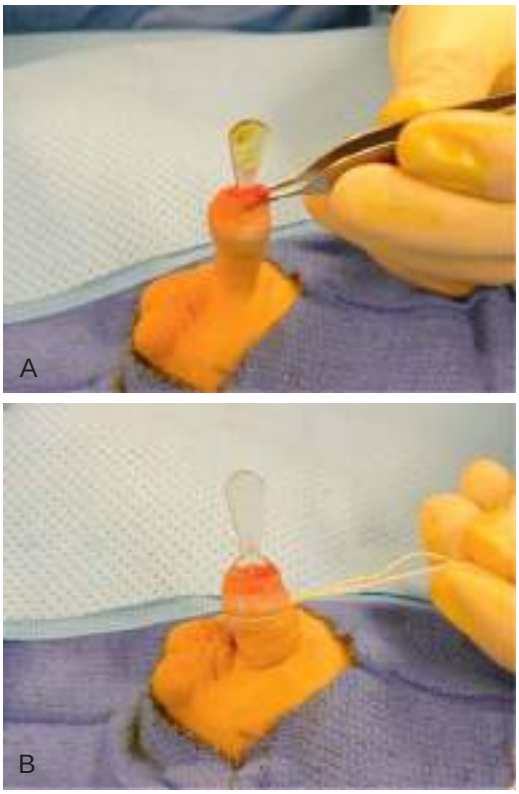

Fig. 26.20 The PlastiBell technique. **A,** The PlastiBell is placed over the glans inside the prepuce. **B,** A string is then tied around the prepuce and positioned in the groove of the bell. The excess foreskin is trimmed, and the handle is broken off the bell. The foreskin remnant and bell are expected to slough in 1 to 2 weeks. (From Holcomb, G. W., Murphy, J. P., & Ostlie D. J. [2014]. *Ashcraft's pediatric surgery* [6th ed.]. Elsevier.)

Alternatively, buffered lidocaine may be administered using a ring block with injections around the base of the penis. To ensure adequate anaesthesia, circumcision should not be performed for at least 5 to 8 minutes after these injections (Gardner et al., 2021).

A topical anaesthetic cream (EMLA) can be applied to the penis at least 1 hour before the circumcision. The area where the prepuce attaches to the glans is well coated with 1 g of the cream and then covered with a transparent occlusive dressing or finger cot. Just before the procedure, the cream is removed. Blanching or redness of the skin can occur.

After the circumcision, the newborn should be comforted until he is quieted. If the parents were not present during the procedure, the newborn should be returned to them. The newborn should be positioned to breastfeed, or placed skin-to-skin with the parent or other care provider. Afterward, the newborn may be fussy for several hours and may have disturbed sleep–wake states and disorganized feeding behaviours. Some newborns will go into a deep sleep after circumcision until they are awakened for feeding. Oral acetaminophen may be administered before the procedure and every 4 hours thereafter (as ordered by the health care provider) for a maximum of five doses in 24 hours or a maximum of 75 mg/kg/day.

Care of the newly circumcised newborn. Postcircumcision protocols vary. In many settings, the circumcision site is assessed for bleeding every 15 to 30 minutes for the first hour and then hourly for the next 4 to 6 hours. The nurse needs to monitor the newborn's urinary output, noting the time and amount of the first voiding after the circumcision.

If bleeding occurs from the circumcision site, the nurse applies gentle pressure with a folded sterile gauze pad. A hemostatic agent such as Gelfoam® powder or sponge can be applied to help control bleeding. If bleeding is not easily controlled, a blood vessel may need to be ligated. In this event, one nurse notifies the physician and prepares the necessary equipment (i.e., circumcision tray and suture material) while another nurse maintains intermittent pressure until the health care provider arrives.

Nurses provide education for parents that is related to care of the circumcised newborn, which includes observing for complications such as bleeding or infection (see Patient Teaching box: Care of the Circumcised Newborn).

PATIENT TEACHING

Care of the Circumcised Newborn

Wash hands before touching the newly circumcised penis.

Check for Bleeding

- Check circumcision for bleeding with each diaper change.
- If bleeding occurs, apply gentle pressure with a folded sterile gauze square. If bleeding does not stop with pressure, notify the primary health care provider.

Observe for Urination

- Check to see that the newborn urinates after being circumcised.
- The newborn should have wet diapers appropriate for age.

Keep Area Clean

- Change the diaper and inspect circumcision at least every 4 hours.
- Wash the penis gently with warm water to remove urine and feces. Apply petrolatum liberally to the glans with each diaper change (omit petrolatum if PlastiBell was used). Do not use newborn wipes because they can contain alcohol.
- Do not wash the penis with soap until the circumcision is healed (5 to 6 days).
- Use a sponge bath only until circumcision heals.
- Apply the diaper loosely over the penis to prevent pressure on the circumcised area.

Check for Infection

- Glans penis is dark red after circumcision, then becomes covered with yellow exudate in 24 hours. This is normal and will persist for 2 to 3 days. Do not attempt to remove it.
- Redness, swelling, or discharge indicates infection. Notify the primary health care provider if you think the circumcision area is infected.

Provide Comfort

- Circumcision is painful. Handle the area gently.
- Provide acetaminophen as required and ordered by the health care provider.
- Provide comfort measures such as holding the newborn skin-to-skin, cuddling, rocking, and giving opportunities for non-nutritive sucking for a day or two.

Pain in the Newborn

Newborn Responses to Pain. While pain in the newborn and pain in later life can be qualitatively different, research has substantiated that newborns do experience pain (Blackburn, 2018). This counters previous thinking that the immaturity of the nervous system prevented or blunted pain sensation and that newborns were incapable of remembering painful experiences.

Pain has physiological and psychological components. It's psychological component and the diffuse total body response to pain exhibited by the newborn led many health care providers in the past to believe that newborns, especially preterm newborns, do not experience pain. The central nervous system is well developed, however, as early as 24 weeks of gestation. The peripheral and spinal structures that transmit pain information are present and functional between the first and second trimesters. The pituitary–adrenal axis is also well developed at this time, and a fight-or-flight reaction is observed in response to the catecholamines released in response to stress.

The physiological response to pain in newborns can be life-threatening. Pain response can decrease tidal volume, increase demands on the cardiovascular system, increase metabolism, and cause neuroendocrine imbalance. The hormonal–metabolic response to pain in a term newborn has greater magnitude and shorter duration than that in adults. The newborn's sympathetic response to pain is less mature and therefore less predictable than an adult's.

Pain response is influenced by a variety of factors, such as characteristics of the painful stimulus, gestational age, biological factors, and behavioural state. The source, location, and timing of the pain affect the response; newborns respond differently to acute pain than to prolonged or recurrent pain. Pain perception and stress can be greater in preterm newborns, although they often display less vigorous pain responses than term newborns (Maxwell et al., 2013). There can be genetic differences in pain responses related to the amount and type of neurotransmitters and receptors available to mediate pain. The behavioural state of the newborn also affects the pain response. Those who are more awake tend to have more robust pain responses than those in sleep states (Gardner et al., 2021).

The most common behavioural sign of pain is a vocalization or crying, ranging from a whimper to a distinctive high-pitched, shrill cry. Facial expressions include grimacing, eye squeeze, brow contraction, deepened nasolabial furrows, a taut and quivering tongue, and an open mouth (Figure 26.21) (Harrison et al., 2015). The newborn will flex and adduct the upper body and lower limbs in an attempt to withdraw from the painful stimulus. The preterm newborn has a lower-than-normal threshold for initiation of this flex response (Blackburn, 2018).

Pain can result in significant changes in heart rate, BP (increased or decreased), intracranial pressure, vagal tone, respiratory rate, and oxygen saturation. Newborns respond to painful stimuli with release of

Fig. 26.21 Signs of discomfort: note eye squeeze, brow bulge, nasolabial furrow, and wide-spread mouth. (Courtesy Kathryn Alden.)

epinephrine, norepinephrine, glucagon, corticosterone, cortisol, 11-deoxycorticosterone, lactate, pyruvate, and glucose (Blackburn, 2018) (Box 26.6).

Assessment of Pain in the Newborn. In assessing pain, the nurse needs to consider the health of the newborn, the type and duration of the painful stimulus, environmental factors, and the newborn's state of alertness. For example, severely compromised newborns may be unable to generate a pain response even though they are, in fact, experiencing pain.

Pain should be assessed and documented on a regular basis for all newborns, and a pain management plan should be developed if required. Assessing pain in a newborn can be difficult given the nonverbal communication signs that need to be taken into account. Because of this, a minimum of 30 seconds of visual observation by the nurse is recommended to assess newborn pain. Although many validated scoring systems have been developed to help in this assessment, no universal tool has yet to be adopted (Witt et al., 2016). Validated pain scales developed for newborn assessment are summarized in Table 26.4. See Evolve website for Nursing Skills: Pain Assessment and Management in the Full-Term Newborn. Further discussion of pediatric pain management is in Chapter 34.

TABLE 26.4 Validated Pain Scales for Assessing Newborn Procedural Pain

Pain Scale	Assessment Parameters
NIPS (Neonatal Infant Pain Score)	Facial expression, crying, breathing, arm and leg movements
PIPP (Premature Infant Pain Profile)	Gestational age, behavioural state, heart rate, oxygen saturation, facial expression
NFCS (Neonatal Facial Coding System)	Presence of facial expressions associated with irritability: brow bulge, eye squeeze, nasolabial furrow, open lips
DAN (Douleur Aiguë du Nouveau-Né)	Facial responses, limb movements, vocal expression of pain
EDIN (Échelle Douleur Inconfort Nouveau-Né)	Facial expression, extremity tone, sleeping pattern, comfort level, interaction level

BOX 26.6 Manifestations of Acute Pain in the Newborn

Physiological Responses

Vital signs—Observe for variations.
- Increased heart rate
- Increased blood pressure
- Rapid, shallow respirations

Oxygenation
- Decreased transcutaneous oxygen saturation ($tcPo_2$)
- Decreased arterial oxygen saturation (Sao_2)

Skin—Observe colour and character.
- Pallor or flushing
- Diaphoresis
- Palmar sweating

Laboratory evidence of metabolic or endocrine changes
- Hyperglycemia
- Lowered pH
- Elevated corticosteroids

Other observations:
- Increased muscle tone
- Dilated pupils
- Decreased vagal nerve tone
- Increased intracranial pressure

Behavioural Responses

Vocalizations—Observe quality, timing, and duration.
- Crying
- Whimpering
- Groaning

Facial expression—Observe characteristics, timing, orientation of eyes and mouth.
- Grimaces
- Brow furrowed
- Chin quivering
- Eyes tightly closed
- Mouth open and squarish

Body movements and posture—Observe type, quality, and amount of movement or lack of movement; relationship to other factors.
- Limb withdrawal
- Thrashing
- Rigidity
- Flaccidity
- Fist clenching

Changes in state—Observe sleep, appetite, activity level.
- Changes in sleep–wake cycles
- Changes in feeding behaviour
- Changes in activity level
- Fussiness, irritability
- Listlessness

Modified from Blackburn, S. (2018). *Maternal, fetal, and neonatal physiology: A clinical perspective* (5th ed.). Elsevier; Gardner, S. L., Enzman-Hines, M., & Agarwal, R. (2021). Pain and pain relief. In S. L. Gardner, B. S. Carter, M. Enzman-Hines M, et al. (Eds.), *Merenstein & Gardner's handbook of neonatal intensive care: An interprofessional approach* (9th ed.). Elsevier.

Healthy term newborns are exposed to fewer sources of pain than preterm newborns in an NICU where painful procedures are inherent to care management. Even in low-risk newborns, nurses need to assess for signs of discomfort as part of routine assessments, especially during and after routine procedures such as heel sticks, injections, and circumcision.

Management of Pain in the Newborn. The goals of the management of pain in a newborn are to (1) minimize the intensity, duration, and physiological cost of the pain and (2) maximize the newborn's ability to cope with and recover from the pain. Nonpharmacological and pharmacological strategies are used. It is important to note that despite research evidence, policies, and standards of practice focused on assessing and managing pain in newborns, acute newborn pain remains undermanaged and, in some cases, unmanaged (Gardner et al., 2021).

Nonpharmacological management. A variety of nonpharmacological pain management techniques are used with newborns. Nurses and parents may combine two or more techniques as they seek to promote newborn comfort and reduce pain.

Non-nutritive sucking on a pacifier is a common comfort measure used with newborns. Oral sucrose in small amounts given with a syringe with or without a pacifier for sucking is safe and effective in reducing newborn pain during single events (Bueno et al., 2013; Kassab et al., 2012; Stevens et al., 2016). Oral sucrose and non-nutritive sucking given a few minutes before a painful procedure may help reduce the discomfort.

Skin-to-skin contact with a parent, also known as *kangaroo care*, during a painful procedure can help reduce pain (Harrison et al., 2015). Breastfeeding or breast milk helps reduce pain during heel lancing and blood collection (Cong et al., 2013; Reece-Stremtan et al., 2016). Many health care providers have integrated breastfeeding into their routine when taking blood work from the newborn as an effective and readily available method of decreasing pain.

One of the most common measures is swaddling or snugly wrapping the newborn with a blanket. Swaddling limits the newborn's boundaries, aids in self-regulation, and reduces physiological and behavioural stress resulting from acute pain (Pillai Riddell et al., 2015). Swaddling is popular among nurses and parents as a comfort measure for calming a fussy baby and for promoting sleep. However, it is important that it is done properly. Safe swaddling involves wrapping the baby snugly in a lightweight blanket with the arms extended, legs flexed, and hips in neutral position without rotation (CPS, 2018). In the early newborn period, nurses often swaddle newborns with the arms flexed (Figure 26.22).

Other nonpharmacological measures for reducing pain in newborns include touch, massage, rocking, holding, and environmental modification (e.g., low noise and lighting). Combining these nonpharmacological methods results in more effective pain reduction. Distraction with visual, oral, auditory, or tactile stimulation can be helpful in managing pain in term newborns or older infants (see Evidence-Informed Practice box: Nonpharmacological Pain Relief for Newborns). Sensorial saturation uses multiple senses to diminish minor pain. This technique involves speaking softly to the newborn, massaging the face, and providing oral sucrose solution on the tongue (Bellieni et al., 2012).

Pharmacological management. Pharmacological agents are used to alleviate pain in newborns that is associated with procedures. Local anaesthesia is routinely used during procedures such as circumcision and chest tube insertion. Topical anaesthesia is used for circumcision, lumbar puncture, venipuncture, and heel sticks. Nonopioid analgesia

EVIDENCE-INFORMED PRACTICE

Nonpharmacological Pain Relief for Newborns

Ask the Question

For term newborns, what complementary or alternative pain relief is effective for minor painful procedures, such as heel stick?

Databases Used

Cochrane Collaborative Database, National Guidelines Clearinghouse (AHRQ), CINAHL, and PubMed

Critically Analyze the Evidence

Pain scores in newborns are used to assess physical and behavioural changes that help determine pain levels. Physical measures typically include heart rate, respiratory rate, and peripheral oxygen saturation. Other physiological measures include gas exchange across skin, skin sensitivity measures, and electroencephalogram (EEG). Ways to measure behavioural changes include various scales utilizing breathing patterns, states of arousal, facial tension, leg movement, activity, cry, and consolability.

- Sucrose is effective at decreasing pain response for single painful procedures, especially when paired with sucking (Stevens et al., 2016).
- Skin-to-skin contact during painful procedures such as heel stick decreases behavioural pain scores but not physiological measures and is safe. Skin-to-skin with breastfeeding is the first choice for single painful procedures, for the multisensorial and synergistic comfort it brings. It also provides the parents with a caretaking role (Johnston et al., 2014).
- Breastfeeding or breastmilk is an effective method of pain relief during heel lancing (Reece-Stremtan et al., 2016).
- For preterm newborns until 3 years of age, pain reactivity and immediate pain regulation were significantly improved with non-nutritive sucking, swaddling, and holding/rocking (Pillai Riddel et al., 2015).
- A randomized control study of 102 newborns found that the smells of lavender and breast milk decreased both physiological and behavioural responses to pain during heel stick more than control (Akcan & Polat, 2016).
- Newborns in a Canadian neonatal intensive care unit whose mothers were present during a painful procedure were more likely to receive effective pain management strategies than those newborns whose mothers were not present, indicating that parents may have a positive influence on pain management in their children (Johnston et al., 2011).

Apply the Evidence: Nursing Implications

- For newborns who experienced a painful stimulus, subsequent painful procedures caused increased response (Gokulu et al., 2016). This has implications for decreasing the initial pain response as much as possible, especially in the neonatal critical care setting where multiple painful stimuli may be necessary.
- Nonpharmacological pain relief methods for newborns utilize the gate-control theory to distract the newborn's attention by using strong single or multisensorial stimulation. Warmth, touch, sensory attention, swaddling, rocking, breastfeeding, sucking a sweet solution, and smells decrease pain scores.
- Parents who are taught these techniques become active participants in their newborn's procedural care. However, they need clear education that using sucrose is not an appropriate long-term strategy for use at home.
- Comfort measures may work best when initiated a few minutes prior to the procedure, to allow the newborn time to relax and reorganize.
- Procedures other than single heel stick or needlestick should be evaluated for pharmacological analgesia.

(oral liquid acetaminophen) is effective for mild to moderate pain from inflammatory conditions. Morphine and fentanyl are the most widely used opioid analgesics for pharmacological management of newborns' pain. Continuous or bolus IV infusion of opioids provides effective and safe pain control. Other methods for managing newborns' pain are epidural infusion, local and regional nerve blocks, and intradermal or topical anaesthetics (Gardner et al., 2021). See Chapter 34 for further discussion of pain management.

Promoting Parent–Newborn Interaction

Nurses play an important role in promoting early social interaction between parents and their newborn. From birth throughout the hospital stay, nurses assess attachment behaviours (see Chapter 23) and provide support and education to parents as they become acquainted with the newborn. Nurses working in outpatient settings or home care provide follow-up assessments and care related to parent–child interactions. By teaching parents to recognize newborn cues and respond appropriately, the nurse facilitates development of the parents' confidence in meeting the needs of their newborn (see Family-Centred Care box: Helping Parents Recognize, Interpret, and Respond to Newborn Behaviours).

The sensitivity of the parent to social responses of the newborn is basic to development of a mutually satisfying parent–child relationship (van der Voort et al., 2014). Sensitivity increases over time as parents become more aware of their newborn's social capabilities. In supporting parents, nurses need to consider cultural beliefs and traditions that influence parenting behaviours and newborn care practices (see Cultural Awareness box: Cultural Beliefs and Practices Regarding Newborns).

The activities of daily care during the newborn period are the best times for newborn and family interactions. While caring for their newborn, the parent (or other family member) can talk to the newborn, play baby games, caress and cuddle the baby, and perhaps use massage.

FAMILY-CENTRED CARE

Helping Parents Recognize, Interpret, and Respond to Newborn Behaviours

Learning to read a baby's body language can enable parents to be more effective in preventing and solving issues around the newborn's sleeping, eating, and crying and enhances parent–newborn interaction. Nurses can teach new parents the following:

1. Identify three newborn "zones," traditionally referred to as newborn *states*.
   "Resting zone": also known as sleep states
   - Still/deep sleep: Newborn is completely still. Breathing is regular. No spontaneous activity. No movement of eyes, and eyelids stay shut. No vocalizing. Muscles are totally relaxed.
   - Active/light sleep: Newborn may wiggle or vocalize. Eyes may flash open. Newborn may make sucking movements—but still be asleep.

   "Ready zone": alert state
   - Newborn's eyes are bright. Newborn can focus on an object or person. Newborn reacts to stimulation. Motor activity is minimal.

   "Rebooting zone": fussy/crying state
   - Newborn's motor activity increases and is jerky. Newborn is less responsive and moves from fussing to crying.
2. Identify signs of stress.
   When babies are stressed or overstimulated they show changes in their body and behaviour. These changes are called *SOSs* (Signs of Over-Stimulation), traditionally referred to as a baby's stress response.
   - Body SOSs: changes in colour (becoming more red or pale); changes in breathing (becoming more irregular or choppy); changes in movement (becoming jerky or having more tremors)
   - Behavioural SOSs: "spacing out" (going from an alert state to a drowsy state); "switching off" (gaze aversion, or looking away from parent); "shutting down" (going from drowsy to a sleep state)

   When the baby shows an SOS, parents should decrease stimulation and increase support by doing one or several of the following:
   - Quiet one's voice
   - Glance away from the baby
   - Encourage baby to suck on a finger or mother's breast
   - Place the baby skin-to-skin
3. Help baby sleep well.
   Distinguish active/light sleep from still/deep sleep.
   Parent's care:
   - Prepare the baby to sleep: feed in a quiet, dark room at night and an active, light environment during the day.
   - Get the baby to sleep: put the baby down for sleep while they are still awake.
   - Help the baby stay asleep: don't pick them up during active/light sleep.

- After breastfeeding is well established, notice when the sleeping baby moves into active/light sleep. Wait and see if the baby will transition from active/light sleep back to deep/still sleep—and sleep a bit longer.

4. Help the baby eat well.
   - Recognize early signs of hunger during the first few weeks: wiggling, making sucking movements, bringing hand to mouth.
   - Notice if a fragile baby "spaces out" or "shuts down" when trying to eat. Bring this baby skin-to-skin and decrease stimulation before resuming feeding.
   - If a parent needs to wake a fragile or small baby to eat, do so from active/light sleep, not from still/deep sleep.
5. Help a crying baby: Consider what "TO DO."
   - **T**: Talk quietly to the baby in sing-song voice.
   - **O**: Observe to see if the baby takes self-calming actions: brings hand to their mouth, making sucking movements, or moves into the fencing reflex position.
   - **DO**: Bring the baby's hands to their chest; encourage sucking; make gentle "shooshing" sounds; and/or bring baby skin to skin.
6. Play with the baby so they can learn and grow.
   - Demonstrate baby's ability to look at a parent's face, watch a toy move, or turn to parent's voice.
   - Watch for an SOS during play. If an SOS occurs, decrease stimulation and increase support as described earlier in box.
   - Observe baby's developing process of interaction: first, getting quiet and still; second, turning toward parent; third, turning toward and looking at parent.
   - Reinforce benefits of sensitive, face-to-face parent interaction with baby.

Data from Tedder, J. L. (2008). Give them the HUG: An innovative approach to helping parents understand the language of their newborn. *Journal of Perinatal Education, 17*(2), 14–20; Tedder, J. L. (n.d.) *H.U.G.: Help-understanding-guidance for young families*. http://www.hugyourbaby.org.

Feeding is an optimal time for interaction because the newborn is usually awake and alert, at least at the beginning of the feeding. Too much stimulation should be avoided after feeding and before a sleep period. In Figure 26.23 a great-grandmother and newborn are shown engaging in arousal, imitation of facial expression, and smiling. Older children's contact with a newborn is encouraged and should be supervised according to the developmental level of the child (Figure 26.24).

CULTURAL AWARENESS

Cultural Beliefs and Practices Regarding Newborns

Nurses working with childbearing families from cultures and ethnic groups other than their own must be aware of cultural beliefs and practices that are important to individual families. People with a strong sense of heritage may hold traditional health beliefs despite adopting other Canadian lifestyle practices. These health beliefs may involve practices regarding the newborn. It is important for nurses to inquire with families if there are any cultural beliefs or practices that would affect their care while in hospital.

Discharge Planning and Teaching

Providing newborn care can cause much anxiety for the new parent. Support from nursing staff can be an important factor in determining whether new parents seek and accept help in the future. The nurse should try to avoid covering all the content at one time because the parents can be overwhelmed by too much information and become anxious. However, because new parents go home quickly from the hospital, it can be difficult for nurses to teach all the content that is necessary. It is important to start teaching on admission to the hospital. Community health nurses may visit families after birth and provide teaching, but this is not a standard practice across the country.

To set priorities for teaching, the nurse should follow parental cues. Learning needs should be identified before beginning to teach. Normal growth and development and the changing needs of the infant (e.g., for personal interaction and stimulation, growth milestones, exercise, injury prevention, and social contacts), as well as the topics that follow, should be included during discharge planning with parents. Safety issues should also be addressed (see Family-Centred Care box: Infant Safety).

FAMILY-CENTRED CARE

Infant Safety

- Never leave your baby alone on a bed, couch, or table. Even newborns can move enough to eventually reach the edge and fall off.
- Never put your baby on a cushion, pillow, beanbag, or waterbed to sleep. Your baby may suffocate. Also, do not keep pillows, large floppy toys, or loose plastic sheeting in the crib.
- Always lay the baby flat in bed on their back for sleep. Do not place your baby on the abdomen or side for sleep.
- When using an infant carrier, place the carrier on the floor in a place where you can see the baby. It should never be on a high place, such as a table, couch, or store counter.
- Infant carriers do not keep your baby safe in a car. Always place your baby in an approved car safety seat when travelling in a motor vehicle (car, truck, bus, or van). Car safety seats are recommended for travel on trains and airplanes as well. Use the car safety seat for *every* ride.
- Your baby should be in a rear-facing infant car safety seat from birth until at minimum 1 year or until exceeding the car seat's limits for height and weight. Do not be in a rush to turn the car safety seat to the forward-facing position. The car safety seat should be in the back seat of the car (Figure 26.25). This precaution is especially important in vehicles with front passenger air bags because when air bags inflate, they can be fatal for infants and toddlers. See Chapter 35, Motor Vehicle Injuries for further discussion on car seat safety.
- When bathing your baby, never leave them alone. Infants can drown in 2 to 5 cm of water.
- Be sure that your hot water heater is set at 49°C (120°F) or less. Always check bath-water temperature with your elbow before putting your baby in the bath.
- Do not tie anything around your baby's neck. Pacifiers, for example, tied around the neck with a ribbon or string can strangle your baby.
- Check your baby's crib for safety. Slats should be no more than 5.7 cm apart. The space between the mattress and sides should be less than two finger-widths. The bedposts should have no decorative knobs.
- There should be no bumper pads, pillows, blankets, stuffed toys, or other items in the baby's crib because of the risk for suffocation.
- Keep the crib or playpen away from window blind and drapery cords; your baby could strangle on them.
- Keep the crib and playpen well away from radiators, heat vents, and portable heaters. Linens in the crib or playpen can catch fire if they come into contact with these heat sources.
- Install smoke detectors on every floor of your home. Check them once a month to be sure they are working properly. Change batteries twice a year.
- Avoid exposing your baby to cigarette or cigar smoke in your home or other places. Passive exposure to tobacco smoke greatly increases the likelihood that your baby will have respiratory symptoms and illnesses.
- Be gentle with your baby. Do not pick your baby up or swing your baby by the arms or throw them up in the air. Never shake the baby.

Community Follow-up. In some jurisdictions in Canada, community health nurses will provide follow-up after birth through phone calls or home visits. During follow-up visits particular attention should be paid to the newborn regarding feeding habits, weight changes, and jaundice assessments. Parental bonding with the newborn should be assessed as well as family adaptation to their new family member. Resources and community programs should be discussed with parents, as needed, as well as reinforcement of vaccination guidelines. Warning signs of postpartum depression in either parent warrant further investigation.

Fig. 26.25 Rear-facing newborn seat in rear seat of car. Newborn is placed in seat when going home from the hospital. (Courtesy Brian and Mayannyn Sallee.)

Temperature. Parents need to understand practical information related to thermoregulation. The nurse should discuss the following topics in parent teaching:

- The causes of elevation in body temperature (e.g., overwrapping, cold stress with resultant vasoconstriction, or response to infection) and the body's response to extremes in environmental temperature
- Ways to promote normal body temperature, such as dressing the newborn appropriately for the environmental air temperature and protecting the newborn from exposure to direct sunlight, and how to assess whether the newborn is hot or cold by feeling the back of the neck
- Technique for taking the newborn's axillary temperature, and normal values for axillary temperature
- Signs to be reported to the primary health care provider, such as high or low temperatures with accompanying fussiness, lethargy, irritability, poor feeding, and excessive crying

Respirations. The nurse can provide information to parents regarding the normal characteristics of newborn respirations, emergency procedures, and measures to protect the newborn. It is helpful to discuss signs of the common cold and to offer suggestions related to care of the newborn who experiences this type of illness. The following points are included in teaching about respirations:

- Normal variations in the rate and rhythm
- Reflexes such as sneezing to clear the airway (this is normal and does not mean the newborn has a cold)
- Steps to take if the newborn appears to be choking
- The need to protect the newborn from the following:
  - Exposure to people with upper respiratory tract infections and respiratory syncytial virus
  - Exposure to second-hand and third-hand tobacco smoke
  - Suffocation from loose bedding, water beds, and beanbag chairs; drowning (in bath water); entrapment under excessive bedding or in soft bedding; anything tied around the newborn's neck; blind cords near cribs; poorly constructed playpens, bassinets, or cribs
- Avoid the use of baby powder, which is a commonly aspirated substance. Whenever a powder is used, it should be placed in the caregiver's hand and then applied to the skin. It should be kept away from the newborn's face.
- Notify the health care provider if the newborn develops symptoms such as difficulty breathing or swallowing, nasal congestion, excess

drainage of mucus, coughing, sneezing, decreased interest in feeding, or fever.

If the newborn has a respiratory illness such as the "common cold," the following suggestions can be helpful:

- Feed smaller amounts more often to prevent overtiring the newborn.
- Hold the baby in an upright position to feed.
- For sleeping, raise the baby's head and chest by raising the mattress 30 degrees. (Do not use a pillow.)
- Avoid drafts; do not overdress the baby.
- Use only medications prescribed by a pediatric health care provider. Do not use over-the-counter medications without health care provider approval.
- Use nasal saline drops in each nostril and suction well with a bulb syringe to decrease and relieve secretions.

Feeding Patterns. Nurses need to teach parents about newborn feeding and provide assistance based on whether they have chosen breastfeeding or formula feeding. The newborn should be put to the breast ideally within the first hour after birth. Newborns should be allowed to feed when they awaken and demonstrate typical hunger cues, regardless of the amount of time since the previous feeding. This concept is commonly referred to as "cue-based" or "on-demand" feeding. Breastfed babies feed more often than formula-fed babies because breast milk is digested faster than formulas made from cow's milk and the stomach empties sooner as a result. Exclusively formula-fed newborns will typically awaken and cue to feed every 3 to 4 hours. Breastfed newborns feed an average of 8 to 12 times per day. Water and dextrose water supplements are not recommended in the newborn period as these have the tendency to decrease breastfeeding. For a thorough discussion of newborn feeding, see Chapter 27.

Elimination. Awareness of the normal elimination patterns of newborns helps parents recognize issues related to voiding or stooling. The following points are included in teaching about elimination:

- Colour of normal urine and number of voidings to expect each day; approximately one wet diaper for each day of life until the fifth to seventh day; then frequent, clear, pale yellow voiding (see Table 27.3 and Figure 27.9)
- Changes to be expected in the colour of the stool (i.e., meconium to transitional to soft yellow or golden yellow) and the number of bowel movements, plus the odour of stools for breastfed or formula-fed newborns (see Box 25.1; Figure 25.6 and Table 27.3)
- Formula-fed newborns may have as few as one stool every other day after the first few weeks of life; stools are pasty to semiformed.
- Breastfed newborns should have at least five stools every 24 hours from 7 to 28 days of age (PHAC, 2018a). The stools are looser and resemble mustard mixed with cottage cheese.

Prevention of Sudden Infant Death Syndrome (SIDS). By definition, sudden infant death syndrome (SIDS) is the death of an infant under the age of 1 year of age which is sudden, unexpected, and without a clear cause. SIDS usually happens during sleep or napping and is the most common cause of death in infants between the ages of 1 month and 1 year (First Nations Health Authority [FHNA], 2017). Current evidence explains SIDS as a disorder arising from a combination of environmental, genetic, and metabolic factors (PHAC, 2018b). The rate of SIDS in Canada is 11.3 per 100 000 live births; in 2013, 43 infants died as a result of SIDS (Canadian Institute of Child Health, 2019). The rate is higher among Indigenous infants and infants from socioeconomically disadvantaged families (PHAC, 2018b). The PHAC guideline recommends placing the infant to sleep in the supine position to prevent SIDS. The prone position has been associated with an increased incidence of SIDS (see Clinical Reasoning Case Study). Other recommendations for preventing SIDS include ensuring a smoke-free environment (before and after birth), providing a safe crib environment (no toys or loose bedding), planning ahead when visiting to ensure a safe sleep place, room sharing for 6 months, avoiding instances of the infant being overheated, and no sleeping in waterbeds or on sofas (FNHA, 2017; PHAC, 2018b). Breastfeeding and pacifier use may also decrease the rate of SIDS (PHAC, 2018b). In addition, co-bedding practices may contribute to unintentional suffocation caused by entrapment or overlaying, often occurring when the infant is sharing a sleep surface with an adult or another child (PHAC, 2018b).

CLINICAL REASONING CASE STUDY

Safe Infant Sleep Practices

The nurse is teaching new parents who live on reserve in Northern Saskatchewan about safe sleep practices for their healthy term newborn son. They ask about whether it is safe for the baby to sleep on a cradle board. The mother states they do not have a crib and thinks that this would be the safest place for the baby to sleep. What information should the nurse provide related to safety concerns for the newborn?

1. Evidence—Is there sufficient evidence to draw conclusions about the safety of the sleep environment in terms of preventing sudden infant death syndrome or infant injury?
2. Assumptions—What assumptions can be made about the following factors related to safe infant sleep?
   a. Infant positioning for sleep
   b. Safe alternatives for a sleep environment
   c. Risk for injury
3. What priorities for nursing care can be drawn at this time?
4. What other teaching should the nurse provide to the couple?

Anatomically, the newborn's shape—a barrel chest and flat, curveless spine—makes it easy for the newborn to roll from the side to the prone position; thus, the side-lying position for sleep is not recommended. When the baby is awake, "tummy time" can be provided under parental supervision so that the infant may begin to develop appropriate muscle tone for eventual crawling; this tummy time is also effective in the prevention of a misshaped head (positional **plagiocephaly**). Newborns should be placed on their stomach several times per day for increasing lengths of time but always when they are awake and supervised by an adult (Cummings & CPS, 2011/2018).

Care must also be taken to prevent the baby from rolling off flat, unguarded surfaces. When a newborn is on such a surface, the parent or nurse who must turn away from the baby even for a moment should always keep one hand placed securely on the newborn. The baby should always be held securely with their head supported because newborns are unable to maintain an erect head posture for more than a few moments. Figure 26.26 illustrates holding a newborn with adequate support.

Fig. 26.26 Holding newborn securely with support for the head. **A:** Holding newborn while moving newborn from scale to bassinet. Baby is undressed to show posture. **B:** Holding baby upright in "burping" position. **C:** "Football" (under the arm) hold. **D:** Cradling hold. Rashes.

Diaper rash. Most infants develop a diaper rash at some time. This dermatitis or skin inflammation appears as redness, scaling, blisters, or papules. Various factors contribute to diaper rash, including infrequent diaper changes, diarrhea, use of plastic pants to cover the diaper, or a change in the infant's diet, such as when solid foods are added.

Parents are instructed in measures to help prevent and treat diaper rash. Diapers should be checked often and changed as soon as the baby voids or stools. Plain water with mild soap is used to cleanse the diaper area; if baby wipes are used, they should be unscented and contain no alcohol. The baby's skin should be allowed to dry completely before applying another diaper. See Evolve site for Nursing Skill: Changing a Diaper.

When diaper rash occurs, it is helpful to use emollients, creams, or other protectants such as zinc oxide ointment to restore skin integrity while providing some protection from the irritants of urine and stool (Visscher et al., 2015).

Although diaper rash can be alarming to parents and annoying to babies, most cases resolve within a few days with simple home treatments. There are instances when diaper rash is more serious and requires medical treatment.

The warm, moist atmosphere in the diaper area provides an optimal environment for *Candida albicans* growth; dermatitis appears in the perianal area, inguinal folds, and lower abdomen. The affected area is intensely erythematous with a sharply demarcated, scalloped edge, often with numerous satellite lesions that extend beyond the larger lesion. The usual source of infection is from handling by persons who do not practise adequate hand hygiene. It may also appear 2 to 3 days after an oral infection (thrush). Therapy consists of applications of an anticandidal ointment, such as clotrimazole or miconazole, with each diaper change. Sometimes the infant also is given an oral antifungal preparation such as nystatin or fluconazole to eliminate any gastrointestinal source of infection.

Other rashes. A rash on the cheeks may result from the newborn's scratching with long unclipped fingernails or from rubbing the face

against the crib sheets, particularly if regurgitated stomach contents are not washed off promptly. The newborn's skin begins a natural process of peeling and sloughing after birth. Dry skin may be treated with an emollient applied once or twice daily (Association of Women's Health, Obstetrical and Neonatal Nurses [AWHONN], 2018). Newborn rash, erythema toxicum (see Figure 25.9, *B*), is a common finding and needs no treatment.

Clothing. Parents commonly ask how warmly they should dress their newborn. A simple rule of thumb is to dress the child as they would dress themselves, adding or subtracting clothes and wraps for the child as necessary. Feeling the temperature of the skin at the back of the baby's neck is often an indicator of whether the child is too hot or cold. Overheating should be avoided (PHAC, 2018b). A hat or bonnet is needed to protect the scalp and minimize heat loss if the weather is cool, or to protect against sunburn and shade the eyes if it is sunny and hot. Overdressing in warm temperatures can cause discomfort, as can underdressing in cold weather. Overdressing the infant has also been associated with SIDS. Parents are encouraged to dress the baby in flame-retardant clothing. Infant sunglasses are available to protect the eyes when outdoors.

For sleep, newborns are safest when placed to sleep in fitted one-piece sleepwear that is comfortable at room temperature and does not cause them to overheat (PHAC, 2018b). For additional warmth, the newborn can be dressed in fitted clothing in layers as needed.

For the first 2 to 3 months until the infant is able to roll over, safe swaddling for sleep can be done using a lightweight blanket or wrap (not in combination with a sleep sack). The head, neck, and chin are not covered, and the wrap should not be tight around the chest or legs.

Car Seat Safety. Infants should travel only in federally approved, rear-facing safety seats secured in the rear seat (see Figure 26.25). The safest area of the car is in the middle of the back seat. A car seat that faces the rear gives the best protection for the infant's disproportionately weak neck and heavy head. In this position, the force of a frontal crash is spread over the head, neck, and back; the back of the car seat supports the spine. Car seats have expiration dates on them as well as Canadian Standards Association stickers. A car seat that has been in a previous car accident should not be used. See Additional Resources for more information on car seat installation and Chapter 35.

! NURSING ALERT

A rear-facing car seat should be used for infants from birth to at least 10 kg (22 lb), and the child must be able to walk unassisted. If the child meets these criteria and is under 1 year of age, they should remain in a rear-facing car seat. It is advisable to keep a child in a rear-facing car seat even after these criteria have been met.

To secure the infant in the rear-facing car safety seat, shoulder harnesses are placed in the slots at or below the level of the infant's shoulders. The harness is snug, and the retainer clip is placed at the level of the infant's armpits as opposed to on the abdomen or neck area. The car seat is secured by using the vehicle seat belts.

Rear-facing infant seats should never be placed in the front seat. Serious injury can occur if the air bag inflates, because these types of infant seats fit close to the dashboard. If the infant must ride in the front seat, the air bag must be turned off. For cars with side air bags, parents should read the vehicle owner's manual for information about placement of car seats next to a side air bag.

Bulky clothing such as a coat or snow suit can compress if there is a car accident, causing the straps of the harness to loosen and placing the infant at risk for injury. Parents should dress their infant in thinner layers; for warmth, they can place a blanket or coat over the buckled harness straps (CPS, 2018). Add-on features such as head supports that do not come with the car seat should not be used. They can affect the safety of the car seat (CPS, 2020a).

! NURSING ALERT

In cars equipped with air bags, rear-facing infant seats should not be placed in the front seat unless the air bag has been deactivated. Serious injury can occur if the air bag inflates, because these types of infant seats fit closer to the dashboard than a passenger does.

Non-Nutritive Sucking. Sucking is the newborn's chief pleasure. However, sucking needs may not be satisfied by breastfeeding or bottle-feeding alone. In fact, sucking is such a strong need that newborns who are deprived of sucking, such as those with a cleft lip, will suck on their tongues. Some newborns are born with sucking pads on their fingers or lips that developed during in utero sucking. Several benefits of non-nutritive sucking have been demonstrated, such as an increased weight gain in preterm newborns, greater ability to maintain an organized state, and less crying.

When parents are concerned about the sucking of fingers, thumbs, or pacifiers they may try to restrain this natural tendency. Before giving advice, nurses should investigate the parents' feelings and base the guidance they give on the information solicited. For example, some parents may have no concerns about the use of a finger but may find the use of a pacifier objectionable. In general, there is no need to restrain either practice, unless thumb sucking persists past 4 years of age or past the time when the permanent teeth erupt. Parents are advised to consult with their health care provider on this topic.

There is compelling evidence that use of pacifiers helps prevent SIDS. It is suggested that parents consider offering a pacifier for naps and bedtime (Ponti & CPS, 2003/2018). The pacifier should be used when the infant is placed supine for sleep, and it should not be reinserted once they fall asleep. No newborn should be forced to take a pacifier. Pacifiers should be cleaned often and replaced regularly and should not be coated with any type of sweet solution. Pacifier use for breastfeeding newborns should be delayed for 3 to 4 weeks to ensure that breastfeeding is well established.

A parent's excessive use of the pacifier to calm the child should also be explored, however. It is not unusual for parents to place a pacifier in the newborn's mouth as soon as the child begins to cry, thus reinforcing a pattern of distress relief.

If parents choose to let their child use a pacifier, they need to be aware of certain safety considerations before purchasing one. Homemade, improvised, or poorly designed pacifiers can be dangerous because the entire object may be aspirated if it is small, or a portion may become lodged in the pharynx. Safe pacifiers are made of one piece that includes a shield or flange large enough to prevent entry into the mouth and a handle that can be grasped (Figure 26.27).

Bathing and Umbilical Cord Care

Bathing. Bathing serves a number of purposes. It provides opportunities for (1) cleansing the newborn, (2) observing the newborn's condition, (3) promoting comfort, and (4) promoting parent–child–family interaction.

An important consideration in skin cleansing is preservation of the skin's acid mantle, which is formed from the uppermost horny layer of the epidermis, sweat, superficial fat, metabolic products, and external substances such as amniotic fluid and microorganisms. To protect the newborn's skin, it is best to use a cleanser with a neutral pH and preferably without preservatives or with preservatives recognized as

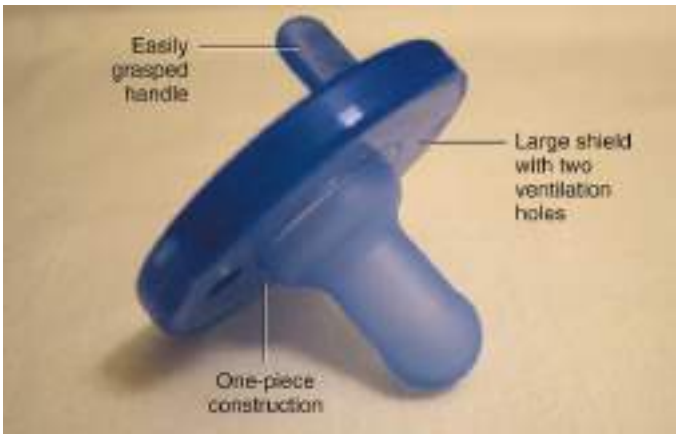

Fig. 26.27 Design of a safe pacifier. (Courtesy Julie Perry Nelson.)

safe and well tolerated in newborns. Antimicrobial cleansers should not be used (AWHONN, 2018).

Although the sponging technique may be used, bathing the newborn by immersion or swaddled bathing results in less heat loss and less crying and is thus recommended even with the umbilical cord still intact. For immersion bathing, the newborn is placed in warm water (38°C [100.4°F]) deep enough to cover the shoulders, but not the head and neck (Lund & Durand, 2021) (Figure 26.28). Swaddled bathing is a type of immersion bathing in which the newborn is swaddled in a blanket or towel and immersed in a tub of warm water. One body part at a time is unwrapped and washed (AWHONN, 2018) (Figure 26.29).

Ideally the initial bath is delayed for at least 6 to 8 hours after birth until the newborn has reached thermal and cardiorespiratory stability. In some birthing facilities, the bath may be delayed for as long as 24 hours or longer as per WHO recommendations (WHO, 2018). This bath should be performed at the parent's bedside. Tap water and a minimal amount of pH-neutral or slightly acidic cleanser are recommended. Following the bath, the newborn should be immediately dried, diapered, and either wrapped in warm blankets or placed skin-to-skin with a parent. A cap should be placed on the head. Until the initial bath is completed, hospital personnel must wear gloves to handle the newborn. Some hospitals do not recommend bathing newborns while they are in the hospital; the first bath may be done after the newborn is discharged home.

Fig. 26.28 Initial newborn bath by immersion. (Courtesy Allison and Matthew Wyatt, Eagle, CO.)

Fig. 26.29 A swaddle immersion bath is bathing the newborn while they are loosely swaddled in a blanket. (iStock.com/Shoko Shimabukuro)

A daily bath is not necessary for achieving cleanliness and may do more harm by disrupting the integrity of the newborn's skin; cleansing the perineum after a soiled diaper and daily cleansing of the face may suffice. In general, newborns should not be bathed more frequently than every other day; the hair can be shampooed once or twice a week.

The newborn bath time provides a wonderful opportunity for parent–newborn social interaction. While bathing the baby, parents can talk to the child, caress and cuddle them, and engage in arousal and imitation of facial expressions and smiling. Parents can pick a time for the bath that is easy for them and when the baby is awake, usually before a feeding.

Umbilical cord care. The goal of cord care is to prevent or decrease the risk for hemorrhage and infection. The umbilical cord stump is an excellent medium for bacterial growth and can become infected. Hospital protocol determines the technique for routine cord care. The current recommendations for cord care include cleaning the cord with water (and cleanser if needed to remove debris) during the initial bath and subsequently cleaning with plain water. Evidence does not support the routine use of antiseptic or antimicrobial preparations for cord care (AWHONN, 2018; Lund & Durand, 2021). The umbilical cord begins to dry, shrivel, and blacken by the second or third day of life. The stump deteriorates through the process of dry gangrene; thus, odour alone is not a positive indicator of *omphalitis* (infection of the umbilical stump).

The umbilicus should be inspected often for signs of infection (e.g., foul odour, redness, swelling, and purulent discharge), granuloma (i.e., small, red, raw-appearing polyp where the umbilical cord separates), bleeding, and discharge. The cord clamp may be removed when the cord is dry, in about 24 to 36 hours, although this is not routine practice in all hospitals (Figure 26.30). Some institutions send the newborn home with the clamp still in place and it will fall off when the cord falls off. It is important to ensure that if a cord clamp remover is used, it is disinfected between uses.

Cord separation time is influenced by several factors, including type of cord care, type of birth, and other perinatal events. The average cord separation time is 10 to 14 days, although it can take up to 3 weeks for this to occur. Some dried blood may be seen in the umbilicus at separation (Figure 26.31).

See the Family-Centred Care box: Newborn Bath for information regarding tub and sponge bathing, skin care, cord care, trimming nails, and dressing the newborn.

FAMILY-CENTRED CARE

Newborn Bath

Timing

- Newborns do not need a bath every day; every 2 to 3 days is often enough.
- Fit bath time into the family's schedule.
- Give a bath at any time convenient to you but not immediately after a feeding period because the increased handling can cause regurgitation.

Prevent Heat Loss

- The temperature of the room should be no cooler than 26° to 27°C (79° to 81°F), and the bathing area should be free of drafts.
- The water temperature should be between 38° and 40°C (100° to <104° F). A water thermometer is useful for determining appropriate water temperature.
- Control heat loss during the bath to conserve the newborn's energy. Bathing the newborn quickly, exposing only what is being washed, and thoroughly drying the newborn are all important parts of the bathing technique.

Gather Supplies and Clothing Before Starting

- Clothing suitable for wearing indoors: diaper, shirt, sleeper
- Towels for drying newborn and a clean washcloth
- Tub placed in a safe place on a sturdy surface or sink for water
- Mild cleanser with a neutral pH and preferably with no preservatives
- Diaper
- Lightweight blanket

Bathe the Baby

- Bring the baby to the bathing area when all supplies are ready.
- Never leave the baby alone on the bath table or in bath water, not even for a second! If you have to leave, take the baby with you or put the baby back into the crib.
- Fill the tub to try to cover as much of the baby's body as you feel comfortable. Babies like to have as much of their body under water as possible (preferably to cover shoulders).
- Test temperature of the water. It should feel pleasantly warm to the elbow 38.0° to 40.0°C (100° to 104°F).
- Do not hold the baby under running water—water temperature may change, and the newborn may be scalded or chilled rapidly.
- If sponge bathing is to be performed (usually only necessary if circumcision is healing), undress the newborn and wrap in a towel with the head exposed. Uncover the parts of the body you are washing, taking care to keep the rest of the baby covered as much as possible to prevent heat loss.
- Always work from clean to dirty. Start with the face, neck, and ears first. Do not use soap on the face. Cleanse the eyes from the inner canthus outward, using separate parts of a clean washcloth for each eye. For the first 2 or 3 days, there may be a discharge resulting from the reaction of the conjunctiva to the ointment used as a prophylactic measure against infection. After 2 to 3 days of age, any discharge should be considered abnormal and reported to the health care provider.
- Cleanse ears and nose with twists of moistened cotton or a corner of the washcloth. Do not use cotton-tipped swabs because they may cause injury. The areas behind the ears need daily cleansing.
- Wash between the skinfolds. Place your hand under the baby's shoulders and lift gently to expose the neck, lift the chin, and wash the neck, taking care to cleanse between the skinfolds.
- Wash the genital area last.
- Pat dry gently.
- If the hair is to be washed, begin by wrapping the baby in a towel with the head exposed. Hold the baby in a football position (under the arm) with one hand, using the other hand to wash the hair. Wash the scalp with water and shampoo that is mild for the eyes and safe for babies. Massage the scalp gently, rinse well, and dry thoroughly. A blow dryer is never used on a newborn because the temperature is too hot for a baby's skin.
- Wash hair with the baby wrapped to limit heat loss.
- Scalp desquamation, called *cradle cap*, often can be prevented by removing any scales with a fine-toothed comb or brush after washing. If the condition persists, notify the health care provider.

(Continued)

Skin Care

- If the skin appears dry or cracking, apply an emollient (lotion) once or twice daily. Check with your pediatric health care provider about the type of emollient to use.
- The fragile skin can be injured by too vigorous cleansing. If stool or other debris has dried and caked on the skin, soak the area to remove it. Do not attempt to rub it off because abrasion may result. Cleanse gently using a mild cleanser, and pat dry.
- Babies are prone to sunburn and should be kept out of direct sunlight. Use of sunscreens should be discussed with the health care provider but are not recommended for the first 6 months of life.
- Babies often develop rashes that are normal. Newborn acne resembles pimples and can appear at 2 to 4 weeks of age, resolving without treatment by 6 to 8 months. Heat rash is common in warm weather, which appears as a fine red rash around creases or folds where the baby sweats.

Cord Care

- Cleanse with plain water around base of the cord where it joins the skin. Notify the health care provider of any odour, discharge, or skin inflammation (redness) around the cord. The diaper should not cover the cord because a wet or soiled diaper will slow or prevent drying of the cord and foster infection. When the cord drops off after 10 to 14 days, a few small drops of blood may be seen. If there is active bleeding, notify the pediatric health care provider.

Nail Care

- Use caution cutting the nails—use blunt scissors or a nail file. The nails have to grow out far enough from the skin so that the skin is not cut by mistake. Nails should be kept short so newborns do not scratch themselves. Covering hands with mitts may frustrate newborns who want to suck on them, so it is better to keep nails short. The ideal time to trim the nails is when the baby is sleeping. Soft emery boards may be used to file the nails.

Genital Care

- Cleanse the baby's genitalia daily and after voiding or stooling, using disposable diaper wipes or soft cloths and water.
- For girls, the genitalia may be cleansed by separating the labia slightly and gently washing from the pubic area to the anus.
- For uncircumcised boys, wash and rinse the penis with soap and warm water. Do not attempt to retract the foreskin. In most newborns, the inner layer of the foreskin adheres to the glans and the foreskin cannot be retracted. By age 3 years in 90% of boys, the foreskin can be retracted easily without causing pain or trauma. For others, the foreskin is not retractable until adolescence. As soon as the foreskin is partly retractable and the child is old enough, he can be taught self-care. The circumcised penis does not require any special care other than cleansing with diaper changes, once healing has occurred.
- The newborn's skin should be allowed to dry completely before applying another diaper. Exposing the buttocks to air can help dry up diaper rash. Because bacteria thrive in moist, dark areas, exposing the skin to dry air decreases bacterial proliferation. Zinc oxide ointments can be used to protect the newborn's skin from moisture and further excoriation.
- Wash hair with the baby wrapped to prevent heat loss from the wet scalp, using the football hold.

Newborn Follow-up Care. With shorter hospital stays, the focus and site of newborn care are changing. Across the country varying methods of early follow-up health care visits have been implemented, including follow-up by a visiting nurse or community health team, and home visits by midwives and community health nurses to assess and support breastfeeding and wellness.

Parents should plan for their child's routine follow-up health care at the following ages: within 2 or 3 days to check for status of jaundice, feeding, and elimination; at 1 week of age; then at 2, 4, 6, 9, 12, and 18 months and yearly from 2 to 5 years.

Cardiopulmonary Resuscitation. All personnel working with newborns must have current neonatal **resuscitation** (NRP). Parents should be encouraged to receive instruction in relieving airway obstruction and in CPR. Classes are often offered in hospitals and clinics during the prenatal period or to parents of newborns. Such instruction is especially important for parents whose newborns were preterm or had cardiac or respiratory issues.

Practical Suggestions for the First Weeks at Home. Numerous changes occur during the first weeks of parenthood. Nursing care should be directed toward helping parents cope with newborn care, role changes, altered lifestyle, and changes in family structure resulting from the addition of a new baby.

Parents should be helped to anticipate events during the transition from birthing facility to home. This is especially important for first-time parents. Even the simplest strategies can provide enormous support. Printed materials reinforcing education topics are helpful, as is a list of available community resources and websites that provide reliable information about child care. Classes in the prenatal period or during the postpartum stay are helpful. Instructions for the first days at home include relevant topics such as activities of daily living, dealing with visitors, and activity and rest.

Interpretation of Crying. Crying is a newborn's first social communication. Some babies cry more than others, but all babies cry. They cry to communicate that they are hungry, uncomfortable, wet, ill, or bored and sometimes for no apparent reason at all. The longer parents are around their infants, the easier the task becomes of interpreting what a cry means. Many babies have a fussy period during the day, often in the late afternoon or early evening when everyone is naturally tired. Environmental tension adds to the length and intensity of crying spells. Babies also have periods of vigorous crying when no comforting can help. These periods of crying can last for long stretches until the infants seems to cry themselves to sleep. The nurse should inform new parents that time and infant maturation will take care of these types of cries.

Nurses should instruct new parents about strategies to calm a crying or fussy baby. Certain types of sensory stimulation can calm and quiet infants and help them get to sleep. Important characteristics of this sensory stimulation—whether tactile, vestibular, auditory, or visual—appear to be that the stimulation is mild, slow, rhythmic, and consistently and regularly presented. Tactile stimulation can include skin-to-skin contact, warmth, patting, and back massage. Swaddling may provide widespread and constant tactile stimulation and a sense of security. Vestibular stimulation is especially effective and can be accomplished by mild rhythmic movement such as rocking or by holding the baby upright, as on the parent's shoulder. Some infants respond to being held in a body carrier. Rhythmic sounds can provide auditory stimulation; parents can use devices that provide white noise or sounds resembling the mother's heartbeat.

Many hospitals provide a video on newborn crying to new parents. *The Period of PURPLE Crying* is an example (see Family-Centred Care box: The Period of PURPLE Crying®). It is intended to help parents understand that crying is normal and help them cope with infant crying. Parents need to be taught coping skills of how to deal with crying

and the danger of shaking a baby with an undeveloped brain, which can lead to abusive head trauma (shaken baby syndrome).

Prevention of abusive head trauma focuses on reducing child abuse and maltreatment and increasing education. Education is also focused on family resource centres and home visit programs, particularly in high-risk homes with young parents living in poverty. These programs can include mental and social services. Before discharge from the hospital, new parents should be instructed in the danger of shaking a child (Joyce & Huecker, 2021). Parents should also be informed of clinical manifestations of abusive head trauma (Farrell et al., 2018):

- Alterations in level of consciousness
- Irritable crying or moaning
- Abnormal flexion or extension of extremities
- Repeated or persistent vomiting

FAMILY-CENTRED CARE

The Period of PURPLE Crying®

The Period of PURPLE Crying is a program designed to educate new parents about infant crying and the dangers of shaking a baby. Each letter in the acronym "PURPLE" represents key concepts:

P = Peak of crying. Your baby may cry more each week—the most at 2 months, then less at 3 to 5 months.
U = Unexpected. Crying can come and go and you don't know why.
R = Resists soothing. Your baby may not stop crying, no matter what you try.
P = Pain-like face. Crying babies may look like they are in pain, even when they are not.
L = Long-lasting. Crying can last as much as 5 hours a day, or more.
E = Evening. Your baby may cry more in the later afternoon and evening.

From National Center on Shaken Baby Syndrome, PURPLEcrying.info.

Recognizing Signs of Illness. In addition to explaining the need for well-baby follow-up visits, the nurse should discuss with parents the signs of illness in newborns (see Family-Centred Care box: Signs of Illness). Of particular importance is the parents' assessment of jaundice in newborns discharged early. Parents should be advised to call their pediatric health care provider immediately if they notice increasing jaundice or signs of illness and to ask about over-the-counter medications, such as acetaminophen for infants, to keep at home.

FAMILY-CENTRED CARE

Signs of Illness

Notify the pediatric health care provider if any of these signs occur:

- Fever: temperature above 38°C (100.4°F) axillary; also a continual rise in temperature (**Note:** Tympanic [ear] thermometers are not recommended for babies younger than 3 months.)
- Hypothermia: temperature below 36.5°C (97.7°F) axillary and not able to increase temperature by putting on an extra layer of clothing or putting skin-to-skin
- Poor feeding or little interest in food: refusal to eat for two feedings in a row
- Vomiting: more than one episode of forceful vomiting or frequent vomiting (over a 6-hour period)
- Diarrhea: two consecutive green, watery stools (**Note:** Stools of breastfed newborns are normally looser than stools of formula-fed infants. Diarrhea will leave a water ring around the stool, whereas breastfed stools will not.)
- Decreased bowel movement: in a breastfed newborn, fewer than three stools per day; in a formula-fed infant, fewer than one stool every other day
- Decreased urination: fewer than six wet diapers per day after 6 days of age
- Breathing difficulties: laboured breathing with flared nostrils or absence of breathing for more than 20 seconds (**Note:** A newborn's breathing is normally irregular and between 30 and 60 breaths/min. Count the breaths for a full minute but only if concerned.)
- Cyanosis (bluish skin colour) whether accompanying a feeding or not
- Lethargy: sleepiness, difficulty waking, or periods of sleep longer than 6 hours (most newborns sleep for short periods, usually from 1 to 4 hours, and wake to be fed)
- Inconsolable crying (attempts to quiet not effective) or continuous high-pitched cry
- Bleeding or purulent (yellowish) drainage from umbilical cord or circumcision; foul odour or redness at the site
- Drainage from the eyes

KEY POINTS

- Assessment of the newborn requires data from the prenatal, intrapartum, and postnatal periods.
- The immediate assessment of the newborn includes Apgar scoring and a general evaluation of physical status.
- Knowledge of biological and behavioural characteristics is essential for guiding assessment and interpreting data.
- Gestational-age assessment provides important information for predicting risks and guiding care management.
- Nursing care immediately after birth includes maintaining an open airway, preventing heat loss, and promoting parent–newborn interaction.
- Providing a protective environment is a key responsibility of the nurse and includes such measures as careful identification procedures, support of physiological functions, and ways to prevent infection.
- The newborn has social and physical needs.
- Newborns require careful assessment for physiological and behavioural manifestations of pain.
- Nonpharmacological and pharmacological measures are used to reduce newborn pain.
- Before hospital discharge, nurses provide anticipatory guidance for parents regarding feeding and elimination patterns; positioning and holding; comfort measures; car seat safety; bathing, skin care, cord care, and nail care; and signs of illness.

Newborn Nutrition and Feeding

Marina Green and Kim Dart
Originating US chapter by *Kathryn R. Alden*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe current recommendations for infant feeding.
2. Explain the nurse's role in helping families make informed newborn feeding decisions.
3. Discuss the importance of breastfeeding for infants, mothers, families, and society.
4. Describe the nutritional needs of newborns.
5. Describe the anatomy and physiology of breastfeeding.
6. Recognize newborn feeding-readiness cues.
7. Explain maternal and infant indicators of effective breastfeeding.
8. Examine nursing interventions to facilitate and promote successful breastfeeding.
9. Analyze common difficulties associated with breastfeeding and interventions to help resolve them.
10. Compare powdered, concentrated, and ready-to-use forms of commercial infant formula.
11. Discuss patient teaching for the family who is breastfeeding or formula-feeding their newborn.
12. Discuss the nutritional requirements of the lactating person.

Good nutrition in infancy fosters optimal growth and development. Infant feeding is more than the provision of nutrition; it represents an opportunity for social and psychological interaction between parent and infant. It can also establish a basis for developing good eating habits and influence lifelong health habits.

Through preconception and prenatal education and counselling, nurses play an instrumental role in helping parents make informed decisions about infant feeding. Scientific evidence is clear that human milk provides the best nutrition for infants, and parents should be strongly encouraged to breastfeed. Although many consider commercial infant formula to be equivalent to breast milk, this belief is erroneous. Human milk is the gold standard for infant nutrition. It is species specific, uniquely designed to meet the needs of human infants. The composition of human milk changes to meet the nutritional needs of growing infants. It is highly complex, with anti-infective and nutritional components combined with growth factors, enzymes that aid in digestion and absorption of nutrients, and fatty acids that promote brain growth and development. Infant formulas are usually adequate in providing nutrition to maintain infant growth and development within normal limits, but they are not equivalent to human milk.

Breastfeeding is defined as the transfer of human milk from the mother to the infant; the infant receives milk directly from the mother's breast. *Exclusive breastfeeding* means that the infant receives no other liquid or solid food (Health Canada, Canadian Paediatric Society [CPS], Dietitians of Canada and Breastfeeding Committee for Canada [BCC], 2015). The definition of exclusive breastfeeding can also include vitamins and mineral supplements or medicines (World Health Organization [WHO], 2019).

Whether the parents breastfeed, human milk–feed (feed breast milk through a bottle or cup), or formula-feed, nurses provide support and ongoing education. Parent education and nursing care are necessarily based on current research findings and standards of practice. Nurses and lactation specialists (including **lactation consultants**, who are often nurses) provide education, assistance, assessment, and support for mothers, newborns, and families. During the hospital stay and after hospital discharge, nurses and lactation consultants provide ongoing support and assistance to promote optimal feeding practices and positive health outcomes in a variety of settings.

This chapter focuses on meeting the nutritional needs for normal growth and development from birth to 6 months of age, with an emphasis on the newborn period (the first 1 to 2 months of life), when feeding practices and patterns are established. Both breastfeeding and formula-feeding are addressed. Information on breastfeeding is focused on the direct transfer of milk from mother to infant.

RECOMMENDED INFANT NUTRITION

Human milk is recognized as the normal and optimal food for infants. The World Health Organization (WHO), Health Canada, Canadian Paediatric Society (CPS), Dietitians of Canada, and Breastfeeding Committee for Canada (BCC) recommend exclusive breastfeeding for the first 6 months of life for healthy, term infants (Health Canada et al., 2015; WHO, 2019). Nutrient-rich complementary foods, with particular attention to iron, should be introduced at 6 months with continued breastfeeding for 2 years or longer. If weaned before 12 months, infants should receive iron-fortified infant formula (Health Canada et al., 2015).

Breastfeeding Rates

Breastfeeding initiation rates in Canada have increased from less than 25% in 1965 to 90% in 2015/2016 with regional variation ranging from 57% in Newfoundland and Labrador to 96% in British Columbia and the Yukon (Public Health Agency of Canada [PHAC], 2019). Over half of Canadian mothers continue to breastfeed somewhat for 6 months or longer, although close to 25% of the mothers who initiate breastfeeding stop breastfeeding before their newborn is 1 month old (PHAC, 2019).

The Importance of Breastfeeding

Human milk is designed specifically for human infants and is nutritionally superior to any alternative. It is considered a living tissue because it contains almost as many live cells as blood. It is bacteriologically safe and always fresh. The nutrients in human milk are more easily absorbed than those in formula. Extensive evidence exists concerning the health benefits of breastfeeding and human milk for infants, with some of the benefits extending into adulthood (Table 27.1).

Contraindications to Breastfeeding

Most maternal illness is compatible with breastfeeding, and, in some instances, breastfeeding may be protective for the infant. Some contraindications to breastfeeding exist and include the following (Lawrence & Lawrence, 2016; Pound et al., 2012/2017; WHO, 2015):

- Maternal cancer therapy, diagnostic and therapeutic radioactive isotopes or radioactive iodine
- Active tuberculosis not under treatment in the mother
- Human immunodeficiency virus (HIV) infection in the mother, in high-income countries
- Galactosemia (classic) in the infant

TABLE 27.1 Benefits of Breastfeeding

Benefits for the Infant/Child	Benefits for the Mother	Benefits for Families and Society
• Reduced infant and child mortality • Enhanced maturation of the gastrointestinal tract and immune factors • ↓ risk for gastroenteritis, celiac disease, Crohn disease, necrotizing enterocolitis in preterm infants; obesity in childhood, adolescence, and adulthood • Helps protect against otitis media, respiratory illnesses such as respiratory syncytial virus and pneumonia, urinary tract infections, bacteremia, and bacterial meningitis • Lower incidence of certain allergies among breastfed infants, particularly for families at high risk • Less likely to die from SIDS • May have a protective effect against childhood lymphoma and type 1 and type 2 diabetes mellitus • Decreased risk of dental malocclusions • May enhance cognitive developmental for term and preterm infants • Pain relief for newborns undergoing painful procedures	• Decreased postpartum bleeding and more rapid uterine involution • Decreased risk of ovarian cancer, breast cancer, rheumatoid arthritis, hypertension, hypercholesterolemia, cardiovascular disease, and type 2 diabetes • More rapid postpartum weight loss • May provide protection against development of osteoporosis • Delayed return of menses • Unique bonding experience • Increased maternal role attainment • May provide protection against perinatal mood disorders when breastfeeding difficulties are appropriately addressed	• Convenient; ready to feed • No bottles or other necessary equipment • Less expensive than infant formula • Reduced health care costs • Less parental absence from work because of ill infant • Reduced environmental burden related to disposal of formula packaging and equipment

SIDS, sudden infant death syndrome.

Postpartum breastfeeding and cardiovascular risk assessment in patients following pregnancy complications. *Journal of Obstetrics and Gynaecology Canada. 41*(5), 737. https://doi.org/10.1016/j.jogc.2019.02.247.

- Maternal substance use (e.g., cocaine, methamphetamines, marijuana). Mothers on methadone treatment plans can breastfeed.
- Maternal human T-cell leukemia virus type 1 or II (HTLV)
- Some medications (although rare) that may exert an untoward effect on the breastfeeding infant; use of these requires consultation of the health care provider and available references, such as Hale (2019) or LactMed (see Additional Resources).

Conditions that are NOT considered contraindications to breastfeeding are as follows (Lawrence & Lawrence, 2016; Pound et al., 2012/2017):

- Maternal infection with Hepatitis A or C
- Hepatitis B surface antigen (HBsAg)–positive status (newborn receives immunoglobulin and vaccine)
- Mothers who are cytomegalovirus (CMV) positive
- Maternal herpes simplex lesion on a breast (Mothers can continue to breastfeed on the unaffected breast. Avoiding contact with the lesion is important.)

HIV can be passed through breast milk from an HIV-positive patient, even if the viral load is undetectable and the patient is on antiretroviral medications. Thus, formula-feeding is recommended; there are several programs across Canada that provide free formula for HIV-positive patients. Mixed feeding (breastfeeding and other times giving formula) has shown the highest chance of an infant getting HIV. In countries with high HIV prevalence and where diarrhea, pneumonia, and undernutrition are common causes of infant and child mortality, the WHO recommends that mothers living with HIV should breastfeed for at least 12 months and may continue breastfeeding for up to 24 months or longer (similar to the general population) while receiving antiretroviral therapy (ART) (WHO & United Nations Children's Fund, 2016).

The Baby-Friendly Initiative

All parents are entitled to a birthing environment in which breastfeeding is promoted, protected, and supported, an environment providing care based on best evidence rather than traditional practices (PHAC, 2019). To that end, the Baby-Friendly Hospital Initiative (BFHI), a joint effort of the WHO and the United Nations Children's Fund (UNICEF), focuses on "providing optimal clinical care for new mothers and their infants" (WHO, 2018). The foundation of BFHI is 10 identified practices that protect, promote, and support breastfeeding families, also known as "the Ten Steps." Under the BFHI, hospitals providing maternity services meeting the clinical criteria for the Ten Steps can apply for designation as a "Baby-Friendly Hospital." The process of achieving the Baby-Friendly designation has been described as transformative for maternity facilities as the whole environment around infant feeding changes (WHO, 2018).

The benefits of Baby-Friendly designation include the following (WHO, 2019):

- Increased patient-centred care
- Improved staff attitudes about infant feeding
- Increased staff skill levels
- Dramatic decrease in the use of infant formula
- Increased contact between mothers and newborns as the use of newborn nurseries decreased

In Canada, the BCC, the national authority for the BFHI, expanded the BFHI to include community health facilities. To reflect the continuum of care between hospitals and communities, it renamed the BFHI as the Baby-Friendly Initiative (BFI). The BCC has developed the BFI Ten Steps and WHO Code Outcome Indicators for Hospitals and Community Health Services, which has set the international standards for the WHO/UNICEF global criteria within the Canadian context (Box 27.1). The Ten Steps and Practice Outcome Indicators (the Indicators) are the basis for the process by which hospitals and communities can achieve BFI designation, an internationally recognized accomplishment confirming achievement of the Ten Steps and adherence to the WHO International Code of Marketing of Breastmilk Substitutes (BCC, 2021).

BOX 27.1 The BFI Ten Steps to Successful Breastfeeding in Canada

Critical Management Procedures

1a. Comply with the International Code of Marketing of Breastmilk Substitutes and relevant World Health Assembly Resolutions.
1b. Have a written Infant Feeding Policy that is routinely communicated to all staff, pregnant women/persons, and parents.
1c. Establish ongoing Baby-Friendly Initiative (BFI) monitoring and data-management systems.
2. Ensure that staff have the competencies (knowledge, attitudes, and skills) necessary to support mothers and birthing parents to meet their infant feeding goals.

Key Clinical Practices

3. Discuss the importance and process of breastfeeding with pregnant persons and their families.
4. Facilitate immediate and uninterrupted skin-to-skin contact at birth. Support mothers and birthing parents to respond to the newborn's cues to initiate breastfeeding as soon as possible after birth.
5. Support mothers and parents to initiate and maintain breastfeeding and manage common difficulties.
6. Support mothers and parents to exclusively breastfeed for the first 6 months, unless supplements are medically indicated.
7. Promote and support mother–infant togetherness.
8. Encourage responsive, cue-based feeding for newborns. Encourage sustained breastfeeding beyond 6 months with appropriate introduction of complementary foods.
9. Discuss the use and effects of feeding bottles, artificial nipples, and pacifiers with parents.
10. Provide a seamless transition between the services provided by the hospital, community health services, and peer-support programs.

The number of BFI-designated facilities in Canada is steadily increasing. In 2021, there are 21 hospitals, 8 birthing centres, 1 native health centre, and 125 community health centres designated as Baby-Friendly facilities in Canada (BCC, 2020; PHAC, 2019). The BFI is an important step toward re-establishing a culture that supports breastfeeding in Canada as well as providing evidence-informed, family-centred care in maternity facilities (PHAC, 2019). All breastfeeding parents have a protected human right to breastfeed anytime and anywhere, including in the work environment (PHAC, 2019).

Recent updates of the BFHI (WHO, 2018) and BFI (BCC, 2021) have helped to allay some misconceptions about the BFI. Some health providers interpreted the BFI as eliminating discussions with families about formula and the practicalities of formula-feeding. One of the key messages of the BFI, however, is that health care providers have the responsibility to ensure that parents have the information and support they need to make informed feeding decisions. Health care providers must provide parents with support and information regarding safe, alternative feeding methods when a baby's diet needs to be supplemented or when parents decide to use infant formula

(Baby Friendly Initiative Ontario, 2019). It is also important to recognize that much of the care outlined in the BFI applies to all families feeding their infants. For example, all families need information about responsive feeding, infant care during painful procedures, skin-to-skin contact, mother–baby togetherness, and professional and peer support (PHAC, 2019).

Informed Decisions About Infant Feeding

In Canada, breastfeeding initiation rates of over 90% indicate that most mothers want to breastfeed their newborns. However, many mothers begin supplementing early, leading to premature weaning of their infants.

In some cases mothers decide to combine breastfeeding and formula-feeding. However, this practice may be associated with a shorter duration of breastfeeding (PHAC, 2019; Registered Nurses' Association of Ontario [RNAO], 2018). To make fully informed decisions, patients should be provided with the opportunity to discuss their goals and concerns about infant feeding and receive information on the importance of breastfeeding for the baby, mother, family, and community; the health consequences of not breastfeeding; the risks and costs of formula; and the difficulty of reversing the decision once breastfeeding is stopped (RNAO, 2018). Patients also need to be aware of the critical importance of support from a partner, employer, and community. Without this support the decision to breastfeed may not be practical for the mother, and they need to be supported in whatever decision they make, depending on their life circumstances.

For example, if a mother comes from a community where breastfed infants are rarely seen and the women in their family have not breastfed, they may not envision that the possibility of breastfeeding exists for them. When their concerns are addressed they are better able to make autonomous decisions from a wide range of choices, rather than choosing from what may be perceived as only limited choices.

Breastfeeding. Mothers most often choose to breastfeed because they are aware of the benefits to the infant (Nelson, 2012); this choice reinforces the need for prenatal education about the importance of breastfeeding. Breastfeeding is a natural extension of pregnancy and childbirth; it is much more than simply a means of supplying nutrition for infants. Many people seek the unique bonding experience between mother and infant that is characteristic of breastfeeding.

The support of the partner and family is a major factor in a person's decision to breastfeed and in their ability to do so successfully. Patients are more likely to breastfeed successfully when partners and family members have a positive view of breastfeeding and support the mother's decision. Ideally, prenatal preparation includes the partner and family, who need information about the benefits of breastfeeding and how they can participate in infant care and nurturing (PHAC, 2019; Roll & Cheater, 2016).

There appears to be a correlation between maternal weight and infant feeding decisions: pregnant patients who are overweight or obese are less likely to breastfeed than patients who are underweight or of average weight (Kair et al., 2019). Also, the same method of infant feeding tends to be selected for each of a mother's children. If the first child was breastfed, subsequent children will likely also be breastfed.

The decision to breastfeed exclusively is related to the patient's knowledge about the health benefits to the infant and the patient's comfort level with breastfeeding in social settings (Hedburg, 2013). The likelihood that patients will breastfeed exclusively may be greater if they made the decision to do so during pregnancy (PHAC, 2019). In a metasynthesis of 14 qualitative studies about decision making regarding infant feeding, Nelson (2012) reported that common barriers to breastfeeding included lack of comfort or uneasiness with breastfeeding, pain, lifestyle incompatibility, discomfort with public breastfeeding, and a lack of formal support.

Individualized, needs-based prenatal breastfeeding education is important to ensure that pregnant clients have the correct information to make the decision to breastfeed (PHAC, 2019). Each encounter with an expectant parent is an opportunity to dispel myths, clarify misinformation, and address personal concerns. Connecting expectant patients with persons who are breastfeeding or who have successfully breastfed and are from similar backgrounds may be helpful for all involved. Peer counselling programs, such as those instituted by the La Leche League, are beneficial, particularly in lower socioeconomic groups, where formula-feeding is more common.

It has been shown that pregnant patients who perceive their health care providers as supportive of breastfeeding are more likely to breastfeed than are those who perceive them as neutral or favouring formula-feeding. The more often breastfeeding is mentioned during the prenatal period, the more likely patients will breastfeed. Therefore, it is important that all health care providers know about the importance of breastfeeding and provide positive messages about it (PHAC, 2019).

Additionally, to provide effective support for the mother, health care providers must be knowledgeable about the basic process of breastfeeding, breastfeeding assessment and care, and interventions for common concerns (Box 27.2).

Formula-Feeding. Parents choose to formula-feed for many reasons. For some patients, the decision to start formula-feeding or to switch to formula arises from circumstances beyond their control (e.g., insufficient milk production, maternal disease incompatible with breastfeeding). These patients may need support as they work through the range of emotions they may feel, such as guilt, shame, and loss (PHAC, 2019).

BOX 27.2 Guidelines for Breastfeeding Support

During pregnancy, perform an assessment that includes intent to breastfeed, breastfeeding history, access to breastfeeding support, a breast examination, and a medication use history.

Develop a prenatal care plan to prepare the patient for lactation.

Inform the mother and their family of the importance of early and frequent skin-to-skin contact after birth.

After birth, the nurse:

- Ensures uninterrupted skin-to-skin contact immediately after birth until the newborn completes their first feeding
- Promotes nonseparation of mothers and babies—rooming-in 24 hours a day and encouraging family support around the clock
- Teaches responsive feeding to help parents identify early feeding cues
- Encourages breastfeeding early and often—at least 8 to 12 times per day (without supplementation)
- Helps mothers to recognize when their babies are feeding well
- Encourages breastfeeding, especially for preterm and low-birth-weight newborns
- Reinforces the recommendation for exclusive breastfeeding for the first 6 months, with the introduction of complementary foods at 6 months and continued breastfeeding up to 2 years and beyond
- Ensures community follow-up

Family centred maternity and newborn care: National guidelines. https://www.canada.ca/en/public-health/services/publications/healthy-living/maternity-newborn-care-guidelines-chapter-6.html Registered Nurses' Association of Ontario (RNAO). (2018). Breastfeeding: Promoting and supporting the initiation, exclusivity, and continuation of breastfeeding in newborns, infants and young children. http://rnao.ca/bpg/guidelines/breastfeeding-best-practice-guidelines-nurses.

Other parents make a conscious decision to formula-feed. Whatever the reason the person has for making this decision, it should be explored and supported. These reasons can include personal reason, lack of appropriate support, and sometimes a lack of information and understanding of the importance of breastfeeding. Myths and misconceptions about breastfeeding may influence a person's decision making. Some patients see formula-feeding as more convenient or less embarrassing than breastfeeding. Some view formula-feeding as a way to ensure that the partner or other family members and day care providers can feed the baby. Some patients lack confidence in their ability to produce breast milk of adequate quantity or quality. Patients who have had previous unsuccessful breastfeeding experiences may choose to formula-feed subsequent infants. Some patients see breastfeeding as incompatible with an active social life, or they think it will prevent them from going back to work and thus limit the duration of breastfeeding. Modesty issues and cultural and societal barriers may exist against breastfeeding in public. A major barrier for many patients is the influence of family and friends (Nelson, 2012).

Other people may make the decision not to breastfeed based on previous trauma that has occurred in their life. A history of sexual abuse may make it difficult for a person to make the decision to breastfeed, as it reminds them of previous abuse. Other patients who have mental illness may find it difficult to breastfeed. Whatever the reason a person has for not breastfeeding, nurses need to understand these reasons and provide support in the choice that the patient makes. Patients have the right to receive support and information to make the decision that is right for them. Providing the opportunity to discuss concerns with the use of sensitive, open-ended questions will help nurses ensure that patients are provided with the evidence-based information that they need.

Cultural Influences on Infant Feeding

Experiences such as birth and breastfeeding are shaped by the context in which they occur. As such, beliefs and perceived community norms are significant influences on infant feeding. Current feeding practices in Canada are affected by a long tradition of bottle-feeding and aggressive formula marketing (PHAC, 2019). Beliefs about infant feeding are also deeply embedded in beliefs and practices about child-rearing. Other North American beliefs may include, for example, that children are "spoiled" by being held or carried too much, or that breastfed babies need to learn how to bottle-feed, and feedings need to be scheduled or timed; these beliefs may all affect breastfeeding duration and success.

In addition to Canadian cultural influences, many regional and ethnic cultural influences within Canada can affect decisions and practices regarding infant feeding. Nurses knowledgeable in and sensitive to various cultural factors influencing infant feeding practices among their patients will be more effective in caring for families. At the same time, they must not assume that generalized observations about any cultural group hold true for all members of that group. Nurses should also reflect on their own cultural experiences (see Chapter 2).

Among Indigenous Peoples are communities unique in culture, language, and history; thus, their breastfeeding practices and beliefs vary. For example, generally the historical tradition among Indigenous people was to breastfeed infants until they were able to digest other food sources. Breastfeeding was thought to nourish, protect, guide, comfort, and ensure a strong bond between infant and mother, contributing to a good life (Best Start Resource Centre, 2017). This traditional practice shifted to bottle-feeding in the 1950s when infant formula was introduced to these communities. Since then, the incidence of breastfeeding among this population tended to be somewhat lower than that for the non-Indigenous Canadian population, although this trend is shifting toward an increase in breastfeeding among Indigenous populations (McQueen et al., 2013; UNICEF, 2009).

Among the Cree women of Northern Quebec, breastfeeding is the norm and is considered good for the health of the baby. These patients accept the traditional view that, in order to make milk, they must eat a large amount and expect to have difficulty losing their pregnancy weight. The Cree concept of *miyupimaatisiiun*, or "being alive well," which places emphasis on quality of life rather than on aspects of the physical body, has been a starting point for community-based programs supporting breastfeeding while addressing issues of obesity in this population. Current recommendations for promotion and support of breastfeeding for all Indigenous patients include careful attention to the social determinants of breastfeeding experiences and attitudes toward breastfeeding in communities (Best Start Resource Centre, 2017; Eni et al., 2014).

Because of beliefs about the harmful nature or inadequacy of colostrum, some cultures apply restrictions on breastfeeding for a period of days after birth. Such is the case for some cultures in Southern Asia, the Pacific Islands, and parts of sub-Saharan Africa. Before the mother's milk is deemed to be "in," babies are fed prelacteal food such as honey or clarified butter in the belief that these substances will help clear out meconium. Other cultures begin breastfeeding immediately after birth and offer the breast each time the infant cries.

A common practice among Mexican patients is *las dos cosas* ("both things"). This refers to combining breastfeeding and feeding commercial infant formula. It is based on the belief that, by combining the two methods, the mother and infant receive the benefits of breastfeeding, and the infant receives the additional vitamins from infant formula (Bartick & Reyes, 2012). This practice may result in a decrease in milk supply and babies refusing to latch on to the breast, leading to early termination of breastfeeding.

Some cultures have specific beliefs and practices related to the mother's intake of foods that foster milk production. Korean mothers often eat seaweed soup and rice to enhance milk production. Hmong mothers believe that boiled chicken, rice, and hot water are the only appropriate nourishments during the first postpartum month. The balance between energy forces, hot and cold, or yin and yang is integral to the diet of the lactating mother. Latin Americans, Vietnamese, Chinese, East Indians, and Arabs often use this principle in choosing foods for particular conditions. "Hot" foods are considered best for new mothers. This belief does not necessarily relate to the temperature or spiciness of foods; for example, chicken and broccoli are considered "hot," whereas many fresh fruits and vegetables are considered "cold." Families often bring desired foods into the health care setting. It used to be common practice in Canada to offer beer to enhance milk production. Today, more commonly, Canadian breastfeeding patients believe that herbs such as fenugreek will act as galactagogues.

Faith-based breastfeeding traditions are also evident. The Qur'an stipulates breastfeeding for Muslim children for at least 2 years. Some Muslim patients practise the tradition of a 40-day rest period, during which the person is relieved of housekeeping duties and other women help care for them. Some Jewish patients follow the Talmud, which directs that children be put to the breast immediately and suckled 18 months to 2 years.

Cultural attitudes regarding modesty and breastfeeding are important considerations in whether a person breastfeeds their baby. In some Canadian communities, someone who is breastfeeding may experience discrimination if they feed their child in public. Persons immigrating to North America tend to acquire the local customs of their new home; although breastfeeding may have been common in their own country, they may abandon the practice in their new country, considering it "outdated" or as practice rarely seen in public and not "Canadian."

Language barriers may also prevent successful breastfeeding and counselling when patients cannot connect with resources in their language. With the large percentage of immigrants in Canada, it is incumbent on nurses to provide breastfeeding support services in a culturally

sensitive manner and, where possible, in the family's native language. One of the goals of the Canada Prenatal Nutrition Program (CPNP) is to provide long-term funding to community groups to develop or enhance programs for breastfeeding education and support (PHAC, 2020).

Sociocultural values may preclude the mother from receiving adequate information on breastfeeding. For example, if the family is strongly patriarchal and the father is the only English-speaking person in the family and acts as translator, the necessary information being conveyed to the mother by the health care provider may not be correctly translated.

Lactation and LGBTQ2 Families

Nurses need to be aware that many parenting and breastfeeding challenges that are common for heterosexual patients also occur in same-sex or queer families. At the same time, some LGBTQ2 individuals may have specific parenting and infant feeding questions and concerns related to co-nursing and induced lactation, chestfeeding versus breastfeeding, or breastfeeding after breast augmentation (in transgender women).

Increasingly, LGBTQ2 persons are becoming parents and providing human milk to their infants through a variety of methods. At the same time, there is a lack of research, clinical papers, and commentaries in the literature on the topic of lactation and LGBTQ2 patients. These families face lactation and family adjustment issues similar to those of heterosexual families while also dealing with unique challenges (Farrow, 2015). For example, in lesbian couples who become parents, one woman may give birth and breastfeed, and the co-parent may choose to induce lactation so that she can also feed the baby. Induction of lactation involves medications and pumping. The co-parent may decide to breastfeed using a supplemental feeding device with expressed milk from the mother who gave birth. Same-sex parents may adopt a newborn who was born to a surrogate; the surrogate may provide expressed milk (Wilson et al., 2015).

Transgender men may give birth and provide human milk through breastfeeding (also known as *chestfeeding*) (Wolfe-Roubatis & Spatz, 2015). In feeding discussions and physical examination of transgendered individuals, the nurse needs to be sensitive to the potential for processes of pregnancy and lactation that affect *gender dysphoria* (when an individual feels discomfort about parts of the body not matching the person's gender) (Farrow, 2015). Nurses, lactation consultants, and other health care providers who care for LGBTQ2 families can provide more effective care if they are familiar with the needs of these parents. The use of appropriate language specific to the person who is feeding their infant is also important. Detailed information is available from Rainbow Health Ontario and Milk Junkies (see Additional Resources at the end of the chapter).

NUTRIENT NEEDS

Except in very rare situations, infants receiving sufficient volumes of milk receive the appropriate nutrients for growth. It is important to assess how well the infant feeds and signs of sufficient growth.

Fluids

During the first 2 days of life the fluid requirement for healthy newborns (more than 1 500 g) is 60 to 80 mL of water per kilogram of body weight per day. From day 3 to 7 the requirement is 100 to 150 mL/kg/day; from day 8 to day 30 it is 120 to 180 mL/kg/day (Dell, 2016). In general, neither breastfed nor formula-fed newborns need to be given water, not even those living in very hot climates. Breast milk contains 87% water, which easily meets the newborn's fluid requirements. Feeding water to newborns can decrease caloric consumption at a time when they are growing rapidly.

Newborns have room for little fluctuation in fluid balance and should be monitored closely for fluid intake and water loss. They lose water through excretion of urine and insensibly through respiration. Under normal circumstances they are born with some fluid reserve, and some of the weight loss during the first few days is related to fluid loss. However, in some cases they do not have this fluid reserve, possibly because of inadequate maternal hydration during labour or birth.

Energy

Infants require adequate caloric intake to provide energy for growth, digestion, physical activity, and maintenance of organ metabolic function. Energy needs vary according to age, maturity level, thermal environment, growth rate, health status, and activity level. The caloric (energy) maintenance and growth requirement for breastfed term newborns averages 85 to 100 kcal/kg/day; the requirement is 100 to 110 kcal/kg/day for formula-fed newborns (Blackburn, 2018).

Human milk provides an average of 67 kcal/100 mL or 20 kcal/30 mL. The fat portion of the milk provides the greatest amount of energy. Infant formulas are made to simulate the caloric content of human milk. Usually a standard formula contains 20 kcal/30 mL, although the composition differs among brands.

Carbohydrates

According to the Institute of Medicine (IOM) (2005), the recommended Adequate Intake (AI) for carbohydrates in the first 6 months of life is 60 g/day and 95 g/day for the second 6 months. Because newborns have only small hepatic glycogen stores, carbohydrates should provide at least 40 to 50% of the total calories in the diet. Moreover, newborns may have limited ability for gluconeogenesis (formation of glucose from amino acids and other substrates) and ketogenesis (formation of ketone bodies from fat), the mechanisms that provide alternative sources of energy.

As the primary carbohydrate in human milk and commercially prepared formula, lactose is the most abundant carbohydrate in the diet of infants up to 6 months of age. Lactose provides calories in an easily available form. Its slow breakdown and absorption probably also increase calcium absorption. Corn syrup solids or glucose polymers are added to infant formulas to supplement the lactose in cow's milk and provide sufficient carbohydrates.

Oligosaccharides, another form of carbohydrate found in breast milk, are critical in the development of microflora in the intestinal tract of the newborn. These prebiotics promote an acidic environment in the intestines, preventing the growth of Gram-negative and other pathogenic bacteria, thus increasing the newborn's resistance to gastrointestinal (GI) illness.

Fat

Fats provide a major source of energy for infants, supplying as much as 50% of the calories in breast milk and formula. The recommended AI of fat for infants younger than 6 months is 31 g/day (IOM, 2005). The fat content of human milk is composed of lipids, triglycerides, and cholesterol; cholesterol is an essential element for brain growth. Human milk contains the essential fatty acids (EFAs) linoleic acid and linolenic acid and the long-chain polyunsaturated fatty acids arachidonic acid (ARA) and docosahexaenoic acid (DHA). Fatty acids are important for growth, neurological development, and visual function. Cow's milk contains fewer of the EFAs and no polyunsaturated fatty acids. Most formula companies add DHA to their products, although there is a lack of evidence supporting the benefit (Lawrence & Lawrence, 2016).

Modified cow's milk is used to make most infant formulas, but the milk fat is removed and replaced by another fat source, such as corn oil, that can be more easily digested and absorbed by the infant. If whole milk or evaporated milk without added carbohydrate is fed to infants, the resulting fecal loss of fat (and therefore loss of energy) may be excessive because the milk moves through the infant's intestines too quickly for adequate absorption to take place. This can lead to poor weight gain. There is evidence that whole milk may also increase the infant's chances for developing allergies from exposure to cow's milk protein.

Protein

High-quality protein from breast milk, infant formula, or other complementary foods is necessary for infant growth. The protein requirement per unit of body weight is greater in the newborn than at any other time of life. For infants younger than 6 months the recommended AI for protein is 9.1 g/day (IOM, 2005).

Human milk contains the two proteins whey and casein in a ratio of approximately 70:30, compared with the ratio of 20:80 in most cow's milk–based formula (Blackburn, 2018). This whey/casein ratio in human milk makes it more easily digestible and produces the soft stools seen in breastfed infants. The primary whey protein in human milk is alpha-lactalbumin; this protein is high in essential amino acids needed for growth. The whey protein lactoferrin in human milk has iron-binding capabilities and bacteriostatic properties, particularly against Gram-positive and Gram-negative aerobes, anaerobes, and yeasts. The casein in human milk enhances the absorption of iron, thus preventing iron-dependent bacteria from proliferating in the GI tract (Lawrence & Lawrence, 2016). The amino acid components of human milk are uniquely suited to the newborn's metabolic capabilities. For example, cystine and taurine levels are high, whereas phenylalanine and methionine levels are low.

Vitamins

With the exception of vitamin D, human milk contains all of the vitamins required for infant nutrition, with individual variations based on maternal diet and genetic differences. Vitamins are added to cow's-milk formulas to resemble levels found in breast milk. Although cow's milk contains adequate amounts of vitamin A and B complex, vitamin C (ascorbic acid), vitamin E, and vitamin D must be added.

Vitamin D facilitates intestinal absorption of calcium and phosphorus, bone mineralization, and calcium resorption from bone. Canadian recommendations regarding vitamin D supplementation are based on Canada's northern geographic latitude, current practices related to protection from the sun, prevalence of vitamin D–deficiency rickets, and history of safe use of vitamin D supplementation. Health Canada recommends that all breastfed, healthy term infants in Canada receive a daily vitamin D supplement of 10 mcg (400 IU) (Health Canada, 2020). Supplementation should begin at birth and continue until the infant's diet includes at least 10 mcg (400 IU) per day of vitamin D from other dietary sources or until the breastfed infant reaches 1 year of age (Health Canada et al., 2015).

Vitamin K, required for blood coagulation, is produced by intestinal bacteria. However, the gut is relatively sterile at birth, and a few days are needed for intestinal flora to become established and to produce vitamin K. To prevent hemorrhagic issues in the newborn, an injection of vitamin K is routinely given within the first 6 hours after birth, following initial stabilization of the baby and family–baby interaction (Ng et al., 2018) (see Chapter 26, Medication Guide on vitamin K).

The breastfed infant's vitamin B_{12} intake depends on the mother's dietary intake and stores. Mothers who are on strict vegetarian (vegan) diets and those who consume few dairy products, eggs, or meat are at risk for vitamin B_{12} deficiency. Breastfed infants of vegan mothers should be supplemented with vitamin B_{12} from birth.

Minerals

The mineral content of commercial infant formula is designed to reflect that of breast milk. Whole cow's milk is much higher in mineral content than human milk, which also makes it unsuitable for infants in the first year of life. Minerals are typically highest in human milk during the first few days after birth and decrease slightly throughout lactation.

The ratio of calcium to phosphorus in human milk is 2:1, an optimal proportion for bone mineralization. Although cow's milk is high in calcium, the calcium/phosphorus ratio is low, resulting in decreased resorption. Consequently, young infants (less than 12 months) fed whole cow's milk are at risk for hypocalcemia, tetany, and seizures. The calcium/phosphorus ratio in commercial infant formulas is between the ratios of human and cow's milk.

Milk of all types is low in iron; however, iron from human milk is better absorbed than that from cow's milk, iron-fortified formula, or infant cereals. Breastfed infants draw on iron reserves deposited in utero and benefit from the high lactose and vitamin C levels in human milk that facilitate iron absorption. The infant who is totally breastfed normally maintains adequate hemoglobin levels for at least the first 6 months of life. After that time, meat, meat alternatives, iron-fortified cereals, and other iron-rich foods may be added to the diet. Access to traditional iron-rich foods should be encouraged and facilitated in Indigenous communities. Infants weaned from the breast before 6 months of age and all formula-fed infants should receive an iron-fortified commercial infant formula until 12 months of age (Health Canada et al., 2015).

Newborns with low birth weight (birth weight less than 2.5 kg) who are predominantly breastfed (i.e., greater than 50% of intake) are recommended to have iron supplementation. Infants with a birth weight of 2.0 kg to 2.5 kg should receive an iron supplement of 1 to 2 mg/kg/day for the first 6 months of age, and infants with a birth weight less than 2.0 kg should receive an iron supplement of 2 to 3 mg/kg/day for the first year of age (Unger et al., 2019).

Fluoride levels in human milk and commercial formulas are low. This mineral, which is important in the prevention of dental caries, can cause staining of the permanent teeth (fluorosis) in excess amounts. Fluoride supplementation should be considered for any child over age 6 months whose drinking water is deficient in fluoride or if other factors put the child at high risk for developing dental caries (Canadian Dental Association, 2012; Health Canada et al., 2015).

ANATOMY AND PHYSIOLOGY OF LACTATION

Breast Anatomy

Each female breast is composed of approximately 15 to 25 segments (lobes) embedded in fat and connective tissues and well supplied with blood vessels, lymphatic vessels, and nerves (Figure 27.1). Within each lobe is glandular tissue consisting of alveoli, the milk-producing cells, surrounded by myoepithelial cells that contract to send the milk forward to the nipple during milk ejection. Each nipple has multiple pores that transfer milk to the suckling infant. The ratio of glandular to adipose tissue in the lactating breast is approximately 2:1, compared with a 1:1 ratio in the nonlactating breast. Within each breast is a complex, intertwining network of milk ducts that transport milk from the alveoli to the nipple. The milk ducts dilate and expand at milk ejection (Wambach & Riordan, 2016) (Figure 27.2). The nipple and areola are very elastic so that they can be drawn fully into the infant's mouth for deep latch-on (Lawrence & Lawrence, 2016).

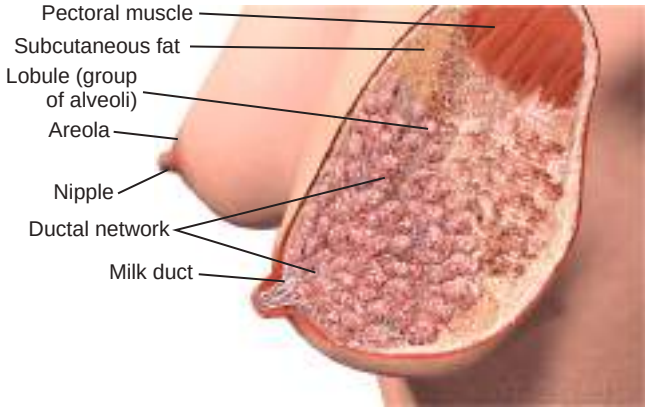

Fig. 27.1 Anatomy of the lactating breast. (Copyright © 2013 Medela.)

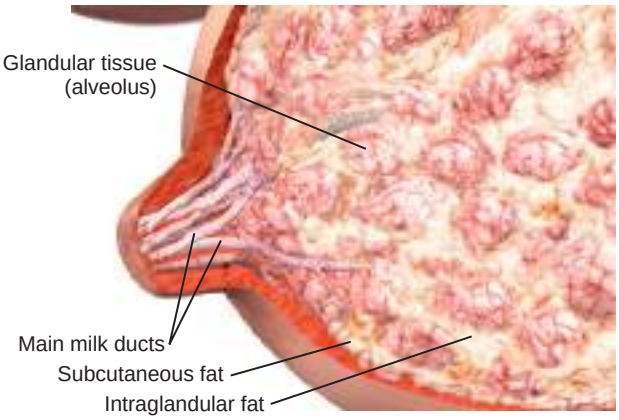

Fig. 27.2 Enhanced view of milk glands and ducts. (Copyright © 2013 Medela.)

The size and shape of the breast are not accurate indicators of its ability to produce milk. The amount of fat tissue in the breast does not affect breast storage capacity or milk production (Wambach & Riordan, 2016). Although nearly every postpartum patient can lactate, a small number have insufficient glandular development to breastfeed their infants exclusively. Typically, these patients experience few breast changes during either puberty or early pregnancy. In some cases, they are still able to produce some breast milk, although the quantity may not be sufficient to meet the nutritional needs of the infant. These mothers can offer supplemental nutrition to support optimal infant growth. Devices are available to allow mothers to offer supplements while the baby is nursing at the breast.

Lactogenesis

After the mother gives birth, a precipitous fall in progesterone triggers the release of **prolactin** from the anterior pituitary. During pregnancy, prolactin prepares the breasts to secrete milk and during lactation to synthesize and secrete milk. Prolactin levels are highest during the first 10 days after birth, gradually declining over time but remaining above baseline levels for the duration of lactation. Prolactin is produced in response to newborn suckling and emptying the breasts (lactating breasts are never completely empty; milk is constantly being produced by the alveoli as the infant feeds) (Figure 27.3, *A*). Milk production is a *supply-meets-demand system* (i.e., as milk is removed from the breast, more is produced). Incomplete removal of milk from the breasts can lead to decreased milk production.

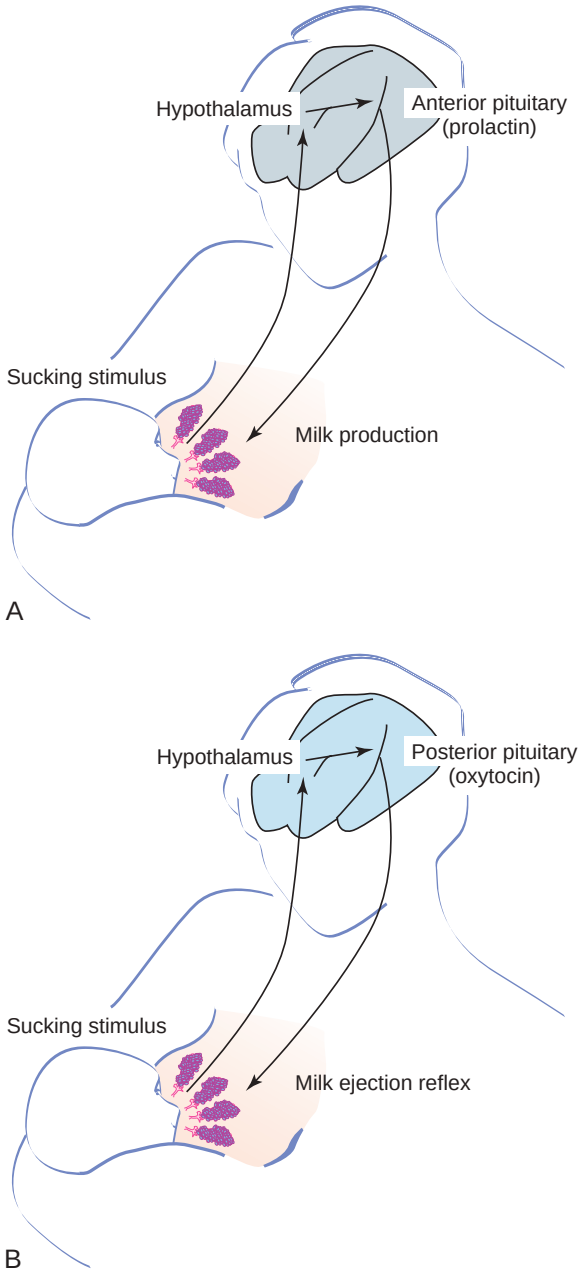

Fig. 27.3 Maternal breastfeeding reflexes. **A:** Milk production. **B:** Milk ejection reflex (let-down).

Oxytocin is another hormone essential to lactation. As the nipple is stimulated by the suckling infant, the posterior pituitary is prompted by the hypothalamus to produce oxytocin. This hormone is responsible for the **milk ejection reflex (MER)**, or *let-down reflex* (see Figure 27.3, *B*). The myoepithelial cells surrounding the alveoli respond to oxytocin by contracting and sending the milk forward through the ducts to the nipple. The MER is triggered multiple times during a feeding session. Thoughts, sights, sounds, or odours that the mother associates with their baby (or other babies), such as hearing the baby cry, can trigger the MER. Many breastfeeding mothers report a tingling "pins and needles" sensation in the breasts as milk ejection occurs, although some mothers can detect milk ejection only by observing the sucking and swallowing of the infant. The MER also can occur during sexual activity

because oxytocin is released during orgasm. The reflex can be inhibited by fear, stress, and alcohol consumption.

Oxytocin is the same hormone that stimulates uterine contractions during labour. Consequently, the MER can be triggered during labour, as evidenced by leakage of colostrum. This reflex readies the breasts for immediate feeding by the newborn after birth. Oxytocin has the important function of contracting the mother's uterus after birth to control postpartum bleeding and promote uterine involution. Oxytocin is also released by the newborn's movements while in skin-to-skin contact immediately after birth (RNAO, 2018). Thus, mothers who breastfeed are at decreased risk for postpartum hemorrhage, especially when skin-to-skin contact after birth remains uninterrupted.

Uterine contractions that occur with breastfeeding can be painful during and after the feeding for the first 3 to 5 days. These "after-pains" are more common in multiparas and patients who give birth to multiples and tend to resolve completely within 1 week after birth.

Prolactin and oxytocin have been referred to as the *mothering hormones* because they affect the postpartum patient's emotions as well as their physical state. Many people report feeling thirsty or relaxed during breastfeeding, probably as a result of these hormones.

The nipple-erection reflex is an integral part of lactation. When the newborn cries, suckles, or rubs against the breast, the nipple becomes erect, facilitating the newborn's ability to latch on to the breast effectively. Nipple sizes, shapes, and ability to become erect vary with individuals. Some people have flat or inverted nipples that do not become erect with stimulation; these patients may need assistance to help their newborns achieve an effective latch. Their newborns should not be offered bottles or pacifiers until breastfeeding is well established.

Uniqueness of Human Milk

Human milk is the ideal food for human infants. It is a dynamic substance with a composition that changes to meet the changing nutritional and immunological needs of the growing infant. Breast milk is specific to the needs of each infant; for example, the milk produced by mothers of preterm newborns differs in composition from that of mothers who give birth at term.

Human milk composition and volumes vary according to the stage of lactation. Milk secretion begins during pregnancy at approximately 16 to 18 weeks of gestation, occurring at the beginning of **lactogenesis** stage I, as the breasts prepare for milk production (Table 27.2).

TABLE 27.2 Key Stages of Lactogenesis

Stage of Lactogenesis	Description
Stage I (secretory differentiation)	Beginning in mid-pregnancy to day 2 or day 3 postpartum, the breasts develop the capacity to secrete breast milk, including the secretion of colostrum.
Stage II (secretory activation)	Beginning on day 2 or day 3 postpartum until day 8, breast milk volume increases rapidly and then abruptly levels off.
Stage III (galactopoiesis)	From approximately day 9 postpartum and onward, the volume of breast milk produced is maintained through a supply and demand mechanism.
Stage IV (involution)	Involution occurs, on average, 40 days after the last breastfeed, when breast milk secretion ceases.

Source: Riordan, J., & Wambach, K. (2016). *Breastfeeding and human lactation* (enhanced 5th ed.). Jones & Bartlett Learning.

The milk consumed by the newborn in the first few days is called *colostrum*, a clear, yellowish fluid rich in antibodies and higher in protein but lower in fat than mature milk (Lawrence & Lawrence 2016). The high protein level of colostrum facilitates binding of bilirubin, and the laxative action of colostrum promotes early passage of meconium. Colostrum is important in the establishment of normal *Lactobacillus bifidus* flora in the newborn's digestive tract. Stage II of lactogenesis begins at birth as progesterone levels drop sharply when the placenta is removed. It gradually changes to transitional milk. By 3 to 5 days after birth the patient experiences a noticeable increase in milk production. This is often referred to as *the milk coming in*. Breast milk continues to change in composition for approximately 10 days, when the mature milk is established. This is stage III of lactogenesis (Lawrence & Lawrence, 2016).

The composition of human milk changes over time as the infant grows and develops. Fat is the most variable component of human milk with changes in concentration over a feeding, over a 24-hour period, and across time. Variations in fat content exist between breasts and among individuals (Lawrence & Lawrence, 2016). The amount of fat in human milk varies based on milk synthesis and rate of milk removal.

The degree to which milk is removed signals the amount of milk to be made for the next feeding. Breast fullness (when milk accumulates in the breast) slows the rate of milk synthesis. More frequent and complete milk removal will produce more milk. Milk storage capacity of breasts varies greatly irrelevant of breast size. Mothers with a small storage capacity can produce plenty of milk overall, but the infant has a more frequent breastfeeding pattern (Mannel et al., 2013).

Milk production gradually increases as the baby grows. Infants have fairly predictable **growth spurts** (at approximately 10 days, 3 weeks, 6 weeks, 3 months, and 6 months), when more frequent feedings stimulate increased milk production. These growth spurts usually last 24 to 48 hours, after which the infants resume their usual feeding pattern as the patient's milk supply increases.

NURSING CARE

Pregnancy

Nurses can begin to support breastfeeding patients with education and anticipatory guidance beginning as early as possible during and even before pregnancy. Prenatal preparation ideally includes the partner, or another significant support person, and provides information about the importance of breastfeeding and how the partner can participate in infant care and nurturing.

Connecting expectant parents with other parents from similar backgrounds who are breastfeeding or have successfully breastfed is often helpful. Breastfeeding support groups such as La Leche League provide information about breastfeeding along with opportunities for breastfeeding mothers to talk with one another and share concerns.

Early Postpartum

For some patients the first opportunity for education about breastfeeding occurs in the postpartum period. Even patients who have indicated the desire to formula-feed can benefit from information about the importance of breastfeeding, key principles of getting breastfeeding off to a good start, and support as they learn how to feed their babies, although it is important to be respectful of a patient's choices and to support the decision that is made. Learning along with other new parents can be encouraging (Figure 27.4).

For patients, key components of breastfeeding success include self-efficacy and effective professional and peer support. Promoting feelings of competence and confidence in the breastfeeding patient and

Fig. 27.4 Breastfeeding mothers' support group with lactation consultant. (Courtesy Shannon Perry.)

reinforcing the unequalled contribution they are making toward the health and well-being of their newborn can enhance self-efficacy and are the responsibility of the nurse and other health care providers.

The first 2 weeks of breastfeeding can be the most challenging, as parents are adjusting to life with a newborn, the baby is learning to latch on and feed effectively, and the postpartum patient may be experiencing nipple or breast discomfort. This is a time when breastfeeding support is critical as patients are most likely to experience early breastfeeding difficulties, which often result in less exclusive breastfeeding and shorter duration of breastfeeding. Anticipatory guidance during the prenatal period and especially during the hospital stay after birth can provide the patient with information and increase their confidence in their ability to successfully breastfeed their newborn. Patients need access to timely, skilled lactation support following discharge through primary care offices, health departments, or outpatient lactation services. Different forms of support (face-to-face, telephone, virtual, social media) can be effective in different contexts, including mother-to-mother support, family members, and the patient's community members (McFadden et al., 2017).

Common reasons for breastfeeding cessation are insufficient milk supply (whether perceived or real), painful nipples, and difficulties with getting the infant to feed (Brown et al., 2014; Lawrence & Lawrence, 2016). Early and ongoing assistance and support from health care providers to prevent and address issues with breastfeeding can help promote a successful and satisfying breastfeeding experience for breastfeeding parents and infants. Many health care agencies have lactation consultants on staff. These consultants have specialized breastfeeding training and experience to support breastfeeding families who may require more support than that which is provided by the nurse. Lactation consultants are recognized and certified by the International Board of Lactation Consultant Examiners.

Care of the breastfeeding patient and newborn requires that nurses and other health care providers be knowledgeable about the importance and basic anatomical and physiological aspects of breastfeeding. They also need to know how to help patients with feedings and discuss interventions for common issues. Patients should be encouraged to ask for help with breastfeeding, especially while they are in the hospital. The bedside nurse is ideally positioned to provide around-the-clock support. First time mothers in particular are likely to need the most assistance, although patients who have previously given birth may also require more support. It is important not to assume that just because someone has breastfed a previous child they do not require support with a subsequent child.

In the postpartum period, interventions focus on helping the breastfeeding patient and the newborn initiate successful breastfeeding. Interventions to promote successful breastfeeding include educating and assisting patients and their partners with basics such as skin-to-skin contact, early, frequent feeding, latch-on and positioning, cue-based responsive feeding, signs of adequate feeding, and self-care measures such as prevention of engorgement. It is important to provide the parents with a list of resources they can contact after discharge from the hospital.

Nurses can assist patients in learning infant behaviours in relation to breastfeeding and recognizing signs that their baby is ready to feed. Infants exhibit **feeding-readiness cues** or early signs of hunger. Instead of waiting to feed until the infant is crying in a distraught manner or withdrawing into sleep, the patient needs to start breastfeeding when the baby exhibits early feeding cues. Feeding cues are often easiest to recognize when the newborn is held skin-to-skin. Common newborn hunger cues are as follows:

- Hand-to-mouth or hand-to-hand movements
- Sucking motions
- *Rooting reflex*—infant moves toward whatever touches the area around the mouth and attempts to suck
- Mouthing
- Flexed arms and legs with clenched fists held over chest and tummy (sometimes called *hunger posture*)

The ideal time to begin breastfeeding is within the first hour after birth, when the newborn is in the quiet, alert state. Newborns should be placed in direct skin-to-skin contact with the breastfeeding patient until the baby completes their first breastfeeding (Pound et al., 2012/2017). This is true both for patients who gave birth by Caesarean and for those who gave birth vaginally. Newborns not placed skin-to-skin for medical reasons should be returned to the breastfeeding parent at the earliest time possible. Early skin-to-skin contact and delay of newborn bathing during the transitional period after birth have both been linked to successful initiation of breastfeeding and longer duration of exclusive breastfeeding (Moore et al., 2016; PHAC, 2019; RNAO, 2018). Routine procedures such as vitamin K injection, eye prophylaxis, and weighing should be delayed until the newborn has completed the first feeding. As breastfeeding helps the newborn cope with painful procedures, many hospitals include protocols to administer vitamin K while the newborn has their first feeding at the breast (see Evidence-Informed Practice Box: Skin-to-Skin Contact for Full-Term Newborns).

EVIDENCE-INFORMED PRACTICE

Skin-to-Skin Contact for Full-Term Newborns

Ask the Question

What is the evidence for recommending skin-to-skin (STS) contact for full-term newborns?

Search for Evidence

Critically Analyze the Evidence

Health care research concerning STS contact increased in the 1970s following "kangaroo care" (KC) interventions with premature infants in Bogota, Colombia. Subsequent evidence for clinical, physiological, and psychological advantages of KC led to the more inclusive term *kangaroo mother care (KMC),* regarded as safe and superior care for vulnerable infants worldwide. The term *KMC* is now used chiefly to describe a method of intensive care for preterm and very-low-birth-weight newborns that involves extended STS, exclusive breastfeeding, and support of the mother–infant dyad. Recent research also focuses on the impact of STS contact on full-term newborns and their parents. STS contact involves holding the baby naked in a prone position against the skin of the mother's (or partner's) chest between the breasts. The baby wears only a diaper and, if needed, a hat. A blanket or shirt can cover baby and parent.

A 2016 Cochrane Database Systematic Review examined 46 studies involving 3 850 healthy mother–infant dyads and concluded that, for full-term infants, STS contact with their mothers in the first 24 hours of life had a significant positive impact on breastfeeding initiation and duration for 1 to 4 months, improved cardiorespiratory stability, and less crying, with no short- or long-term negative effects (Moore et al., 2016).

Several studies concluded that longer periods of STS contact lead to increased positive impact on breastfeeding for full-term infants. STS contact in the first 3 hours of life contributes to effective suckling and increased exclusive breastfeeding rates in hospitals (Cantrill et al., 2014; Lau et al., 2017). In addition to breastfeeding outcomes, studies show that STS contact can be an effective means of maintaining the newborn's temperature, regulating sleep–wake cycles, and minimizing the impact of painful procedures. Parents report high levels of satisfaction with STS contact, and some evidence is emerging that parent–child interaction is enhanced by STS contact (Huang et al., 2019; Moore et al., 2016). Most studies focus on breastfeeding outcomes; however, the benefits of STS contact are not limited to breastfeeding families. Paternal skin-to-skin contact may also increase the length of breastfeeding duration (Huang et al., 2019; Lau et al., 2017). Nurses should encourage parents who are formula-feeding to practise frequent STS holding so that parents and their infants have more opportunities for attachment and to promote stable infant physiological and behavioural states.

Implications for Practice

There is compelling evidence to support all families in initiating STS contact following birth and encouraging frequent and prolonged STS holding in the newborn period regardless of the method of newborn feeding. Such support can be achieved through education of health care providers, discussion of STS care prenatally with expectant parents, and implementation of supportive policies. In hospitals, policies should include initiating STS contact immediately after any type of birth and limiting unnecessary interruptions for care activities—for example, delaying weighing and the first newborn bath.

It is important to provide STS newborn contact with mothers who have a Caesarean birth whenever possible and policies should be adjusted to facilitate this. Encouraging the partner to hold the newborn STS can promote stabilization of newborn temperature and glucose levels, and enhance breastfeeding duration and parental attachment.

Assessment. A clinical breastfeeding assessment includes assessment of the breastfeeding patient, the baby, and the feeding interaction (PHAC, 2019). Assessment of the patient includes their history relevant to feeding issues (breast changes or surgery, previous breastfeeding experience, their concerns and physical observation of the breasts and nipples). Assessment of the newborn includes history (birth and feeding), gestational age, health and general appearance, oral anatomy, and behaviour (alertness, ability to cue for feedings). The feeding interaction includes assessment of frequency and duration, feeding effectiveness (active sucking, infant firmly attached to the nipple in a way that does not cause damage, signs of milk transfer, and an appropriate pattern of weight loss and gain). A breastfeeding assessment tool known as LATCH was developed by Jensen et al. in 1994. Subsequent research has demonstrated that early LATCH scores are linked to breastfeeding success at 6 weeks of age (Kumar et al., 2006; RNAO, 2018). Higher LATCH scores have been linked to higher milk intake (Altuntas et al., 2015). The tool involves assessing for the following:

L (characteristics of latch-on)
A (degree of audible swallowing)
T (type of nipple)
C (maternal comfort)
H (holding skills)

Systematic assessment of these five aspects can assist the breastfeeding patient and nurse to focus together on what is needed for extra support.

Positioning. The first feeding often occurs while the patient is in a semi-reclining position with the newborn lying prone, skin-to-skin on their bare chest. Their body supports the baby. The newborn is able to use inborn reflexes to latch on to the breast and feed effectively. This approach to breastfeeding is based on a study that found that newborns placed prone on their parent's chest were more likely to exhibit some of their primitive reflexes that facilitated breastfeeding (Colson et al., 2008) (Figure 27.5, *A*). Some patients find this position helpful if they are having difficulty with their baby latching on to the breast.

Nurses should encourage breastfeeding patients to try different positions to find what works best for them and to use good body mechanics to ensure that they are comfortable and feel supported. The cross-cradle or across-the-lap position works well for early feedings, especially with smaller babies (Figure 27.5, *C*). Parents of multiples may find the football or clutch hold helpful to tandem feed. Parents who gave birth by Caesarean may also prefer this position. However, with skilled support and effective pain relief for abdominal pain, many of these patients are comfortable using any position (Figure 27.5, *B*). The side-lying position allows patients to rest while breastfeeding and is often preferred by postpartum patients experiencing perineal pain and swelling (Figure 27.5, *E*). In the early postpartum, patients may need assistance to position their newborn side-lying. Cradling is the most common breastfeeding position for infants who have learned to latch on easily and feed effectively (Figure 27.5, *D*). Before discharge from the birth facility, nurses can help patients find what works and encourage them to experiment with positioning. As long as they go home confident that their baby can latch on for feeding and they can feed their baby well, they do not have to master everything before they go home. See Family-Centred Care box: Helpful Tips When Providing Care to Breastfeeding Parents.

FAMILY-CENTRED CARE

Helpful Tips When Providing Care to Breastfeeding Parents

- Respect the patient's privacy—always knock before entering their room.
- Suggest that the patient empty their bladder and have a glass of water close by before starting to breastfeed.
- Use pillows, or show the family how to use pillows, to support the breastfeeding patient and baby so that both are comfortable and the baby is at the level of the breast facing the breastfeeding patient (belly-to-belly).
- The baby's body should be in alignment (ears, shoulders, and hips are in a straight line).
- The baby's head is in slight extension—the breastfeeding patient's hand is on the baby's back and does not push on the occiput.
- Be at eye level when supporting the patient.
- Wherever possible, take a "hands-off" approach working with the breastfeeding patient rather than latching the baby for them. If other intervention is needed, ensure that the patient has the opportunity to learn to help their baby latch on themselves.

Effective Latch. Latch, or latch-on, is defined as how the infant grasps the breast with their mouth. With an effective latch, the baby grasps the nipple, areola, and breast tissue, making a seal between the mouth and breast to create adequate suction to facilitate milk removal (PHAC, 2019). Obtaining an effective latch involves the following steps:

- Manually express a few drops of colostrum or milk to spread over the nipple. This lubricates the nipple and may entice the baby to open the mouth as the milk is tasted.
- Support the breast if needed with one hand and ensure that the fingers are well back from the areola.
  - Some patients may cup their breast with the thumb on top and four fingers underneath at the back edge of the areola (referred to as the *C hold*) (Figure 27.6, *A*).
  - Patients with larger or fuller breasts may need to support the breast during feeding for at least the first few days until the infant is adept at feeding.
  - Some patients compress the breast slightly so that an adequate amount of breast tissue is taken into the baby's mouth with latching.
- Hold the baby close to the body and breast.

Fig. 27.6 Latching on. **A:** When mouth is wide open, draw baby close. **B:** The nipple should be centred upward in infant's mouth. **C:** As baby latches on, draw infant closer to the breast. Chin should be tucked in close to breast.

- Lightly touch the infant's upper lip with the nipple, which stimulates the mouth to open (rooting reflex).
- Point the nipple toward the newborn's nose, avoiding "centring" the nipple in the mouth.
- Bring the baby in close when their mouth is wide open (see Figure 27.6, *A*); tilt the baby's head slightly so that the chin touches the breast first as the baby comes to the breast (Figure 27.6, *B*).
- Bring the infant to the breast, not the breast to the infant.

An effective latch is functional, meaning that babies that are well latched will begin to suck (PHAC, 2019).

The amount of the areola in the newborn's mouth with latch depends on the size of the newborn's mouth and the size of the areola and nipple. In general, the infant's mouth should cover the nipple and areola, with more of the areola visible above the baby's upper lip than below the lower lip (Figure 27.7).

When the newborn is latched on effectively, the chin is pressed into the breast, and the cheeks and nose may be lightly touching the breast. If the breastfeeding patient is worried about the infant's breathing, they can raise the newborn's hips slightly by tucking the hips in closer to their body, to change the angle of the infant's head at the breast. Depressing the breast tissue around the newborn's nose is not usually necessary unless the patient has very soft, doughy breasts. If the newborn cannot breathe, reflexes will prompt the newborn to move their head and pull back from the breast to breathe.

Once the newborn is latched on and sucking, there are signs to note that the feeding is going well (Box 27.3). Sucking creates a vacuum in the intraoral cavity as the breast is compressed between the tongue and the palate. Though many patients may feel some nipple soreness in the first week when the newborn is latched on and sucking correctly, breastfeeding should not be painful. If the patient feels pinching or pain during the feeding or the nipple looks distorted, reassess the latch and positioning. If breastfeeding is painful, the baby likely has not latched well and the tongue or gums are pinching the nipple. Reviewing the basics of latch and positioning usually alleviates this issue. For a small number of infants *ankyloglossia* ("tongue-tie") may lead to difficulty latching effectively, resulting in low milk intake and maternal nipple pain and trauma. Additionally, if the newborn does not begin to spontaneously suck, assess whether or not the newborn is effectively latched.

Fig. 27.7 Correct attachment (latch-on) of infant at breast. (Courtesy Cumberland Health Authority.)

BOX 27.3 Indications of a Good Latch

- The mother feels a firm tugging sensation on the breast, but feels no pinching or pain.
- The baby sucks with cheeks rounded, not dimpled.
- The baby's jaw glides smoothly with sucking.
- Swallowing is usually audible and sounds like a series of "ca" sounds.
- The baby cannot be easily removed from the breast.
- The mother's nipple is not distorted when the baby releases from the breast.

Any time the signs of adequate latch and sucking are not present, the newborn should be taken off the breast and latch attempted again. To prevent nipple trauma as the newborn is taken off the breast, the breastfeeding patient is instructed to break the suction by inserting their finger in the side of the infant's mouth between the gums and keeping it there until the nipple is completely out of their newborn's mouth (Figure 27.8) (see Nursing Care Plan: Breastfeeding and Infant Nutrition, available on Evolve).

Milk Ejection Reflex. As the newborn begins sucking on the nipple, the MER, or let-down, reflex is stimulated. Several "let-downs" can occur with each feeding session. The following signs indicate that MER has occurred:

- The breastfeeding patient may feel a tingling sensation in the nipples and breasts, although some patients never feel when milk ejection (let-down) occurs.
- The newborn's suck changes from quick, shallow sucks to a slower, deeper, more drawing sucking pattern.
- Audible swallowing is present as the baby sucks ("ca" sounds).
- The patient may feel thirsty and relaxed or drowsy during feedings.
- In the early days the patient feels uterine cramping.
- The opposite breast may leak milk.

! NURSING ALERT

Be cautious in referring to the MER as "let-down." Some patients may interpret let-down as being associated with feelings of depression.

Fig. 27.8 Removing infant from the breast. (Courtesy Marjorie Pyle, RNC, Lifecircle.)

Frequency of Feedings. Newborns consume small amounts of colostrum with frequent feedings during the first 3 days of life. As the breastfeeding patient's milk volume increases and the digestive tract is cleared of meconium, the newborn's fluid intake gradually increases. Feeding patterns vary because every mother–newborn dyad is unique. Breastfeeding frequency is influenced by a variety of factors, including the infant's age and weight, the infant's stomach capacity and gastric emptying time, and the storage capacity of the breast (i.e., the milk available when the breast is full).

Newborns should be fed on the basis of cues, without time restrictions, on average at least eight times per 24 hours (International Lactation Consultant Association [ILCA], 2014; PHAC, 2019) (see Clinical Reasoning Case Study: Newborn Breastfeeding). Some newborns breastfeed every 2 to 3 hours throughout a 24-hour period. Others cluster-feed, breastfeeding every hour or so for three to five feedings and then sleeping for 3 to 4 hours between clusters. During the first 24 hours after birth, most newborns do not awaken this often to feed. Rooming-in and skin-to-skin care will help parents recognize and quickly respond to newborn feeding cues. Encourage families to look for opportunities to feed their newborn; "watch the baby, not the clock." If the newborn is stirring, parents should be encouraged to pick the baby up and offer the breast. After 24 hours of life, if newborns are not consistently beginning to wake on their own to feed at least eight times in 24 hours, parents should be encouraged to wake the baby up to feed and careful assessment of the newborn on how well they are feeding should be done. Feeding frequency is determined by counting from the beginning of one feeding to the beginning of the next. Once the newborn is feeding well and gaining weight adequately, cue-based feeding may look different, with some infants feeding less than eight times in 24 hours.

Nurses need to caution parents against attempting to place newborns on strict feeding schedules. Newborns should be fed whenever they exhibit feeding cues such as hand-to-mouth movements, rooting, and mouth and tongue movements. Crying is a late sign of hunger, and newborns may become frantic when they have to wait too long to feed. Some newborns will shut down or go into a deep sleep when their needs are not met. Understanding and responding to an infant's states and cues (see Chapter 25) are essential to the infant feeding interaction.

Foundational to infant feeding is the concept of responsive feeding. Responsive interactions between parents and infants during feeding is the ideal for families to establish healthy interaction patterns and dietary behaviours, avoiding both underweight and overweight (Black & Aboud, 2011). With responsive breastfeeding, parents recognize that feedings are not just about food. A lot happens within this relationship: love, comfort, and reassurance. Responsive breastfeeding means that parents breastfeed in response to feeding cues as well as when babies are distressed, lonely, or in pain (for example, during painful procedures such as injection of vitamin K and immunizations) (UNICEF UK Baby-Friendly Initiative, 2016). Parents may also breastfeed to relax and cuddle with their child.

Frequent skin-to-skin holding helps mothers to notice state changes and early hunger cues and thus provide the frequent feedings required at the breast in the first few days (see Evidence-Informed Practice box: Skin-to-Skin Contact for Full-Term Newborns). Parents and infants sharing the same room at night is recommended for at least the first 6 months. This practice facilitates breastfeeding and is best practice for prevention of sudden infant death syndrome (SIDS).

Bedsharing, which is when the newborn and parent share the same bed, has been shown to promote breastfeeding initiation duration and exclusivity, although Health Canada recommends against bedsharing, citing concerns about the increased risk of sleep-related infant death (Blair et al., 2020: PHAC, 2018). Health Canada recommends that the safest place for any infant to sleep is in a crib within arm's reach of where the parents sleep. Because many families do practice bedsharing the Academy of Breastfeeding (ABM) recommends that discussions about safe bedsharing be incorporated into guidelines for pregnancy and postnatal care (Blair et al., 2020) (Box 27.4). When a family is bedsharing, conversations should be nonjudgemental and acknowledge the context of the family. It is important not to communicate stigma around bedsharing, as educating all parents about safe bedsharing has the potential to reduce the number of infant deaths (Blair et al., 2020). (See Chapter 26 for more discussion on SIDS.)

BOX 27.4 Elements of Safe Bedsharing Advice, in Order of Importance

1. Never sleep with infants on a sofa, armchair, or unsuitable surface, including a pillow.
2. Place infants to sleep away from any person impaired by alcohol or drugs.
3. Place infants supine for sleep.
4. Place infants to sleep away from secondhand smoke and away from a caregiver who routinely smokes and clothing or objects that smell of smoke (thirdhand smoke). (In cases where the mother smokes, this will not be possible.)
5. The bed should be away from walls and furniture to prevent wedging of the infant's head or body.
6. The bed's surface should be firm, just as with a crib without thick covers (e.g., duvets), pillows, or other objects that could cause accidental head covering and asphyxiation.
7. The infant should not be left alone on an adult bed.
8. Adoption of the C-position ("cuddle curl"), with the infant's head across from the adult's breast, adult's legs and arm(s) curled around the infant, infant on their back, away from the pillow, is the optimal safe sleeping position.
9. There is insufficient evidence to make recommendations on multiple bedsharers or the position of the infant in bed with respect to both parents in the absence of hazardous circumstances. Each locality should consider the cultural circumstances unique to its situation with respect to sleep conditions.

CLINICAL REASONING CASE STUDY

Newborn Breastfeeding

Neide is a 27-year-old woman who gave birth 5 days ago to a 3 540 g male newborn. His current weight is 3 180 g. Neide is being seen in the clinic for a follow-up consultation on breastfeeding and newborn jaundice. On examination the baby is alert, fussy, and visibly jaundiced. Neide states that breastfeeding has not been going as well and she is not certain the baby is receiving enough milk. She states, in tears, that all the baby does is cry and fuss when she places him to the breast, and she wants to try formula. She recalls that yesterday the baby had one or two greenish stools and three wet diapers.

1. Evidence—Is there sufficient evidence to draw conclusions about the effectiveness of the newborn's breastfeeding pattern?
2. Assumptions—What assumptions can be made about the following factors?
   a. The newborn's ability to latch on
   b. The newborn's ability to feed effectively
   c. Adequacy of milk intake
   d. The need for additional newborn assessments
   e. The mother's desire to give the baby formula
   f. The mother's physical and emotional status
3. What implications and priorities for nursing care can be drawn at this time?

Duration of Feedings. The duration of breastfeeding sessions is highly variable for each mother–baby pair. The average time for early feedings is 30 to 40 minutes, with additional time taken to change diapers, burp the baby, or wake the baby to finish the feeding. Thus, for many new parents the whole feeding process may take about an hour. Instructing breastfeeding patients to feed for a set number of minutes is inappropriate. Patients should be encouraged to offer both breasts during the early postpartum period—alternating the breast that they offer first. As the patient's milk supply increases, many patients find that their baby is content after just one breast, except when the infant goes through a growth spurt.

Patients should be shown how to determine when an infant has finished a breast: the infant's suck-swallow pattern has slowed, and the baby appears content and may fall asleep or release the nipple. Other, more subtle, satiation cues include extended and relaxed fingers, arms and legs extended, back arching, or pushing away.

As infants grow, they become more efficient at breastfeeding and, consequently, the length of feedings may decrease. The amount of time an infant spends breastfeeding is not a reliable indicator of the amount of milk the infant consumes because some of the time at the breast is spent in non-nutritive sucking and interaction with the breastfeeding parent.

The infant's stomach capacity gradually increases; comparing the volume to a cherry, a walnut, and a hen's egg is one way to help parents visualize the sizes (Figure 27.9).

Occasionally, a breastfeeding parent with a bountiful milk supply will have a very fussy but thriving infant who appears to act hungry and vomits milk frequently, especially if the patient offers both breasts. Often these babies improve by switching breasts less often as the patient's milk supply becomes more manageable.

Indicators of Effective Breastfeeding. One of the most common concerns of breastfeeding patients is how to determine if the baby is getting enough milk. It is important to teach parents the signs that breastfeeding is going well. Awareness of these signs can help them recognize when issues arise so they can seek appropriate assistance (see Figure 27.9).

During the early days of breastfeeding, keeping a feeding diary can be helpful, recording the time and length of feedings and newborn urine output and the number and colour of bowel movements. The diary can be reassuring to parents and useful to health care providers in assessing adequacy of feeding. Parents are instructed to take this feeding diary to the follow-up visit with their pediatric care provider.

The infant's output is highly indicative of feeding adequacy. It is important that parents are aware of the expected changes in the characteristics of urine output and bowel movements during the early newborn period. As the volume of breast milk increases, urine becomes more dilute and should be light yellow; dark, concentrated urine can be associated with inadequate intake and possible dehydration. (Infants with jaundice often have darker urine as bilirubin is excreted.)

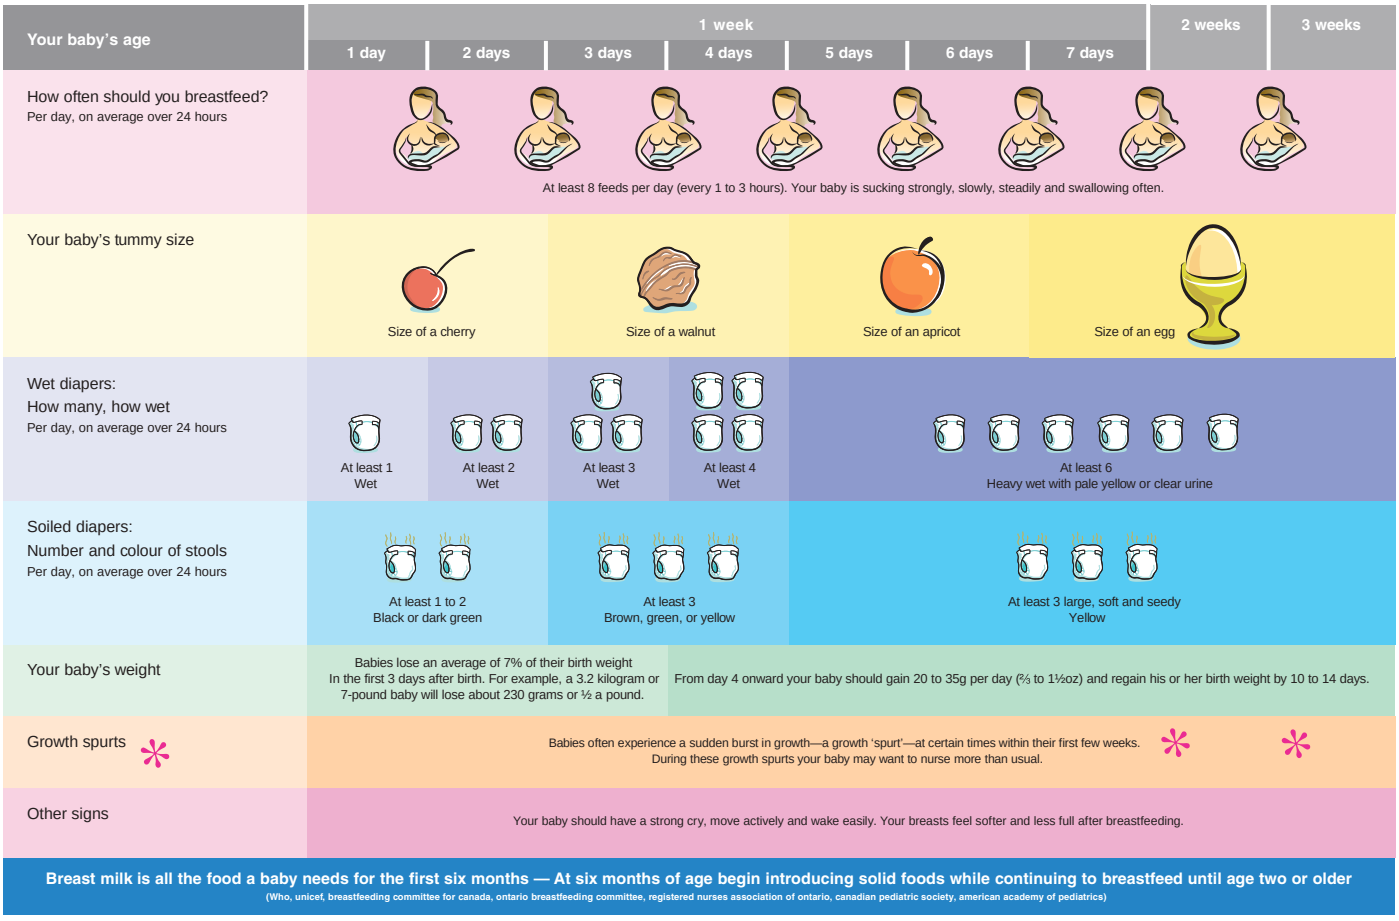

Fig. 27.9 Guidelines for nursing mothers regarding how often to feed and how to know the baby is getting enough to eat. (Courtesy Best Start, http://beststart.org/resources/breastfeeding/pdf/breastfdeskref09.pdf. Reprinted with permission by the Best Start Resource Centre.)

TABLE 27.3 Newborn Urine and Stool Output on Days 1–28 Postbirth

Newborn Age in Days	Voids	Stools
1	1 or more wet, clear, pale, yellow	1 or more meconium
2–3	2–3 wet, clear, pale, yellow	1 or more meconium or greenish brown transition stools
3–5	3–5 wet, clear, pale, yellow	3–4 transition stools changing to loose, yellow
5–7	4–6 wet, clear, pale, yellow	3–6 yellow or golden, generally loose
7–28	Frequent and clear pale yellow	5–10 + yellow

Research on elimination patterns in the first few days is inconsistent. Stooling rather than voiding may indicate sufficient milk intake more reliably. In the first few days, the amount of urine may be small and it may be concentrated, with uric acid crystals that appear as brick-red staining in the diaper. By day 3, when the milk supply increases, more urine is produced (diapers are heavier) and it becomes paler, with no uric acid crystals. Three or fewer stools on day 4 postbirth in combination with delayed lactogenesis requires further assessment and monitoring. Source: Public Health Agency of Canada. (2019). *Family centred maternity and newborn care: National guidelines–Breastfeeding (Chapter 6).* https://www.canada.ca/en/public-health/services/publications/healthy-living/maternity-newborn-care-guidelines-chapter-6.html.

Table 27.3 outlines expected output. Variances from these norms indicate the need for assessment and follow-up.

As the infant gets older, the stooling patterns gradually change; breastfed infants can continue to stool more than once per day or they may stool only every 2 or 3 days or even longer. As long as the baby continues to gain weight and appears healthy, this decrease in the number of bowel movements is normal.

Other factors to assess include the presence of jaundice, weight loss greater than 10%, and whether the infant has regained birth weight by 10 to 14 days of age. See Box 28.2 for calculation of weight loss.

Supplementation. The CPS (Pound et al., 2012/2017) recommends that, unless a medical indication exists, supplements should not be given to breastfeeding newborns. With sound breastfeeding knowledge and practice, supplements are rarely needed. Early supplementation by hospital staff undermines a new parent's confidence and models behaviour that is counterproductive to prolonging breastfeeding.

If a supplement is deemed necessary, the patient's expressed breast milk is the first choice. All breastfeeding patients should be taught how to hand express breast milk and give this to the newborn (see discussion later in chapter). A small amount of colostrum is often all that is required to supplement a newborn. Before supplementation it is important to perform a careful breastfeeding assessment of the breastfeeding patient, the newborn, and the feeding interaction.

Possible indications for supplementary feeding include newborn factors such as hypoglycemia, ineffective feeding, dehydration, weight loss of more than 10% associated with delayed lactogenesis, or delayed passage of bowel movements or meconium stool continued to day 5.

Indications for possible supplementation include severe illness, delayed lactogenesis, or taking medications that are incompatible with breastfeeding (Pound et al., 2012/2017). Patients who have had previous breast surgery, particularly breast reduction, may need to provide supplementary feedings for their infants.

Supplemental feedings may contribute to "nipple preference" (i.e., difficulty knowing how to latch on to the breast or preferring the easy flow from an artificial nipple), engorgement, and low milk supply because the baby becomes overly full and does not breastfeed often enough. Supplementation interferes with the supply-meets-demand cycle of milk production. The parents may interpret the newborn's willingness to take a bottle to mean that the patient's milk supply is inadequate. They need to know that a newborn will automatically suck from a bottle, as the artificial nipple triggers the suck-swallow reflex.

Bottles and Pacifiers. Newborns may become confused going from breast to bottle or bottle to breast when breastfeeding is first initiated. Breastfeeding and bottle-feeding require different oral motor skills. The ways newborns use their tongues, jaw, and lips, as well as the swallowing patterns, are very different. It is recommended that parents avoid giving bottles until breastfeeding is well established, usually at least after 3 to 4 weeks.

If supplemental feeding is needed, nurses can help parents feed their newborn with a spoon, cup or syringe. These devices are especially useful for the small amounts of milk required in the first few days. If the newborn requiring supplemental feeding is able to latch on well, some mothers can provide milk through a feeding tube at the breast. This allows the baby to be supplemented with expressed milk or infant formula while still breastfeeding. A commercial product, a Supplemental Nursing System, is also available (Figure 27.10).

Many parents believe that all babies need to learn how to bottle-feed. However, many breastfed infants wean to a cup never requiring a bottle.

The CPS (Ponti & CPS, 2003/2018) recommends that health care providers recognize pacifier use as a parental choice determined by the needs of their child, and that pacifier use be delayed until breastfeeding is established. Early use of a pacifier may negatively affect milk

Fig. 27.10 Supplemental nursing device. (Copyright © 2013 Medela.)

production (Jaafar et al., 2016), particularly if it is used to delay or avoid breastfeeding. One concern about the use of pacifiers is that feeding cues may be missed; therefore, the infant is not fed as often, which can lead to a decreased milk supply. The CPS recommends that pacifiers not be routinely discouraged, as current evidence suggests a decreased risk of SIDS may be associated with their use, although the evidence is not strong enough to recommend their use for this purpose (Ponti & CPS, 2003/2018). The American Academy of Pediatrics (2016) recommends that parents consider offering a pacifier at nap time and bedtime, having also found a protective effect against the incidence of SIDS, which persists through the sleep period even if the pacifier falls out of the infant's mouth. For premature infants who are unable to fully breastfeed, non-nutritive sucking using a pacifier is beneficial.

Special Considerations

Sleepy newborn. During the first few days of life, some newborns need to be awakened for feedings. If the newborn is awakened from a sound sleep, attempts at feeding are more likely to be unsuccessful. Newborns are more likely to feed if they are awakened from a light or active sleep state. Signs that the newborn is in this sleep state are movements of the eyelids, body movements, and making sounds while sleeping. Unwrapping or undressing the newborn, changing the diaper, sitting the newborn upright, talking to the newborn with variable pitch, gently massaging the newborn's chest and back, and stroking the arms, legs, palms, or soles may bring the newborn to an alert state. Placing the sleeping newborn skin-to-skin on the breastfeeding parent's chest may also stimulate a state change; the infant can be moved to the breast when feeding-readiness cues are apparent (Figure 27.11).

Fussy newborn. In the early days at home some newborns start crying soon after they are put in their beds, requiring to be comforted (see Family-Centred Care box: Baby's Second Night). Other babies awaken from sleep crying frantically. Although they may be hungry, they cannot focus on feeding until they are calmed. Calming techniques include holding the baby close, talking soothingly, and allowing the newborn to suck on their own hand or fingers to settle enough to latch on to the breast. Skin-to-skin care with the breastfeeding parent or partner can effectively calm a fussy baby.

Pain or discomfort may cause fussiness during feeding. This can be caused by a birth injury (bruising of the head, forceps damage, or a fractured clavicle). Careful positioning to avoid pressure on the sore area may help. In some cases, analgesics may be recommended.

Newborns who were suctioned extensively or intubated at birth or forcibly pushed onto the breast to feed can demonstrate an aversion to oral stimulation. The baby may scream and stiffen if anything approaches the mouth. Parents need to spend time holding and cuddling the baby skin-to-skin before attempting to breastfeed.

FAMILY-CENTRED CARE

Baby's Second Night

You've made it through your first 24 hours as a new mom. Maybe you have other children, but you are a new mom all over again . . . and now it's your baby's second night.

All of a sudden, your little one discovers that he's no longer back in the warmth and comfort—though a bit crowded—womb where he spent the last 9 months—and it is SCARY out here! He isn't hearing your familiar heartbeat, the swooshing of the placental arteries, the soothing sound of your lungs, or the comforting gurgling of your intestines. Instead, he's in a crib, swaddled in a diaper, a tee-shirt, a hat, and a blanket. All sorts of people have been handling him, and he's not yet become accustomed to the new noises, lights, sounds, and smells. He has found one thing though, and that's his voice . . . and you find that each time you take him off the breast, where he comfortably drifted off to sleep, and put him in the bassinet—he protests, loudly!

In fact, each time you put him back on the breast he nurses for a little bit and then goes to sleep. As you take him off and put him back to bed—he cries again . . . and starts rooting around, looking for you. This goes on—seemingly for hours. A lot of moms are convinced it is because their milk isn't "in" yet, and the baby is starving. However, it isn't that, but the baby's sudden awakening to the fact that the most comforting and comfortable place for him to be is at the breast. It's the closest to "home" he can get. It seems that this is pretty universal among babies; lactation consultants all over the world have noticed the same thing.

So, what do you do? When he drifts off to sleep at the breast after a good feed, break the suction and take your nipple gently out of his mouth. Don't move him except to gently slide him into an upright neutral position with his head to the side. Don't try and burp him—just snuggle with him until he falls into a deep sleep where he won't be disturbed by being moved. Babies go into a light sleep state (REM) first, and then cycle in and out of REM and deep sleep about every half-hour or so. If he starts to root and act as though he wants to go back to breast, that's fine—this is his way of settling and comforting. During deep sleep, the baby's breathing is very quiet and regular, and there is no movement beneath his eyelids.

Another helpful hint: his hands were his best friends in utero . . . he could suck on his thumb or his fingers anytime he was the slightest bit disturbed or uncomfortable. And all of a sudden he's had them taken away from him and someone has put mittens on him! He has no way of soothing himself with those mittens on. Babies need to touch—to feel—and even his touch on your breast will increase your oxytocin levels, which will help boost your milk supply! So take the mittens off and loosen his blanket so he can get to his hands. He might scratch himself, but it will heal very rapidly—after all, he had fingernails when he was inside you, and no one put mittens on him then!

By the way—this might happen every once in a while at home too, particularly if you've changed his environment, such as going to the doctor's, to church, to the mall, or to the grandparents! Don't let it throw you—sometimes babies just need some extra snuggling at the breast, because for the baby, the breast is "home."

© 2016/Jan Barger RN, MA, IBCLC/Lactation Education Consultants.

An infant who is feeding ineffectively can become fussy during the feeding. Possible reasons include poor latch, a breastfed baby who has become used to instant, rapid flow of milk from previous bottle feeding, or insufficient milk production from the breast. The feeding may begin

well, but the infant soon begins to pull off the breast and cry. Nurses need to provide assistance to help problem solve to find the solution appropriate to the source of the issue.

Fussiness may be related to GI distress (i.e., cramping and gas pains). It can occur in response to an occasional feeding of infant formula or be related to something the breastfeeding parent ingested, although most breastfeeding parents are able to eat a normal diet without causing GI distress to the breastfeeding baby. Persistent crying or refusing to breastfeed can indicate illness. Parents need to be advised to notify the health care provider if the newborn is inconsolable, there is a significant change in their behaviour, or if they will not feed. Parents also need to learn how to cope with normal crying (see Family-Centred Care box: The Period of PURPLE Crying® in Chapter 26).

Some parents find that their babies are less fussy when placed in a sling or carrier. Some slings make it easy to breastfeed without removing the baby from the sling (Figure 27.12).

Slow weight gain. Newborns may lose up 8 to 10% of their birth weight during the first 3 to 5 days after birth; this is mostly water weight acquired in utero or due to the passage of meconium (Kellams et al., 2017). Thereafter, they should begin to gain weight at the rate of 110 to 200 g/week, or 20 to 28 g/day. The breastfed newborn who loses more than 10% of birth weight requires careful assessment regarding feeding behaviours and the milk supply of the breastfeeding parent. The newborn who continues to lose weight after 5 days, does not regain birth weight by 2 weeks, or whose weight is below the tenth percentile by 1 month should be evaluated and closely monitored by a health care provider in collaboration with a lactation consultant (if possible).

Slow or poor weight gain is usually due to one of three factors:

- Breastfeeding adequateness: Is the baby feeding well enough (latched effectively with milk transfer), often enough, and long enough?
- Milk supply: Maternal issues such as delayed or insufficient lactogenesis due to primary reasons such as hormonal issues or insufficient breast development, or secondary issues such as breast surgery, unresolved engorgement, severe intrapartum or postpartum hemorrhage (Sheehan's syndrome), severe stress, medications, or insufficient breast stimulation from infrequent breast emptying (Lawrence & Lawrence, 2016)
- Infant illness or conditions: Babies with increased calorie needs due to congenital heart conditions, those with malabsorption syndromes such as cystic fibrosis, or babies with Down syndrome

Fig. 27.12 Baby breastfeeding while in sling. (Courtesy Julie Perry Nelson.)

Use of the WHO growth charts is recommended for appropriate growth monitoring (Denne, 2015; Health Canada et al., 2015). Slow weight gain must be differentiated from failure to thrive. Some infants gain weight slowly but appear healthy and content, have normal output, and meet their developmental milestones. On the other hand, failing to thrive can be a serious condition that warrants medical intervention (see Chapter 36, Failure to Thrive).

Careful assessment of the breastfeeding parent, the baby, and the feeding interaction is key to nursing care. In most instances the solution to slow weight gain is to increase feeding frequency and to improve the feeding adequateness, positioning, and latch effectiveness. The nurse should evaluate position and latch and help the breastfeeding patient make adjustments as necessary. Increasing the frequency of feedings may be all that is necessary if the baby is able to feed actively at the breast. If the issue is a sleepy baby, parents should be instructed in waking techniques.

Using breast massage during feedings can help increase the amount of milk going to the infant. With this technique, the breastfeeding patient massages their breast from the chest wall to the nipple whenever the baby has sucking pauses. This technique may also increase the fat content of the milk by decreasing breast fullness.

If the baby is unable to feed effectively, the breastfeeding parent may need to express or pump their milk to provide the extra milk that their baby needs. This extra milk or formula can be given with a spoon or cup, syringe, supplemental nursing device (see Figure 27.10), or a bottle. If there are latching difficulties, it is best to avoid using bottles and pacifiers. In most cases, supplementation is needed only for a short time, until the infant gains weight and is feeding adequately.

Most breastfeeding issues require solutions that include the development of a feeding plan in collaboration with the breastfeeding parent that addresses the specific identified issues. Referral to a lactation consultant and/or primary health care provider may be necessary.

Jaundice. **Hyperbilirubinemia** in the newborn is discussed in detail in Chapter 26. Breastfeeding newborns can develop *early-onset jaundice* or *breastfeeding-associated jaundice,* which is associated with insufficient or ineffective feeding and infrequent stooling. Colostrum has a natural laxative effect and promotes early passage of meconium. Bilirubin is excreted from the body primarily through the intestines. Infrequent stooling allows bilirubin in the stool to be resorbed into the newborn's system, thus increasing bilirubin levels (Blackburn, 2018). To prevent early-onset, breastfeeding-associated jaundice, newborns should be breastfed frequently during the first several days of life. Increased frequency of feedings is associated with decreased bilirubin levels.

To treat early-onset jaundice, breastfeeding is evaluated in terms of frequency and length of feedings, effective feeding, and milk transfer. Factors such as a sleepy or lethargic newborn or breast engorgement in the breastfeeding patient can interfere with effective breastfeeding and should be corrected. If the newborn's intake of milk needs to be increased, the breastfeeding patient may require support to express or pump their milk and feed the expressed breast milk to their baby via spoon, cup, or bottle.

Late-onset jaundice or *breast milk jaundice* affects a small number of breastfed newborns and develops between 5 and 10 days of age. Affected newborns are typically thriving, gaining weight, and stooling normally; all pathological causes of jaundice have been ruled out. In the presence of other risk factors, hyperbilirubinemia can be severe enough to require phototherapy. In most cases of breast milk jaundice no intervention is necessary.

Preterm infants. Human milk is the ideal food for preterm infants, with benefits that are unique to the individual preterm infant in addition to those received by healthy term newborn. Human milk enhances

retinal maturation in the preterm infant and improves neurocognitive outcomes; it also decreases the risk of necrotizing enterocolitis. Colostrum and human milk provide protective mechanisms for premature infants by containing components that enhance newborn gut maturation and ensure that microbial colonization of the gut is not altered (Walker, 2017). Greater physiological stability occurs with breastfeeding than with formula-feeding (Lawrence & Lawrence, 2016). Initially, human milk for preterm infants contains higher concentrations of energy, protein, sodium, chloride, potassium, iron, and magnesium than term milk. It is more similar to term milk by approximately 4 to 6 weeks. If the mother's own milk is unavailable, pasteurized donor human milk (PDHM) is recommended for preterm and vulnerable infants (Kim et al., 2010/2018).

If possible, preterm infants should room-in with their parents, experience unrestricted skin-to-skin contact and care provided by the parent, and become fully breastfed. Breastfeeding initiation and progression should be based on the newborn's stability rather than by the gestational age or weight (PHAC, 2019). To support full milk production by breastfeeding patients and eventual breastfeeding by preterm infants, nurses can facilitate skin-to-skin contact, early hand expression, and breast pumping (Morton et al., 2013; Nyqvist et al., 2015) (see Family-Centred Care Box: Enhancing Milk Production for Preterm Infants).

FAMILY-CENTRED CARE

Enhancing Milk Production for Preterm Infants

To maximize milk production, support and encourage mothers to:

- Start expression as soon as possible, ideally within the first hour of birth.
- Provide early and extended skin-to-skin contact.
- Collect and provide early colostrum.
- Hand express initially, then add the use of a breast pump (Figure 27.13).
- Massage the breast while pumping, as combining hand techniques with electric pumping increases milk production in mothers of preterm infants.
- Express or pump milk at least eight times per 24 hours until milk supply is well established.
- Avoid long periods of breast fullness (continue to express or pump at least once during the night).

Adapted from Public Health Agency of Canada. (2019). *Family centred maternity and newborn care: National guidelines – Breastfeeding (Chapter 6).* https://www.canada.ca/en/public-health/services/publications/healthy-living/maternity-newborn-care-guidelines-chapter-6.html.

Fig. 27.13 Nurse explains use of hospital-grade electric breast pump to new mother. (Courtesy Kathryn Alden.)

The role of the nurse who cares for preterm infants includes the following:

- Providing supplies (syringe, cotton-tipped applicator, and container) for colostrum collection immediately after birth. Colostrum is applied on the newborn's lips as oral immune therapy to enhance immunity, as well as for nutrition (Gephart & Weller, 2014).
- Supporting breastfeeding patients to establish an ample volume of milk even before their preterm infant requires full feeding volumes
- Checking in with breastfeeding patients daily to address any issues with milk expression and supply
- Providing information on proper handling and storage of human milk to minimize bacterial growth and/or contamination

Parents of a preterm infant often receive specific emotional benefits by breastfeeding or providing breast milk for their newborn. They find reward in knowing that they can provide the healthiest nutrition for their newborn and experience enhanced feelings of closeness to their newborn through breastfeeding. New breastfeeding parents need ongoing assistance and support as they continue to express milk and fully transition to breastfeeding their preterm infant. Preterm infants are more prone to positional apnea than term newborns. Parents need to be encouraged to find positions that work for them, most often using the modified cradle or football hold and avoiding flexing the newborn's head, which can impede breathing.

Late preterm infants. Newborns born at 34 weeks to 36 weeks of gestation are categorized as *late preterm infants*. Because they exhibit behaviours of both preterm and term newborns they require special attention. These newborns are at risk for feeding difficulties because of their low energy stores and high energy demands (Boies et al., 2016). They tend to be sleepy, with minimal and short wakeful periods. Late preterm infants often tire easily while feeding and have a weak suck and low tone; these factors can contribute to inadequate milk intake. These vulnerable newborns require careful monitoring and active feeding plans including skin-to-skin contact, early hand expression (within the first hour), and feeding of colostrum (with a spoon, dropper, or other device) as they work toward establishing breastfeeding (Boies et al., 2016; Morton et al., 2013; PHAC, 2019). Hand expression and pumping can provide mother's own milk as the ideal supplement when needed. Early and extended skin-to-skin contact promotes breastfeeding and ample milk production and helps prevent hypothermia.

Breastfeeding multiple infants. Breastfeeding is especially beneficial to twins, triplets, and other higher-order multiples because of the immunological and nutritional advantages and the opportunity for the mother to interact with each baby frequently. Additionally, as many multiples have some degree of prematurity, breastfeeding and human milk are particularly important. Most mothers are capable of producing an adequate milk supply for multiple infants.

Parenting multiples can be overwhelming; parents need extra support and help to learn how to manage the needs of two (or more) babies (Figure 27.14). Caring for twins takes planning and organization, especially in the newborn period, when nurses can play a crucial role. Nurses can support breastfeeding parents to establish milk production and assist families as they help their newborns overcome the early feeding challenges. As breastfeeding becomes established, many families find breastfeeding easier, with no bottles or formula to prepare.

To realistically manage time and meet the needs of the newborns to feed and the breastfeeding patient to sleep, many families slightly modify the principles of cue-based feeding. If one baby wakes to feed, they will wake the other baby as well. A typical pattern is that each newborn feeds from one breast per feeding, usually for about 20 to 30 minutes. Some breastfeeding parents assign each infant a breast; others switch infants from one breast to the other, either on a schedule or randomly.

Fig. 27.14 Breastfeeding twins. (iStock.com/LPETTET)

In the first few days after birth nurses can help families:

- Identify babies' cues for feeding.
- Learn to manage time: As the first baby wakes to breastfeed, the nurse gets the second baby ready to breastfeed (changes diapers, etc.) and then changes and settles the first baby while the patient breastfeeds the second baby.
- Assess how well each baby is feeding.
- Plan for support at home.

The same principles for establishing breastfeeding apply to all infants regardless of how many are to be fed. Because many multiples may also be late preterm, feeding assessments are crucial. If one of the newborns is not feeding effectively, breastfeeding patients may also need to express or pump milk in addition to breastfeeding directly. Nurses can help families manage realistic feeding plans to ensure that the babies learn to breastfeed well and that milk production is optimized in the breastfeeding patient.

During the early weeks, parents may find it helpful to keep a record of feeding times and which breast is used for each feeding. To establish milk production, both breasts need to be effectively stimulated or effectively emptied. It may be helpful to alternate breasts; one newborn feeds on the right breast, and one on the left. At the next feeding the newborns are switched to the alternate breast. If one twin feeds more vigorously than the other, that newborn should be alternated between breasts to equalize breast stimulation.

When both infants are able to latch and feed well, often breastfeeding parents can feed the infants simultaneously or "tandem feed." Family members can be shown how they can assist the breastfeeding parent when the parent is ready to try tandem feeding; the parent may wish to experiment with positions. For example, one infant can be held in the football (underarm) hold and the other in the cradle hold, or the infants can each be held in the football position. Each infant can be supported on firm pillows while in the football hold.

The nutritional needs of patients who are breastfeeding multiples vary and are influenced by the number of infants receiving breast milk and the quantity received by each. To breastfeed multiples exclusively, the parent may require 300 kcal less than what is recommended to support their multiple pregnancy. The parent may have insufficient time and energy to adequately meet their nutritional needs while breastfeeding. Suggestions of nutritious snacks and meals that can be stockpiled in the freezer ahead of time may be appreciated.

Expressing and Storing Breast Milk. Breast milk expression is a common practice, typically performed to obtain breast milk for someone other than the mother to feed to the baby. It is often associated with maternal employment. In some situations expression of breast milk is necessary or desirable, such as when engorgement occurs; when the mother's nipples are sore or damaged; when the mother and newborn are separated, as in the case of a preterm infant who remains in the hospital after the mother is discharged; or when the mother leaves the infant with a caregiver and will not be present for feeding. Some patients express milk to have an emergency supply, and some patients choose to pump exclusively, providing breast milk for their infants but never allowing the baby to suckle at the breast. Because pumping and hand expression are rarely as effective as an infant in removing milk from the breast, the milk supply should never be judged on the basis of volume expressed.

Hand expression. All breastfeeding parents should be instructed in how to hand express their colostrum or milk. Hand expression can help with the following (PHAC, 2019):

- Entice a sleepy baby to feed
- Collect colostrum for newborns who require extra milk (late preterm infants or newborns unable to feed effectively)
- Stimulate the breasts
- Express colostrum onto tender or sore nipples
- Relieve fullness of breasts or engorgement
- Collect milk for later use

The process for hand expression is described in the Patient Teaching box: How to Perform Hand Expression. Breastfeeding parents need to be taught that hand expression takes practice and they may not express much milk the first few times they try to do this.

PATIENT TEACHING

How to Perform Hand Expression

- Apply warm, moist towels to the breasts and gently massage to aid in stimulating the milk ejection reflex.
- Wash your hands and get comfortable.
- Place one hand on your breast at the edge of the areola (Figure 27.15, *A*). With your thumb above and fingers below, push thumb and fingers back toward the chest and squeeze fingers and thumb together (see Figure 27.15, *B*).
- Press and release; repeat the movement rhythmically until the milk begins to flow (see Figure 27.15, *C*).
- Catch the milk in a clean cup, bowl, or jar.
- Move your fingers around the areola in a circle to express from different parts of the breast.
- Switch between breasts every few minutes.

Adapted from Public Health Agency of Canada. (2019). *Family-centred maternity and newborn care: National guidelines. Chapter 6: Breastfeeding.* https://www.canada.ca/en/public-health/services/publications/healthy-living/maternity-newborn-care-guidelines-chapter-6.html.

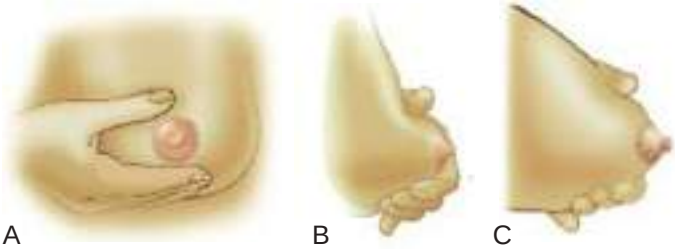

Fig. 27.15 Hand expression. **A:** One hand is placed on breast with thumb above and fingers below. Press back toward chest. **B:** Gently compress the breast while rolling thumb and fingers forward. Maintain steady, light pressure while milk is flowing. **C:** Relax. Rotate hand to all sections of breast. (Reprinted with permission by the Best Start Resource Centre.)

Mechanical milk expression (pumping). For most breastfeeding parents it is recommended that pumping be initiated only after the milk supply is well established and the infant is latching and breastfeeding well. However, when breastfeeding is delayed after birth, such as when babies are ill or preterm, patients should begin pumping with an electric breast pump as soon as possible and continue to pump regularly until the newborn is able to breastfeed effectively.

There are numerous ways to approach pumping. Some parents pump when they first wake up in the morning and after feedings. Others choose to pump one breast while the baby is feeding from the other; this is usually done if the baby typically feeds from only one breast at each feeding. Double pumping (pumping both breasts at the same time) saves time and can stimulate the milk supply more effectively than single pumping (Figure 27.16). The amount of milk obtained when pumping depends on the type of pump being used, the time of day, the time since the baby breastfed, the parent's milk supply, how practiced they are at pumping, and their comfort level (pumping may be uncomfortable for some people). Breast milk may vary in colour and consistency, depending on the time of day, the infant's age, and foods the parent has eaten.

Types of pumps. Many types of breast pumps are available, varying in price and effectiveness. Before purchasing or renting a breast pump, the patient will benefit from counselling by a nurse or lactation consultant to determine which pump best suits their needs. The flange (funnel-shaped device that fits over the nipple or areola) should fit the nipple to prevent nipple pain, trauma, and possible reduction in milk supply. Breastfeeding parents are advised to use the lowest suction setting on the electric pump, increasing gradually if needed and decreasing suction if painful. Breast massage before and during pumping can increase the amount of milk obtained.

Manual or hand pumps are the least expensive pumps and can be most appropriate when milk supply is well established, minimal pumping is needed, and portability and quietness of operation are important.

Hospital-grade electric breast pumps have similar sucking action and pressure to that of the breastfeeding infant (see Figure 27.13). Because hospital-grade breast pumps are very heavy and expensive, portable versions of these pumps are available to rent for home use. Electric self-cycling double pumps are efficient and easy to use. Some of these pumps come with carry bags containing coolers to store pumped milk.

Smaller electric or battery-operated pumps are typically used when pumping is performed occasionally, but some models are satisfactory for the parent who pumps on a regular basis.

Storage of breast milk. Parents who express and feed breast milk to their infant need to be educated about safe practices for handling, storing, and feeding milk. Attention to hand hygiene and proper cleaning of equipment can reduce the risk of bacterial contamination. This is especially important when parents are providing milk for a preterm or ill infant. In a hospital setting, breast milk containers are stored in a designated breast milk refrigerator accessible to staff only, labelled with at least two patient identifiers, date and time of expression. The containers are placed in the refrigerator in a bin identified with the patient's name. Release of breast milk containers from the refrigerator to the patient are double checked by the nurse against the patient's identification band (two identifiers), verifying correct breast milk prior to receipt. In the neonatal intensive care unit (NICU), newborns may have their own designated breast milk refrigerators at their bedside to store specific, individually labelled containers.

The preferred containers for long-term storage of breast milk have hard sides, such as hard plastic (bisphenol A-free) or glass, with an airtight seal or flexible polyethylene bags specifically designed for breast milk storage. Guidelines for storing expressed breast milk for a healthy term newborn are listed in the Family-Centred Care box: Breast Milk Storage Guidelines for Home Use for Full-Term Infants.

FAMILY-CENTRED CARE

Breast Milk Storage Guidelines for Home Use for Full-Term Newborns

- Before expressing or pumping breast milk, wash your hands.
- Wash containers for storing milk in hot, soapy water and rinse thoroughly; they can also be washed in a dishwasher. If the water supply may not be clean, boil containers after washing.
- Write the date of expression on the container before storing milk. A waterproof label is best.
- Store milk in serving sizes of 60 to 120 mL to prevent waste.
- Storing breast milk in the refrigerator or freezer with other food items is acceptable.
- When storing milk in a refrigerator or freezer, place containers in the middle or back of the freezer, not on the door.
- When filling a storage container that will be frozen, fill only three-quarters full, allowing space at the top of the container for expansion.
- To thaw frozen breast milk, place container in the refrigerator for gradual thawing or under warm, running water for quicker thawing. Never boil or microwave.
- Milk thawed in the refrigerator can be stored for 24 hours.
- Thawed breast milk should never be refrozen.
- Shake milk container before feeding the baby and test the temperature of the milk on the inner aspect of your wrist.
- Any unused milk left in the bottle after feeding is discarded.

Human Milk Storage Guidelines

Location of Storage	Temperature	Recommended Safe Duration for Storage
Room temperature	25°C or lower (77°F)	4 hours optimal 6–8 hours acceptable*
Refrigerator	4°C (39°F) or lower	4 days optimal 5–8 days acceptable*
Freezer compartment of refrigerator (with separate doors)	Less than −4°C (24°F)	3–6 months
Freezer (separate chest-type freezer)	Less than −4°C (24°F)	6 months optimal 12 months acceptable

*Under very clean conditions.

ABM clinical protocol no. 8: Human milk storage information for home use for full-term infants, *Breastfeeding Medicine, 12*(7), 390–395.

SAFETY ALERT

Breast milk is never thawed or heated in a microwave oven. Microwaving does not heat evenly and can cause encapsulated boiling bubbles to form in the centre of the liquid, which may not be detected when drops of milk are checked for temperature. Babies have sustained severe burns to the mouth, throat, and upper GI tract as a result of microwaved milk. In addition, microwaving significantly decreases the anti-infective properties and vitamin C content. The safety of low-temperature microwaving is questionable (Lawrence & Lawrence, 2016).

Being Away From the Infant. Many parents successfully combine breastfeeding with employment, school, or other commitments. If feedings are missed, the milk supply may be affected. Some parent's bodies adjust the milk supply to the times they are with the infant for feedings. Other parents must pump while away or their supply diminishes rapidly. Parents should be encouraged to set realistic goals for employment and breastfeeding. Many breastfeeding parents find that a program of breast pumping when away from home and bottle-feeding the infant the expressed milk with or without formula supplementation is successful. Although feeding the infant at home may occur on a demand basis, pumping milk away from home may be needed every 3 to 4 hours to maintain an adequate supply. Lactation rooms that provide space and privacy for pumping are available at many worksites and on college and university campuses.

Careful planning, flexibility, and employer support are key to successful breastfeeding by employed parents. In addition, Canadian maternity benefits permit a new parent who has been employed to have up to 50 weeks of paid leave. Some provinces extend these benefits to self-employed parents.

Weaning. Weaning is initiated when infants are introduced to foods other than breast milk and concludes with the last breastfeeding. Gradual weaning over weeks or months is easier for parents who breastfeed and their infants than abrupt weaning. Abrupt weaning is likely to be distressing for the breastfeeding parent and the baby and physically uncomfortable for the parent.

Weaning is initiated by either the infant or the parent. With infant-led weaning, the infant moves at their own pace in omitting feedings, which usually facilitates a gradual decrease in the parent's milk supply. Parent-led weaning means that the parent decides which feedings to drop. This approach is most easily undertaken by omitting the feeding of least interest to the infant or the one through which the infant is most likely to sleep. Every few days thereafter the parent drops another feeding until the infant is gradually weaned from the breast (Lauwers & Swisher, 2015).

Infants can be weaned directly from the breast to a cup. If the infant is weaned before 1 year of age, iron-fortified formula should be offered instead of whole cow's milk.

If abrupt weaning is necessary, breast **engorgement** often occurs. To relieve the discomfort the breastfeeding parent can take mild analgesics such as ibuprofen, wear a supportive bra, apply ice packs or cabbage leaves to the breasts, and pump small amounts if needed. When possible, it is best to avoid pumping because the breasts should remain full enough to promote a decrease in the milk supply (Lauwers & Swisher, 2015).

Weaning is often a very emotional time for the parent who is breastfeeding; many believe that it is the end to a special, satisfying relationship with the infant and benefit from time to adapt to the changes. Sudden weaning can evoke feelings of guilt and disappointment. Some parents go through a grieving period after weaning. Nurses and others can help the parent by discussing other ways to continue this nurturing relationship with the infant, such as skin-to-skin contact while bottle-feeding or holding and cuddling the baby. Support from their partner and other family members is essential at this time.

Milk Banking. For those infants who cannot be breastfed but are vulnerable because of prematurity, illness, or formula intolerance, pasteurized donor human milk (PDHM) is critically important. Because of the anti-infective and growth-promoting properties of human milk, as well as its superior nutrition, PDHM is used in many NICUs for preterm or sick newborns when the parent's own milk is limited or unavailable. PDHM is also used therapeutically in other situations, such as for infants with short gut syndrome, infants with IgA deficiency who are not breastfed, and older children or adults with IgA deficiency (Brady et al., 2020).

PDHM is recommended for preterm infants if the mother's own milk is not available despite substantial lactation support (Kim et al., 2010/2018). The value of PDHM is further emphasized by the Academy of Breastfeeding Medicine (ABM) in their recommendation of pasteurized donor milk for the healthy term and preterm infant when the mother's milk is not available (Eglash et al., 2017).

The Human Milk Banking Association of North America (HMBANA) (see Additional Resources at the end of the chapter) has established annually reviewed guidelines for the operation of donor human milk banks. The milk banks collect, screen, process, and distribute milk donated by lactating mothers. All donors are screened both by interview and serologically for communicable diseases. Donor milk is stored frozen until it is heat processed to kill potential pathogens; it is then refrozen for storage until it is dispensed for use. The heat processing adds a level of protection for the recipient that is not possible with any other donor tissue or organ. Banked milk is dispensed only by prescription. A fee is charged by the bank for processing, but the HMBANA guidelines prohibit payment to donors. At the present time, there are four human milk banks in Canada, which are located in Vancouver, Calgary, Montreal, and Toronto (Héma-Québec, 2014; HMBANA, 2021). The CPS is advocating for more milk banks across the country, as the health benefits, especially for the very preterm infant, are considerable.

Informal milk sharing occurs among some breastfeeding parents for a variety of reasons, including the mother being HIV positive, maternal death, adoption, the patient having glandular hypoplasia, and the patient with breastfeeding challenges who does not want their child to be exposed to infant formula (Spatz, 2016). Medical screening of the donor and safe milk handling practices can maximize the safety of informal breast milk sharing. Health care providers can help families make informed choices about risks and benefits of informal breast milk sharing by evaluating the donor's possible health and safety risks from infectious diseases and medication exposure. The quality and safety of milk collection, storage, and handling are also very important to evaluate. Internet-based and anonymous donors are not recommended (Sriraman et al., 2018).

Care of the Mother

Nutrition. In general, all new parents should eat a healthy, well-balanced diet. However, even breastfeeding parents with a less than ideal diet can produce sufficient milk of sufficient quality. No specific foods that the breastfeeding parent must consume or avoid have been identified. In most cases the person can consume a normal diet, according to their personal preferences and cultural practices.

Nutrition needs during lactation are similar in many ways to those during pregnancy (see Table 12.1). Needs for energy (kilocalories), protein, calcium, iodine, zinc, the B vitamins (thiamine, riboflavin, niacin,

pyridoxine, and vitamin B_{12}), and vitamin C remain greater than nonpregnant needs. The recommendations for nutrient intake for some of these needs (e.g., vitamin C, zinc, and protein) are slightly to moderately higher than during pregnancy. This allowance covers the amount of the nutrients released in the milk, as well as the needs of the mother for tissue maintenance. With the decrease in maternal blood volume to nonpregnant levels after birth, maternal iron and folic acid needs also decrease. Many lactating patients have a delay in the return of menses; this conserves blood cells and also reduces iron and folic acid needs. It is especially important that the calcium intake be adequate; if it is not, a supplement of 600 mg of calcium per day may be needed. A DHA supplement and a multivitamin (vitamins D, B_{12}, B_2) may be needed for patients who are undernourished and those on vegan diets.

The recommended energy intake for the first 6 months is an increase of 330 kcal more than the patient's nonpregnant intake. Consuming an extra one or two snacks during the day is sufficient to meet the extra calories needed. It is difficult to obtain adequate nutrients for maintenance of lactation if total caloric intake is less than 1 800 kcal, therefore calorie restriction should be avoided. Because of the deposition of energy stores, the patient who has gained the optimal amount of weight during pregnancy is heavier after birth than at the beginning of pregnancy. As a result of the caloric demands of lactation, the lactating mother usually experiences a gradual but steady weight loss. Most patients rapidly lose several kilograms during the first month after birth, whether or not they breastfeed.

Medications or diets that promote weight loss are not recommended for breastfeeding parents. Rapid loss of large amounts of weight can be detrimental, given that fat-soluble contaminants to which the parent has been exposed are stored in body fat reserves and these can be released into the breast milk. Another potential consequence of excessive weight loss is reduced milk production. For most breastfeeding parents a weight loss of 1 to 2 kg (2.2 to 4.4 lb) per month is safe; however, if weight loss exceeds this amount, careful evaluation of infant weight and feeding pattern is recommended as well as an evaluation of the breastfeeding parent's diet (Lawrence & Lawrence, 2016).

Fluid intake must be adequate to maintain milk production. It is important to drink fluids regularly to prevent thirst. There is no need to consume more fluids than those needed to satisfy thirst.

Exercise. There is no reason for breastfeeding parents to restrict their physical activity. Activities such as hiking, jogging, swimming, and aerobics can all be continued with no detrimental effect on milk supply or composition. It is often more comfortable for the breastfeeding person to engage in exercise soon after feeding, when their breasts are as empty as possible. Wearing a well-designed, supportive bra may also help.

Rest. All breastfeeding parents should rest as much as possible, especially in the first 1 to 2 weeks after birth. Fatigue, stress, and worry can limit the parents' energy to attend to the needs of a newborn. Breastfeeding parents should be encouraged to sleep when their baby sleeps. Breastfeeding in a side-lying or reclining position promotes rest for the new parent. Household chores and care for other children can be done by the partner, grandparents or other relatives, and friends.

Breast care. A normal bathing routine is all that is required to keep the breasts clean. Additional cleaning of the breasts is not necessary. Soap can have a drying effect on nipples. Breast creams are not routinely recommended because they may block the natural oil secreted by Montgomery's glands on the areola. Flat or inverted nipples may be improved with the use of breast shells in a bra, although there is a lack of evidence to support the effectiveness of doing so. It is thought that these hard plastic devices exert mild pressure around the base of the nipple to encourage nipple eversion. Breast shells are also useful for sore nipples (in addition to treating the cause of the soreness), to keep clothing from touching the nipples (Figure 27.17).

Fig. 27.17 Breast shells.

Breastfeeding parents with heavier breasts may feel more comfortable wearing a bra. This may decrease stretching of the ligament that supports the breast (Cooper's ligament). If they are comfortable without a bra then there is no reason to wear one. Those people who choose to wear a bra benefit from choosing a comfortable, well-fitting, nonbinding one. Wearing of underwire bras or improperly fitting bras may result in clogged milk ducts.

To manage milk leakage between feedings the use of breast pads (disposable or washable) inside the bra may be helpful. Plastic-lined breast pads are not recommended because they trap moisture and can contribute to sore nipples. To stop leakage, the breastfeeding parent can be alert to any sensation, such as tingling, that their milk is letting down and stop leaking by pressing straight back on their nipples or folding their arms across their chest to apply pressure.

Effect of menstruation. The return of menstrual periods varies among lactating persons. Many will resume menstruation by 6 months postpartum, although for some this may not occur until lactation has ceased. Menstruation has no effect on breastfeeding. There are no hormonal effects on the infant, although some babies may seem fussy for the first day. The quality of milk is not affected (Lawrence & Lawrence, 2016).

Sexual sensations. Some people who are lactating experience rhythmic uterine contractions during breastfeeding. Such sensations are not unusual because uterine contractions and milk ejection are both triggered by oxytocin, but they may be disturbing to some breastfeeding parents who perceive them to be similar to orgasm.

Breastfeeding and contraception. Breastfeeding may confer a period of infertility for up to 6 months. Breastfeeding delays the return of ovulation and menstruation; however, ovulation may occur before the first menstrual period after birth. The lactational amenorrhea method (LAM) of birth control can be highly effective in the following conditions:

- The infant is less than 6 months old.
- The baby is being exclusively breastfed (day and night) at intervals of less than 4 hours during the day and no more than 6 hours during the night, with long duration of each feeding and no supplementation.
- The parent's menstrual period has not returned (see Chapter 8 for further discussion).

The contraceptive methods least likely to affect breastfeeding and milk production are the LAM, natural family planning, barrier methods (diaphragm/cap, spermicides, condoms), and intrauterine devices. Hormonal contraceptives containing estrogen, including combined estrogen-progesterone pills or injectables, are not recommended for breastfeeding parents because of the potential for reducing milk supply. Progestin-only contraceptives (pill, injection, or implant) are better options, although their use is not recommended during the early postpartum period (Berens et al., 2015) (see Chapter 8).

Breastfeeding during pregnancy. People who conceive while breastfeeding may choose to continue to breastfeed throughout the subsequent pregnancy if there are no medical contraindications (e.g., risk of preterm labour). For pregnant persons who are breastfeeding, adequate nutrition is especially important to promote normal fetal growth.

Nipple tenderness associated with early pregnancy can cause discomfort when nursing the older child. The taste and composition of breast milk are altered during pregnancy, which can prompt some children to self-wean (Lawrence & Lawrence, 2016).

When the second baby is born, colostrum is produced. The practice of breastfeeding a newborn and an older child is called *tandem nursing*. Encourage parents to feed the newborn first, to ensure that the newborn is receiving adequate nutrition. The supply-meets-demand principle works just as with breastfeeding multiple babies.

Diabetes. The patient living with type 2 diabetes is encouraged to breastfeed. In addition to benefits for the infant and parental satisfaction, breastfeeding has an antidiabetogenic effect. Blood glucose levels and insulin requirements are lower because of the carbohydrate used in milk production. During lactation, the diabetic patient may be able to eat more food and still take less insulin. However, insulin dosage must be adjusted as the infant is weaned. Some diabetic patients are at increased risk for sore nipples caused by monilial infections and may have an increased risk for mastitis (Lawrence & Lawrence, 2016).

As newborns of diabetic mothers are at higher risk of hypoglycemia after birth, many pregnant patients may opt to collect colostrum at the end of their pregnancy to provide to their newborns after birth should the blood sugar be low. It is safe practice to advise diabetic pregnant patients with low-risk pregnancies to express colostrum after 36 weeks of gestation (Forster et al., 2017).

Breastfeeding after breast surgery. Previous breast surgery can affect milk production and milk transfer to the infant. Before undergoing breast surgery patients should discuss with their surgeon the potential impact of the surgery on their ability to breastfeed. Specific types of breast surgery and techniques used will determine the effect on glandular tissue, nerve pathways, and ductal tissue. Most women who have had augmentation mammoplasty (breast implants) are able to breastfeed successfully. However, if the implant was inserted through the areola or if the procedure was done because of hypoplastic or asymmetrical breasts, there can be concerns about adequate milk production. Reduction mammoplasty (breast reduction) is more likely to limit milk production because of interference with milk ducts, removal of glandular tissue, and nerve damage. It is not possible to accurately predict prenatally how much milk patients with a history of breast reduction surgery will produce. Providing support to patients to facilitate maximum milk production and effective feeding by the infant is imperative. This includes trans-men who may have undergone breast reduction but still plan to chestfeed their infants. Parents must also be taught to carefully monitor their infants for signs of adequate feeding. Many parents unable to exclusively breastfeed will continue to partially breastfeed; some will use a nursing supplementer to provide supplemental feeding while they continue to offer the breast (see Figure 27.10).

It is possible for some patients with a history of breast cancer to breastfeed. However, treatment for breast cancer (surgery, radiation, chemotherapy) can result in reduced milk supply or absence of lactation in the affected breast.

Breastfeeding and the parent with obesity. Patients who are overweight or obese are more likely to experience delayed onset of lactogenesis stage II and reduced milk production than are persons of average weight. Breastfeeding duration tends to be shorter among this population of patients (Kair et al., 2019). Early skin-to-skin contact is less prevalent among mothers with obesity compared with overweight and normal-weight mothers, yet this practice had the highest association with exclusive breastfeeding at 1 week among obese mothers. Therefore, this practice needs to be encouraged immediately after birth in women with obesity (Kair et al., 2019).

For patients who have had bariatric surgery and plan to breastfeed, it is important to know when the surgery was performed. Nutrient and weight losses tend to stabilize approximately 12 to 18 months following the procedure. If the person is consuming at least 1 800 kcal/day and their weight has stabilized, their milk supply may be adequate. Patients who have undergone a malabsorptive procedure such as a Roux-en-Y gastric bypass should take daily dietary supplements, including a prenatal vitamin, vitamin B_{12}, and iron with vitamin C (to maximize absorption).

Medications. Few medications are contraindicated during lactation. Safety considerations of specific medications during breastfeeding include the following:

- Pharmacokinetics of the medication in the breastfeeding parent's system
- Absorption, metabolism, distribution, storage, and excretion in the infant
- Body weight and gestational and chronological age of the infant
- Breastfeeding pattern

In general, any medication routinely given to infants is safe for breastfeeding parents. Parents should be cautioned about taking any medications except those that are deemed essential and should consult with their health care provider before taking any medication. Current, reliable online information about the safety of medications and breastfeeding can be accessed through LactMed, a website provided by National Library of Medicine (see Additional Resources).

Medications that are absolutely contraindicated for breastfeeding parents include antimetabolite and cytotoxic medications. Other medications that are generally contraindicated are amiodarone, chloramphenicol, doxepin, lithium, and radiopharmaceuticals (Hale, 2019).

Certain medications can reduce maternal milk production and should be avoided. These include ergot alkaloids (bromocriptine, cabergoline, ergotamine) and pseudoephedrine (Hale, 2019).

As the use of antidepressant medications rises among the perinatal population, there are increasing concerns about the effects of these medications on breastfeeding infants. A review of psychotropic medications indicates that the safest antidepressant drugs for breastfeeding parents are sertraline, paroxetine, and fluvoxamine because there is minimal transfer into human milk. Antidepressants that are contraindicated while breastfeeding include citalopram and fluoxetine because of the high levels excreted in breast milk, their long half-life, and adverse effects on the infant (Sriraman et al., 2015).

Substance Use.

Alcohol, smoking, and caffeine. Breastfeeding parents should be encouraged to limit alcohol intake because of their infant's rapidly developing central nervous system and underdeveloped ability to metabolize alcohol. It is speculated that the infant's psychomotor development may be affected by maternal alcohol use. Frequent or heavy drinking can also impair the parent's judgement and functioning (Health Canada et al., 2015; PHAC, 2019). Alcohol passes freely from the parent's blood into breast milk, with peak levels occurring in 30 to 60 minutes on an empty stomach and 60 to 90 minutes when consumed with food. The MER and milk production can be adversely affected by parental alcohol intake. Some mothers attempt to time their consumption to minimize exposure to their infant (e.g., consume alcohol immediately after a feeding rather than before). Contrary to popular belief, alcohol does not increase breast milk production, nor does pumping and discarding milk accelerate removal of alcohol from the milk (Lawrence & Lawrence, 2016). Totally prohibiting alcohol

consumption may discourage parents from breastfeeding. Parents should be given information about minimizing and adjusting their consumption of alcohol.

Breastfeeding parents should be advised to stop or reduce smoking (Health Canada et al., 2015). Smoking can impair milk production; it also exposes the infant to the risks of passive smoking. Nicotine is transferred to the infant in breast milk, whether the parent smokes or uses a nicotine patch, although the effect on the infant is uncertain. If a parent continues to smoke, they should be advised that breastfeeding remains important for their infant's health and may mitigate some of the negative effects of exposure to tobacco smoke on the infant. Lactating parents who continue to smoke should be advised not to smoke within 2 hours before breastfeeding, and they, along with other family members who smoke, should go outside to smoke.

Moderate intake of caffeine by lactating parents appears to pose no risk to healthy full-term infants. Minimal amounts of caffeine pass through to the infant in the breast milk. Caffeine intake can lead to a reduced iron concentration in breast milk and consequently contribute to the development of anemia in the infant. The caffeine concentration in breast milk is only approximately 1% of the mother's plasma level, but caffeine seems to accumulate in the infant especially if they are preterm (Lawrence & Lawrence, 2016). Breastfed infants of mothers who drink large amounts of coffee or caffeine-containing soft drinks may be unusually active and wakeful.

Other substances. Drugs such as marijuana, cocaine, heroin, amphetamines, and phencyclidine are contraindicated for breastfeeding parents. However, cannabis use is legal in Canada and is the most common drug used by pregnant persons (Perinatal Services BC, 2020). Parents on stable methadone maintenance programs can breastfeed. Their infants may have decreased severity of neonatal opioid withdrawal symptoms (NOWS) when they are receiving the parent's milk (Lawrence & Lawrence, 2016).

Using a harm reduction approach when counselling patients enables health care providers to build a trusting relationship with patients to support informed decisions about cannabis use. Parents should be taught the following related to cannabis use (Perinatal Services BC, 2020):

- There is no known amount of cannabis that is safe to consume during pregnancy and lactation.
- Tetrahydrocannabinol (THC) may be present in human milk up to 30 days after cannabis is consumed.
- There is a lack of information on the short- and long-term effects on parental health and children's growth and development.

Herbal preparations. Many cultural practices include the use of herbs and teas for pregnant and nursing parents, sometimes as a galactagogue (to increase milk supply). It is important to respect practices that are not harmful to parents or babies. Although most are considered safe, others contain pharmacologically active compounds that may have detrimental effects, particularly on the newborn. There is a lack of safety and effectiveness evidence for the use of herbs as galactagogues (Wambach & Riordan, 2016; PHAC, 2019). Herbal preparations should be used with caution because of the lack of standardization, regulation, and efficacy evidence (Brodribb & the ABM, 2018; Mortell & Mehta, 2013; PHAC, 2019). A thorough history should include the composition of any herbal remedies (Amer et al., 2015). Each remedy should then be evaluated for its compatibility with breastfeeding.

Common Breastfeeding Concerns

Breastfeeding parents may experience some common concerns. In most cases complications are preventable when parents receive appropriate information. Best practices, such as those outlined in the Baby-Friendly Initiative, and early recognition and resolution of issues are important in preventing interruption of breastfeeding and promoting the parent's comfort and sense of well-being. Emotional support provided by nurses is essential to help allay frustration and anxiety and to prevent early cessation of breastfeeding.

Engorgement. Breast fullness at around the third day postpartum is a reassuring sign of normal lactation. When mothers experience more intense fullness or engorgement, breasts become enlarged, reddened, painful, shiny, and edematous. Nipples may become effaced, milk flow decreases, and the newborn can have difficulties latching on. Factors that contribute to engorgement include delayed initiation of breastfeeding, infrequent or time-restricted feedings, feeding supplementation, inefficient infant latch, breast surgery, or any situation where milk stasis occurs (PHAC, 2019). As unrelieved engorgement can decrease milk production and cause involution of the breast tissue, prevention and treatment are essential. The nurse's ability to assess effective breastfeeding and support mothers will help to prevent engorgement and maximize milk production potential. Frequent, effective feeding (or milk removal) and breast massage may minimize severe symptoms (PHAC, 2019) (see Clinical Reasoning Case Study: Breastfeeding: Engorgement). See Table 27.4 for symptoms of and treatment for engorgement.

CLINICAL REASONING CASE STUDY

Breastfeeding: Engorgement

The nurse on the mother–baby unit is caring for Johanna, a 37-year-old primipara who gave birth to a baby girl by emergency Caesarean 3 days ago. During the morning assessment, the nurse observes that Johanna's breasts are engorged and when Johanna tries to latch her baby on to her breast the nipple is flat, and her baby could not stay on the breast. The engorgement seems to have happened overnight while Johanna was sleeping. Johanna is scheduled for discharge today.

1. Evidence—Does the nurse have enough evidence at this time to draw conclusions about the engorgement and feeding issues facing this mother and newborn?
2. Assumptions—What assumptions can be made about the following issues?
   a. The need to relieve the engorgement
   b. Johanna's understanding of milk production
   c. The newborn's ability to feed effectively
3. What implications and priorities for nursing care can be identified at this time?
4. How can the nurse provide culturally safe care to this woman?
5. Should Johanna and her baby be discharged?

When mild engorgement occurs, the nurse should assure the mother that this is usually a temporary condition that resolves within 24 hours. To avoid more severe engorgement, ensure that the newborn is feeding effectively and frequently.

When engorgement occurs as a result of excessive intravenous fluids during labour, for example, during an induction or a Caesarean birth, the nipple and areola can become distended or flattened, making it difficult for the newborn to latch on successfully. A technique called *reverse pressure softening* is used to manually displace the areolar interstitial fluid inward by softening the areola, thus making it easier for the newborn's mouth to grasp the nipple and areola with latching (Kujawa-Myles et al., 2015; Lauwers & Swisher, 2015).

Plugged Milk Ducts. A milk duct can become plugged or clogged, causing an area of the breast to become swollen and tender. This area typically does not empty or soften with feeding or pumping. A small

TABLE 27.4 Comparison of Symptoms and Management of Engorgement, Plugged Ducts, and Mastitis

	Engorgement	Plugged Duct	Mastitis
tOnset	Gradual, usually 3–5 days postpartum or with sudden cessation of breastfeeding or pumping	Gradual—usually over a few hours	Sudden, after 8–10 days postpartum or anytime
Site	Bilateral	Unilateral	Usually unilateral, often involving upper outer quadrant of breast. Can be bilateral
Swelling and heat	Generalized warmth and fullness; painful, shiny, and edematous with diffuse red areas. The nipple may be effaced, milk often does not flow easily, and the infant can have difficulties latching.	May shift in size, with little or no heat. Palpable and mobile mass with sharp edges. Can have overlying erythema	Localized, red, hot, swollen. Can involve part of or all of the breast. Erythema and pain are present. Can be accompanied by induration or an inflammatory mass
Pain	Generalized	Mild, localized	Intense but localized pain and tenderness
Body temperature	<38.4°C	<38.4°C	Associated with a fever >38.4°C
Systemic symptoms	Feels well	Feels well	Flulike symptoms, body aches, and chills
Cause	Infrequent or ineffective feedings, unnecessary supplements, or any conditions causing milk stasis	Specific cause is unknown but may be due to inadequate draining of the breasts (possibly because of hand placement, missed feedings, restricted clothing, or an overabundant milk supply)	Sore damaged nipples or inadequate draining of the breasts
Treatment	Continue breastfeeding. A warm shower or compresses or breast soaks before breastfeeding may facilitate the milk ejection reflex. Massage the breast gently and hand express breast milk or colostrum to soften the areola and facilitate latch before breastfeeding. Use of cold compresses between feedings reduces edema and can provide comfort. Frequent breastfeeding, starting with the engorged breast, may provide relief. Anti-inflammatory medications compatible with breastfeeding may be required.	Continue breastfeeding. Use different feeding positions, such as having the infant's chin or nose toward the blocked area, plus frequent effective feeding and hand expressing if necessary. Massage the area of the plugged duct after feedings. Rule out the presence of a milk blister or pimple on the surface of the nipple. In extreme cases, the blister can be drained.	Continue breastfeeding. If breastfeeding is too painful, hand express or use a breast pump. Start breastfeeding on the affected side. If this side is too painful, start on the unaffected side until milk let-down and then switch. Antibiotic treatment, analgesics, and antipyretics may be required. Adequate fluid intake is important. Recurrence in the same location warrants further evaluation to rule out an underlying mass or other abnormality.

white pearl may be visible on the tip of the nipple; this pearl is the curd of milk blocking the flow. The mother is afebrile and has no generalized symptoms (see Table 27.4). Plugged milk ducts can increase susceptibility to breast infection. For recurrent plugged ducts, taking lecithin, a fat emulsifier, may be useful for the breastfeeding parent (Lawrence & Lawrence, 2016).

Mastitis. Although the term **mastitis** means inflammation of the breast, it is most often used to refer to infection of the breast (Lawrence & Lawrence, 2016; PHAC, 2019) (see Table 27.4). Certain factors may predispose a patient to mastitis. Inadequate emptying of the breasts is common, related to engorgement, plugged ducts, a sudden decrease in the number of feedings, abrupt weaning, or wearing underwire bras. Sore, cracked nipples may lead to mastitis by providing a portal of entry for the causative organism (staphylococci, streptococci, and *E. coli* are most common). Stress and fatigue, parental illness, ill family members, breast trauma, and poor parental nutrition also are predisposing factors for mastitis (Lauwers & Swisher, 2015; Lawrence & Lawrence, 2016). Breastfeeding parents should be taught the signs of mastitis before discharge from hospital and be advised to call their health care provider promptly if the symptoms occur.

Complications of mastitis include breast abscess, chronic mastitis, and fungal infections of the breast. Most complications can be prevented by early recognition and treatment.

Sore Nipples. Many parents expect breastfeeding to be painful, based on stories they have heard from family and friends; however, breastfeeding is not supposed to be painful. While mild nipple discomfort at the beginning of feedings is common, severe soreness and abraded, cracked, or bleeding nipples are not normal and most often result from poor latch, improper suck, or infection.

Severe nipple pain can be related to vasospasm or Raynaud's phenomenon (Lawrence & Lawrence, 2016). The key to preventing sore nipples is correct breastfeeding technique. Limiting the time at the breast does not prevent sore nipples; instead, soreness is often the result of the lactating parent allowing the baby to latch on to the breast before the mouth is open wide.

For the first few days after birth, the breastfeeding parent may experience some mild discomfort with the newborn's initial sucks. This should quickly dissipate as the milk begins to flow and acts as a lubricant. To make the initial sucks less painful, the parent can express a few drops of milk to moisten the nipple and areola before latch. If the lactating parent

continues to experience nipple pain or discomfort after the first few sucks, the nurse or lactation consultant can help them evaluate the latch and baby's position at the breast. If the nipple pain continues, the parent needs to remove the baby from the breast, breaking suction with their finger in the baby's mouth. Repositioning the breastfeeding parent or newborn may be helpful in resolving the nipple discomfort. The parent can then proceed to attempt latch again, making sure that the baby's mouth is open wide before latching them on to the breast (see Figure 27.6).

The newborn's suck can be assessed by a lactation consultant or a nurse who is specially trained, by inserting a clean gloved finger in the newborn's mouth and stimulating the newborn to suck. If the newborn is not extruding the tongue over the lower gum and the mother reports pain or pinching with sucking, the newborn may have a short frenulum (commonly referred to as being "tongue-tied"). In some cases, ankyloglossia is corrected surgically to free the tongue for less painful, more effective breastfeeding (Rowan-Legg & CPS Community Paediatrics Committee, 2015/2018).

The treatment for sore nipples is first to identify the cause and then attempt to address it. Early assessment and intervention are essential to increase the likelihood that the parent will continue to breastfeed. Once the issue is identified and corrected, sore nipples should heal within a few days, even though the baby continues to breastfeed regularly. When sore nipples occur, the parent is advised to start the feeding on the least sore nipple. It is important to assess the nipples for cracking or other damage to the skin integrity, which increases the risk of infection. If there is any break in the skin, the parent is advised to wipe the nipples with water after feeding to remove the baby's saliva. A thin coating of a topical antibiotic may help reduce the risk of infection and promote healing (the antibiotic cream or ointment should be removed before breastfeeding). Sore nipples should be open to air as much as possible.

Rapid healing of sore nipples is critical to relieve the parent's discomfort, maintain breastfeeding, and prevent mastitis. Although numerous creams, ointments, and gel pads have been used to treat sore nipples, there is insufficient evidence that glycerine gel dressings, lanolin, or all-purpose nipple ointment significantly improved maternal perceptions of nipple pain. Applying expressed breast milk may be beneficial in the short-term experience of nipple pain (Dennis et al., 2014).

Antifungal creams are used to treat yeast infections on nipples. Use of antiseptic sprays and premoistened towelettes containing alcohol is not recommended.

! NURSING ALERT

Nurses must assess the patient's allergies prior to applying lanolin ointment. Lanolin is made from sheep's wool so must not be used on people who have a wool allergy.

If nipples are extremely sore or damaged and if the parent cannot tolerate breastfeeding, they may need to use an electric breast pump for 24 to 48 hours to allow the nipples to begin healing before resuming breastfeeding. They should use a pump that effectively empties the breasts.

! NURSING ALERT

The patient who has a sudden onset of sore nipples or experiences sore nipples after days or weeks of comfortable breastfeeding likely has some type of nipple infection, most often bacterial or fungal (candidiasis). Other possible causes are skin conditions such as psoriasis, allergic reactions, or vasospasm. Careful assessment and referral for treatment are needed.

Silicone (flexible) nipple shields may be helpful for a lactating parent with flat or inverted nipples and particularly for preterm babies who have trouble latching and maintaining suction, as well as for babies who develop a preference for a bottle nipple and refuse the breast (Wambach & Riordan, 2016). While nipple shields help protect abraded, sore nipples, the cause of the pain must be determined and remedied promptly. The shield should be applied on the nipple areola area just before putting the baby on the breast: the brim of the shield is flipped up, the shield placed directly over the nipple, and the brim gently patted down. Nipple shields should be used for a short time only, or the baby may become so accustomed to them that they refuse the breast. In addition, lactation consultants should closely monitor the infant's growth and intake of milk.

Monilial infections. Sore nipples occurring after the newborn period are often due to a *Candida* or monilial (yeast) infection. The breastfeeding patient usually reports severe nipple pain and tenderness, burning, or stinging, and they may have sharp, shooting, burning pains in the breasts during and after feedings. The nipples appear somewhat pink and shiny or may be scaly or flaky; there may be a visible rash, small blisters, or thrush. Most often, the pain is out of proportion to the appearance of the nipple. Yeast infections of the nipples and breast can be excruciatingly painful and can lead to early cessation of breastfeeding if not recognized and treated promptly.

Infants may or may not exhibit symptoms of monilial infection. Oral thrush and a red, raised diaper rash are common indications of a yeast infection. An affected infant is often fussy and gassy. When feeding, the infant is likely to pull off the breast soon after starting to feed, crying with apparent pain. The infant may be biting or gumming at the breast.

The most common predisposing factors for yeast infections of the breast are previous antibiotic use, vaginal yeast infections, and nipple damage.

Parents and infants must be treated simultaneously, even if the infant has no visible signs of infection. Treatment for the patient is typically an antifungal cream applied to the nipples after feedings and, in some cases, a systemic antifungal medication such as fluconazole. Most health care providers prescribe an oral antifungal medication, such as nystatin or fluconazole, for infants. Treatment should continue for at least 14 days even after symptoms begin to improve in 1 to 2 days (Lawrence & Lawrence, 2016). Good hand hygiene is essential to prevent the spread of yeast.

Insufficient Milk Supply. A common reason that people stop breastfeeding is perceived or actual insufficient milk supply (Brown et al., 2014; Lauwers & Swisher, 2015). Careful evaluation of the mother–infant dyad is needed, including assessment of infant weight gain or loss, feeding technique, and milk transfer and consideration of possible medical causes for low supply (e.g., medications, glandular insufficiency, previous breast surgery). Stress and fatigue can cause decreased milk production.

Interventions for increasing milk supply are based on causative factors. In many cases the breastfeeding parent is encouraged to spend time with the baby skin-to-skin, increase feeding frequency, express milk using an electric pump, rest as much as possible, consume a healthy diet, and reduce stress. If nonpharmacological measures to increase milk supply are not effective, pharmaceutical galactagogues (medications used to increase milk supply) may be prescribed by the health care provider. Metoclopramide and domperidone are the most commonly prescribed medications; both are dopamine antagonists typically used to treat gastroesophageal reflux. They also increase prolactin levels, which enhances milk production. Metoclopramide has unpleasant adverse effects such as fatigue, irritability, and depression; there is a risk of severe allergic reaction. Domperidone is often prescribed for lactating patients in Canada to increase milk production (Brodribb & the ABM, 2018; Flanders et al., 2012). Health Canada issued a warning about the use of domperidone based on two studies reporting an association of domperidone with abnormal heart rhythms and sudden

cardiac death (Bozzo et al., 2012). When prescribing domperidone, health care providers are advised to use caution when medications that interfere with domperidone metabolism or prolong the QT interval are also used, and with its use in the breastfeeding patient who has an underlying cardiac disease.

Follow-up After Hospital Discharge

Concerns such as infant feeding patterns, jaundice, or breast discomfort may occur after discharge. Thus, it is the nurse's role to educate the breastfeeding parent about potential challenges they may encounter once they are home. It is critical that the patient receive a list of resources for help with breastfeeding concerns and that they know who and when to call for assistance. Community resources for breastfeeding parents include lactation consultants, physicians, nurses in pediatric or obstetrical offices, community health nurses, and peer support groups.

Telephone follow-up by hospital, office, or community health nurses within the first day or two after discharge can provide a means of identifying any concerns and offering needed advice and support. Newborns discharged should meet specific criteria for physiological stability and safety (including successful feedings) and have arrangements to be seen by a health care provider, usually within 48 hours. Late preterm infants require careful assessment of effective feeding and adequate thermoregulation before discharge (Whyte & CPS Fetus and Newborn Committee, 2010/2019). In some settings and circumstances, home care follow-up is available for patients after hospital discharge.

FORMULA-FEEDING

Parent Education

Parents may use formula as their child's sole milk source or as a supplement to human milk. Formula used before the first birthday should be iron-fortified.

Families using formula need clear, evidence-informed guidance on best practices. Since the vast majority of postpartum patients in Canada initiate breastfeeding, nurses may be less familiar with providing guidance for families using formula. However, nurses are in an ideal position to provide individualized education to parents about formula use. If families intend to use formula at home, it is important to discuss best practices before discharge. Because of the lack of clear information about the practical aspects of formula-feeding, parents often rely on advice from friends, family, and marketing materials. Inaccurate advice or unsafe practices for formula preparation and feeding may put the infant at risk for foodborne illness and burns.

Nurses can avoid inadvertently marketing particular brands of formula by ensuring that appropriate education materials from community health departments are used rather than providing patient materials produced by formula companies.

The WHO International Code of the Marketing of Breast-Milk Substitutes (WHO, 1981) provides guidance to health care providers to ensure the provision of safe and adequate nutrition for infants, by protecting and promoting breastfeeding and ensuring the proper use of breast milk substitutes, when necessary, on the basis of appropriate marketing and adequate information.

Readiness for Feeding

The first feeding of formula is ideally given after the initial transition to extrauterine life. Newborns generally show feeding cues within the first hour of birth (see discussion regarding cues earlier under Early Postpartum). Other feeding-readiness cues include stability of vital signs, bowel sounds, an active sucking reflex, and an effective breathing pattern, Crying is a late hunger cue. If the baby is frequently held skin-to-skin, subtle hunger cues will become more obvious to the parents.

Feeding Patterns

In the first 24 to 48 hours of life, a newborn typically consumes 10 to 30 mL of formula at a feeding. Intake gradually increases during the first week of life as the capacity of the stomach increases to 60 to 90 mL by the end of the first week. The newborn should be fed in response to hunger and satiation cues or at least eight times in 24 hours, even if that requires waking the newborn for the feedings; however, rigid feeding schedules are not recommended. The infant showing an adequate weight gain can be allowed to sleep at night and be fed only on awakening. Most newborns need six to eight feedings in 24 hours, and the number of feedings decreases as the infant matures. Usually, by 3 to 4 weeks after birth, a fairly predictable feeding pattern develops, although scheduling feedings arbitrarily at predetermined intervals may not meet a newborn's needs.

Parents will usually notice an increase in the infant's appetite at ages 7 to 10 days, 3 weeks, 6 weeks, 3 months, and 6 months. These appetite spurts correspond to growth spurts. The amount of formula per feeding should be increased by about 30 mL at these times to meet the baby's needs.

Responsive Feeding. The concept of responsive feeding should be understood and applied to bottle-fed infants (see discussion above in Frequency of Feedings). Responsive feeding when bottle-feeding by offering the bottle in response to feeding cues and pacing the feeds avoids the risk of overfeeding. Many of the principles can be applied in order to enhance the parent–infant relationship while bottle-feeding, by encouraging parents to:

- Cuddle the baby skin-to-skin.
- Sit comfortably, holding the infant closely in a semi-upright position.
- Watch for and respond promptly to feeding cues.
- Gently invite the infant to take the nipple without forcing the infant to finish the bottle.
- Watch how the baby responds to the feeding. If the infant shows signs of distress, lower the bottle to slow the flow of milk.
- Give most of the feedings themselves in the early weeks to help their infant feel secure and build a close and loving relationship (UNICEF UK Baby Friendly Initiative, 2016).
- Consider feedings as a time of peaceful relaxation with their child.
- Avoid propping the bottle or letting small children feed the infant unsupervised to avoid the risk of choking.
- Look for signs of satiation to avoid overfeeding, which can contribute to obesity (stopping sucking, falling asleep, moving the mouth away).
- Remove the bottle from the infant's mouth before the infant is asleep. When teeth erupt, leaving the bottle in the child's mouth by propping or when they can hold it themselves may cause nursing-bottle caries, or decay of the first teeth, resulting from continuous bathing of the teeth with carbohydrate-containing fluid as the infant sporadically sucks the nipple.

Feedings provide opportunities for interaction and cognitive growth, as well as to bond with the infant through touching, talking, singing, or reading aloud.

Healthy newborns coordinate sucking, swallowing, and breathing as they feed. The typical fast flow of milk from bottles can create difficulty for an infant trying to learn to feed. A slow-flow nipple is often used for the first few weeks.

Traditionally, infants are positioned in a semi-reclining position with the bottle held upright to fill the nipple, to decrease the air in the bottle and prevent the air from going into the infant's stomach (Figure 27.18, *A*). *Paced bottle-feeding* may be a more physiological approach. With this method of feeding the bottle is held at more of

Fig. 27.18 A: Bottle-feeding: traditional technique with infant semi-reclining (iStock.com/Artfoliophoto). **B:** Paced bottle-feeding: infant is more upright. (Courtesy Cheryl Briggs, BSN, RNC-NIC.)

a horizontal angle (see Figure 27.18, *B*); when the baby pauses between bursts of sucking, the parent lowers the bottle to slow the flow of milk, until the infant is ready to resume sucking (Hughes & Donovan, 2019).

Parents should be encouraged to observe the infant for signs of stress during feeding, including turning the head, arching the back, choking, sputtering, changing colour, moving the arms, and tensing fists (Lauwers & Swisher, 2015). When these signs occur, the parent should stop feeding. For preterm infants, careful assessment is required to ensure that the newborn is physiologically ready to bottle feed. For the term newborn parents can calm the newborn before resuming. The signs can indicate that the term newborn is finished with the feeding and does not want to drink any more.

Most infants swallow air when fed from a bottle and need a chance to burp several times during a feeding. Parents should be taught various positions that can be used for burping (Figure 27.19).

Common Concerns. Parents need to know what to do if the infant spits up. They may need to decrease the amount of feeding or feed smaller amounts more frequently. Burping the infant several times during a feeding, such as when the infant's sucking slows down or stops, can decrease spitting. Holding the baby upright for 30 minutes after feeding and avoiding bouncing or placing them on the abdomen soon after the feeding is finished can also help. Spitting can be a normal occurrence, the result of overfeeding, or symptomatic of gastroesophageal reflux. Parents should report vomiting of one third or more of the feeding at most feeding sessions or projectile vomiting to the health care provider and should be cautioned to refrain from changing the infant's formula without consulting the health care provider.

Bottles and Nipples. Many styles of bottles and nipples are available. Most babies will feed well with any bottle and nipple. The bottles, nipples, rings, and caps should be washed in hot, soapy water using a bottle

Fig. 27.19 Positions for burping an infant. **A:** Sitting. **B:** On shoulder. **C:** Across lap. (Courtesy Julie Perry Nelson.)

and nipple brush to facilitate thorough cleansing. Most household dishwashers use hot water and are safe for cleaning bottles and nipples. Boiling of bottles and nipples is not always needed. It is best to check with the local Public Health Department regarding recommendations. Recommendations for preterm or vulnerable babies may be more stringent.

Infant Formulas. Most commercial infant formulas are cow's milk based to meet the nutritional requirements of infants until 9 to 12 months of age. The exact composition of infant formula varies with the manufacturer, but all must meet specific standards. Infants who are not breastfed should be given commercial iron-fortified formulas. If this is too expensive, the family may be eligible for services through various income-assistance programs.

The caloric content of standard infant formula is 20 kcal/30 mL. These formulas are altered from cow's milk by removing butterfat, decreasing the protein content, and adding vegetable oil and carbohydrate. Some have demineralized whey added to yield a whey/casein ratio of 60:40. Regardless of the commercial brand, the standard cow's milk–based formulas have essentially the same compositions of vitamins, minerals, protein, carbohydrates, and essential amino acids, with minor variations, such as the source of carbohydrate; nucleotides to enhance immune function; and long-chain polyunsaturated fatty acids (DHA and ARA). However, evidence for the benefit of adding DHA and ARA is inconclusive and for nucleotides is lacking (Health Canada et al., 2015). The composition, processing, packaging, and labelling of all infant formula are regulated under the Canadian Food and Drug Regulations to ensure product safety and quality (Health Canada et al., 2015).

Four main categories of commercially prepared infant formulas are available: (1) cow's milk–based formulas; (2) soy-based formulas; (3) -casein- or whey-hydrolysate formulas, used primarily for children who cannot tolerate or digest cow's milk or soy-based formulas; and (4) amino acid formulas, used for infants with multiple food-protein intolerances.

Soy protein–based formulas are only recommended for infants not able to consume dairy products for religious or cultural reasons or infants with galactosemia (Health Canada et al., 2015). Infants with documented IgE allergies caused by cow's milk should be fed an extensively hydrolyzed protein formula, because about 10 to 14% of infants with cow's milk–based formula intolerance will also have a soy protein allergy. Soy protein–based formulas have not been proved to be effective in preventing colic or allergy in healthy or high-risk infants.

Alternative milk sources such as goat's milk; skim or low-fat milk; condensed milk; or raw, unpasteurized milk from any animal source should not be fed to infants because they are inadequate to support growth and can contain excess protein or an inadequate calcium/phosphorus ratio, which can cause seizures.

SAFETY ALERT

Because of concerns about potential harmful effects of bisphenol A (BPA), parents should be cautioned about using hard plastic polycarbonate baby bottles or containers. BPA is a chemical that is used to harden plastics, prevent bacterial contamination of foods, and prevent can rusting. It is in many food and liquid containers, including baby bottles. In order to avoid exposure to BPA, parents are advised to look for BPA-free bottles or to use glass bottles as an alternative, but parents must be aware of the risk for injury if a glass bottle is dropped or broken. Because heat can cause the release of BPA from plastic, polycarbonate bottles should never be boiled or heated in the microwave.

Formula Preparation. Commercial formulas are available in three forms: powder, concentrate, and ready-to-feed. All are equivalent in nutritional content (20 kcal/30 mL or 68 kcal/100 mL), but they vary considerably in price.

- Ready-to-feed formula is the most expensive but easiest one to use. The desired amount is poured into the bottle. The opened can is refrigerated safely for 48 hours. This type of formula can be purchased in individual disposable bottles for the most convenient and expensive feeding.
- Concentrated formula is less expensive than ready-to-feed formula. It is diluted with equal parts of water and can be stored in the refrigerator for 48 hours after opening.
- Powdered formula is the least expensive formula but is not a sterile product and has been linked with *Cronobacter*, a rare but serious infection. It is easily mixed by using one scoop for every 60 mL of water. Powdered formula is not recommended for premature or low-birth-weight infants for at least 2 months after birth. It is recommended that they be fed liquid formula. If parents use powdered formula they must have specific preparation instructions (see below).

Commercial infant formula must include label directions for preparation and use of the formula with pictures and symbols for the benefit of individuals who cannot read. Some manufacturers translate the directions into many languages, such as French, Chinese, Punjabi, and Vietnamese, to prevent misunderstanding and errors in formula preparation. The water used to mix either powdered or concentrated liquid formula need not contain any fluoride, especially in the first 6 months of life. Excess fluoride can permanently stain the teeth once they appear. Parents must be taught that it is extremely important that formula not be diluted with more water than recommended, in an effort to try to save money. A thorough assessment of parents' formula preparation and of any concerns may indicate a family's financial need, and further support and referral may be required.

SAFETY ALERT

An important aspect to impress on families is that when making formula the proportions must not be altered (i.e., neither diluted to extend the amount of formula nor concentrated to provide more calories). The newborn's kidneys are immature; giving the infant overly concentrated formula can provide protein and minerals in amounts that exceed the excretory ability of the kidneys. In contrast, if the formula is diluted too much (sometimes done to save money), the infant does not consume sufficient calories and grow appropriately.

Water that is used to make formula needs to be boiled for 2 minutes and the water cooled to no less than 70°C, and then the powder is added (Government of Canada, 2021). Bottled water that is labelled as "sterile" is safe for mixing formula. However, nonsterile bottled water should be boiled for 2 minutes and cooled.

If the conditions in the home appear unsanitary, it is important to ensure that families understand how to safely prepare formula; it may be better to recommend the use of ready-to-feed formula, if financially feasible. Any formula left in the bottle after the feeding should be discarded because the infant's saliva has mixed with it. (Instructions for formula preparation and feeding are provided in the Family-Centred Care box: Formula Preparation and Feeding.)

Formula does not need to be warmed before feeding it to term or older infants. Scalds and burns have been reported from the practice of heating milk. Additionally, if the child will be in a day care setting, there is less risk of contamination from formula heated in a communal pot (Jones, 2019).

FAMILY-CENTRED CARE

Formula Preparation and Feeding

Formula Preparation

- Using warm, soapy water, wash your hands, arms, and under your nails; rinse well. Clean and sanitize the surface where you will be preparing the bottles.
- Thoroughly wash bottles, nipples, rings, caps, can opener, and other preparation utensils in hot, soapy water and rinse thoroughly. Squeeze water through nipples to make sure that the holes are open.
- Place bottles, nipples, rings, and caps in a pot and cover with water; boil for 2 minutes; remove items from pot with sanitized tongs and allow them to air dry.
- Note the expiration date on the formula container. It should be used before the expiration date. Any unopened expired formula should be returned to the place of purchase.
- Read the label on the container of formula and mix it exactly according to the directions.
- Water deemed safe by the local health department can be used to make formula. Allow cold water to run for 2 minutes before collecting it. Then bring it to a rolling boil and continue boiling for 2 minutes. If using bottled water, make sure that it is labelled as "sterile"; unsterile bottled water must be boiled. After boiling, allow water to cool to no less than 70° C before mixing the formula. Unused, boiled water can be refrigerated for 24 hours.
- Ready-to-feed: Wash the top of the can with hot soapy water and rinse well. Shake the can before opening. No mixing is needed; do not add water. Pour desired amount of formula into clean bottle; add nipple and ring.
- Concentrated formula: Wash the top of the can with hot, soapy water and rinse well. Shake the can before opening. Pour desired amount of formula into a clean bottle and add an equal amount of cooled boiled water. Add nipple and ring and shake well.
- Powdered formula: Write the date of opening on the lid of the can. If using formula immediately, the powder can be added to previously boiled water that has been cooled to room temperature (25°C). If the formula is to be used later, mix the powder with very hot water (boiled and cooled to no less than 70°C). This will kill harmful bacteria. When made this way, powdered formula can be stored in the fridge for 24 hours. Using the scoop from the container, add one scoop of powdered formula for each 60 mL of prepared water in a clean bottle. For example, if 120 mL of water is in the bottle, add two scoops of powder. Add nipple and ring and shake well.
- If preparing multiple bottles at the same time, place nipple right side up on each bottle and cover with a clean nipple cap. Use bottles within 48 hours. Store prepared formula bottles in the refrigerator.
- Opened cans of ready-to-feed or concentrated formula should be covered and refrigerated. Any unused portions must be discarded after 48 hours.
- Bottles or cans of unopened formula can be stored at room temperature for 2 hours. Otherwise, store prepared formula bottles in the refrigerator.
- Formula does not need to be warmed before feeding your infant, if at room temperature. If you wish to warm the bottle run it under a warm tap or place it in a pan of hot water. Never use a microwave to warm any food to be given to a baby. Test the temperature of the formula by letting a few drops fall on the inside of your wrist. If the formula feels comfortably warm to you, the temperature is correct.

Feeding Techniques and Tips

- Watching for your baby's feeding cues will lead you to feed your baby about eight times in 24 hours—a little less when they are older. A newborn should not go longer than about 4 hours without feeding until a satisfactory pattern of weight gain is established. This period can be as long as 2 weeks. If your baby cries or fusses between feedings, check to see if the diaper should be changed or if the baby needs to be picked up and cuddled. If your baby continues to cry and acts hungry, feed them. Babies do not get hungry on a regular schedule.
- Crying is a late feeding cue. Your baby will begin to wake up, move their hands to their mouth, and begin to stir.
- Think of this time you spend time with your baby as a relaxing time to get to know each other. If the baby smiles, smile back. If the baby is fussy, try to figure out why. Watch for signs that the baby has had enough—turning the head away, stopping sucking, letting the bottle fall out of their mouth, or falling asleep.
- Babies gradually increase the amount of milk they drink with each feeding. The first day or so most newborns consume 15 to 30 mL with each feeding. This amount increases as babies grow.
- If any formula remains in the bottle as the feeding ends, it must be thrown away because saliva from the baby's mouth can cause the formula to spoil.
- Keep a feeding diary, writing down the amount of formula your baby drinks with each feeding for the first week or so. Also record the wet diapers and bowel movements the baby is having. Take this diary with you when you take the baby for the first follow-up visit with the primary health care provider.
- For feeding, hold your baby close to you, preferably skin-to-skin. Talk to them during the feeding. This time is ideal for social interaction and cuddling.
- Gently place the nipple in the infant's mouth, on the tongue. It should touch the roof of the mouth to stimulate sucking. Hold the bottle like a pencil. Keep it tipped so the nipple stays filled with milk and the baby does not suck in air.
- Taking a few sucks and then pausing briefly before continuing to suck again is normal for infants. Some infants take longer to feed than others. Be patient. In the first few days your baby may be quite sleepy. If your infant is falling asleep without eating, you may need to stimulate them by rubbing their back, stroking them, or sitting them up to awaken. While feeding, moving the nipple gently in your infant's mouth may stimulate sucking.
- If your baby is showing signs that the milk is coming too fast or feeds too quickly, try pacing the feeding a little by tipping the bottle to a more horizontal angle. This slows the flow of milk from the bottle.
- Newborns are apt to swallow air when sucking. Give your baby opportunities to burp several times during a feeding. As they get older, you will know better when to stop for burping.
- After the first 2 or 3 days the stools of a formula-fed infant are yellow and soft but formed. The infant may have a stool with each feeding in the first 2 weeks, although this amount can decrease to one or two stools each day. It is not abnormal for formula-fed infants to have a stool every other day.

Safety Tips

- For safety, babies should be held and never left alone while feeding. But more than safety, feeding is the time you get to know each other—it is how your loving relationship begins. Never prop the bottle. The infant might inhale formula or choke on any that was spit up. Babies who fall asleep with a propped bottle of milk or juice can be prone to cavities when the first teeth come in.
- Know how to use the bulb syringe to help an infant who is choking.

Vitamin and Mineral Supplementation. Commercial iron-fortified formula contains all the nutrients needed by the infant for the first 6 months of life. After 6 months, fluoride supplementation of 0.25 mg/day is required if the local water supply is not fluoridated. Vitamin D supplementation is discussed earlier in this chapter.

Weaning From Bottle. Weaning is the process of moving away from a diet of milk only. Parents can begin offering a regular cup and nutritious solid foods to their infant at about 6 months of age. The more gradual the process, the easier it is for the child. Infants have a strong need to suck, and the infant who has had the bottle taken away too early

or abruptly may compensate by sucking on their fingers, thumb, a pacifier, or even their tongue. Therefore, weaning from a bottle should be attempted gradually because the infant has learned to rely on the comfort that sucking provides. Commonly, the feeding before bedtime is the last one to be given up.

COMPLEMENTARY FEEDING: INTRODUCING SOLID FOODS

Complementary feeding is defined as the introduction of solid foods given to the infant in addition to human milk or formula. Health Canada et al. (2015) recommend introducing solid foods at 6 months of age. Introduction of solids is discussed in depth in Chapter 36. In spite of the recommendations from Health Canada, many parents begin complementary feedings earlier than 6 months. The notion that the feeding of solids helps the infant sleep through the night is not true. Parents should not put cereal into the infant's bottle. Introduction of solid foods before the infant is 6 months of age can result in overfeeding and decreased intake of breast milk or formula.

Nurses and other health care providers need to educate parents regarding complementary feedings. This most often occurs during well-baby supervision visits with the pediatric health care provider. Early feeding practices have implications for long-term dietary patterns; therefore, it is essential to teach parents about proper nutrition.

KEY POINTS

- Human milk is species specific and is the recommended form of nutrition for infants. It provides immunological protection against many infections and diseases.
- During the prenatal period, parents should be informed of the importance of breastfeeding for infants, mothers, families, and society.
- Breast milk changes in composition with each stage of lactation, during each feeding, and as the infant grows.
- Newborns should be breastfed as soon as possible after birth and at least eight times per day thereafter.
- Nurses play a key role in helping lactating patients to ensure that newborns latch on to the breast effectively.
- There are objective, measurable indicators that the infant is breastfeeding effectively.
- Breast milk production is based on a supply-meets-demand principle; the more the infant feeds, the greater the milk supply.
- Commercial infant formulas can provide satisfactory nutrition for most infants.
- Infants should be held for all feedings.
- Parents using formula should receive individualized information about the types of commercial infant formulas, safe preparation for feeding, and correct feeding technique.
- Unmodified (whole) cow's milk is not appropriate for feeding the infant during the first year of life.

Infants With Gestational Age–Related Conditions

Jennifer Young

Originating US Chapter by *Debbie Fraser*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Compare and contrast clinical issues associated with preterm, late preterm, and post-term newborns.
2. Discuss respiratory distress syndrome and approaches to treatment.
3. Compare methods of oxygen therapy for the high-risk infant.
4. Describe nursing interventions for nutritional care of the preterm infant.
5. Describe management of the newborn with meconium aspiration.
6. Describe risk factors associated with the birth and transition of an infant of a diabetic mother.
7. Plan developmentally appropriate care for the high-risk infant.
8. Develop a plan to address the unique needs of parents of high-risk newborns.

Modern technology, interprofessional collaboration, and expert nursing care have made important contributions to improving the health and survival of high-risk infants. However, infants who are born considerably before term and survive are particularly susceptible to the development of sequelae related to their preterm birth. This chapter focuses on care of the preterm infant as well as care of other high-risk newborns with gestational age–related complications, such as near-term and post-term newborns. Infants born to mothers with diabetes are included in the discussion because such infants may experience health conditions that place them at risk for altered development and transition.

High-risk infants are most often classified according to birth weight, gestational age, and common pathophysiological conditions (Box 28.1). Intrauterine growth rates are not the same for all newborns, and other factors (e.g., heredity, placental insufficiency, and maternal disease) influence intrauterine growth and birth weight.

PRETERM AND POST-TERM INFANTS

The Preterm Infant

Preterm infants, those born before 37 completed weeks of gestation, are at increased risk for health issues because their organ systems are immature and they lack adequate physiological reserves to function in the extrauterine environment. Morbidity and mortality rates vary among preterm infants. Despite advances in technology and management strategies, the lower the birth weight and the gestational age, the lower the chances of survival among infants born preterm. Preterm birth remains the leading cause of newborn deaths in Canada, accounting for almost 40% (Government of Canada, 2017).

The cause of preterm birth is multifactorial (see Box 20.2). Factors such as poverty (which can contribute to suboptimal health care and prenatal nutrition), maternal infections, previous preterm birth, multiple pregnancies, pregnancy-induced hypertension, and placental conditions that interrupt the normal course of gestation before completion of fetal development are responsible for a large number of preterm births. According to 2015 data, 7.8% of infants born in Canada were preterm, 9.1% were small for gestational age (SGA), and approximately 6.4% were low birth weight (LBW); these rates remain stable (Statistics Canada, 2021). A pan-Canadian interdisciplinary clinical research network, including parents, is working toward preventing and managing the consequences of preterm birth, in addition to improving efforts in knowledge translation of interventions that have demonstrated effectiveness (Shah et al., 2018).

Opinions vary about the practical and ethical dimensions of resuscitation of extremely low-birth-weight (ELBW) infants. Ethical issues associated with resuscitation include whether to resuscitate; who should make that decision; whether the cost of resuscitation is justified; and whether the benefits of technology outweigh the burdens on the infant, family, and society in relation to the infant's quality of life.

Late Preterm Infant

In some neonatal intensive care units (NICUs), **late preterm infants**, born between 34 and 36 6/7 weeks of gestation, may outnumber the patient population of preterm, term, and post-term infants and they

BOX 28.1 Classification of High-Risk Infants

Classification According to Size

Low-birth-weight (LBW)—An infant whose birth weight is less than 2 500 grams (g), regardless of gestational age

Very-low-birth-weight (VLBW)—An infant whose birth weight is less than 1 500 g

Extremely-low-birth-weight (ELBW)—An infant whose birth weight is less than 1 000 g

Appropriate for gestational age (AGA)—An infant whose birth weight falls between the tenth and ninetieth percentiles on intrauterine growth charts

Small for gestational age (SGA) or small-for-dates (SFD)—An infant whose birth weight falls below the tenth percentile on growth charts

Intrauterine growth restriction (IUGR)—Found in infants whose growth in utero does not meet norms for gestational age and sex and is usually less than the third percentile

- Symmetrical IUGR—Growth restriction in which the weight, length, and head circumference are all affected
- Asymmetrical IUGR—Growth restriction in which the head circumference remains within normal parameters, as does length, while birth weight falls below the tenth percentile

Large for gestational age (LGA)—An infant whose birth weight falls above the ninetieth percentile on intrauterine growth charts

Classification According to Gestational Age

Gestational age is the interval, in completed weeks, between the first day of a pregnant patient's last menstrual period and the day of birth.

Preterm (premature) infant—An infant born before 37 completed weeks of gestation, regardless of birth weight

Late preterm infant—An infant born between 34 0/7 and 36 6/7 weeks of gestation, regardless of birth weight

Term infant—An infant born between the beginnings of 37 through 42 completed weeks of gestation, regardless of birth weight

Post-term (postmature) infant—An infant born after 42 completed weeks of gestation, regardless of birth weight

Classification According to Mortality

Live birth—Birth in which the newborn manifests any heartbeat, breathes, or displays voluntary movement, regardless of gestational age. In Canada, an infant born less than 20 weeks of gestation who dies within the first few minutes after birth may be registered as a live birth and then as a newborn death.

Fetal death—Death of the fetus, at any gestational age, before birth, with absence of any signs of life after birth. Only fetal deaths where the product of conception has a birth weight of 500 g or more or the duration of pregnancy is 20 weeks or longer are registered in Canada.

Neonatal death—Death of a newborn less than 28 days of life; early neonatal death occurs in the first week of life; late neonatal death occurs at 7 to 28 days.

Perinatal mortality—Total number of fetal and early neonatal deaths per 1 000 live births

From Government of Canada. (2017). Perinatal health indicators for Canada 2017. *A report of the Canadian Perinatal Surveillance System*. Author; Sauve, R., & McCourt, C. (2009). Infant mortality in Canada. *Journal of Obstetrics and Gynaecology Canada, 31*(4), 351–352; Statistics Canada. (2013). Table 102-4514—Fetal deaths (20 weeks or more of gestation) and late fetal deaths (28 weeks or more of gestation), Canada, provinces and territories, annual (number), CANSIM (database). Ministry of Industry.

often require unique care (Premji & Kau, 2019). Late preterm infants often experience morbidities similar to those of preterm infants, including respiratory distress, hypoglycemia requiring treatment, temperature instability, poor feeding, jaundice, and discharge delays as a result of illness (Forsythe & Allen, 2013). It is estimated that late preterm infants represent 70% of the total preterm infant population and that the mortality rate for this group is significantly higher than that of term newborns (7.1 per 1 000 live births at 34 weeks vs. 0.8 per 1 000 live births at 39 weeks) (Horgan, 2015). Late preterm birth is associated with speech, behavioural, and cognitive challenges at follow-up in children 6 years of age (Talge et al., 2010). Late preterm infants may be discharged early from the hospital and have a higher rate of readmission than that of term newborns due to hyperbilirubinemia, feeding difficulties, and respiratory illnesses (Premji & Kau, 2019). See Table 28.1 for risk factors and nursing interventions for late preterm infants.

Nursing Care

For the high-risk newborn, an accurate assessment of gestational age (see Chapter 26, Gestational Age Assessment) is critical in helping the nurse to identify the potential health issues that the newborn is likely to experience. The response of the preterm infant to extrauterine life is different from that of the term newborn. By understanding the physiological basis of these differences, the nurse, as a member of an interprofessional care team, can assess these infants, determine the appropriate response of the preterm infant, and discern which potential concerns are most likely to occur.

The best environment for fetal growth and development is the uterus of a healthy, well-nourished pregnant person. The goal of care for the preterm infant is to provide an extrauterine environment that approximates a healthy intrauterine environment in order to promote optimal growth and development. Medical and nursing personnel, respiratory therapists, occupational therapists and physiotherapists, dietitians, social workers, case managers, and pharmacists must work as a team and with parents to provide the intensive care needed. The admission of a preterm infant to the NICU is usually an emergent situation, and many members of the interprofessional team may be involved. A rapid initial assessment must be performed to determine the newborn's need for stabilization and life-saving treatment.

When required, resuscitation is started in the birthing unit and the newborn is supported en route to the nursery, where additional resuscitative and stabilization measures are implemented.

Respiratory Support. The preterm infant may have difficulty making the pulmonary transition from intrauterine to extrauterine life. Numerous issues may affect the respiratory system of preterm infants, including the following:

- Decreased number of functional alveoli
- Deficient surfactant levels
- Smaller airway lumen
- Decreased tracheal cartilage
- Obstruction of respiratory passages
- Insufficient calcification of the bony thorax
- Circulating hormones (prostaglandins) that may affect cardiovascular function
- Immature and fragile pulmonary vasculature
- Greater distance between functional alveoli and capillary bed, especially in ELBW infants

In combination, these deficits hinder the newborn's respiratory efforts and can produce respiratory distress or respiratory failure. Early signs of respiratory distress include tachypnea, nasal flaring, and

TABLE 28.1 Late Preterm Infant Assessment and Interventions

Risk Factors	Assessment	Interventions*
Respiratory distress	Assess for cardinal signs of respiratory distress (nasal flaring, grunting, tachypnea, central cyanosis, retractions) and presence of apnea, especially during feedings.	Perform gestational age assessment. Observe for signs of respiratory distress; monitor oxygenation by pulse oximetry; provide supplemental oxygen judiciously.
Thermal instability	Monitor axillary temperature every 30 minutes immediately postpartum until stable; then every 1–4 hours depending on gestational age and ability to maintain thermal stability.	Provide skin-to-skin care in immediate postpartum period for stable newborn. Implement measures to avoid excess heat loss (adjust environmental temperature, avoid drafts). Bathe only after thermal stability has been maintained for 1 hour.
Hypoglycemia	Monitor for signs and symptoms of hypoglycemia. Assess feeding ability (latch, suck and swallow reflexes). Assess thermal stability and signs and symptoms of respiratory distress. Monitor bedside glucose in infants with additional risk factors (IDM, prolonged labour, respiratory distress, poor feeding).	Initiate early feedings of human milk or, when medically indicated, formula. Avoid dextrose water or water feedings. Provide IV dextrose as necessary for hypoglycemia.
Jaundice	Observe for jaundice in first 24 hours. Evaluate maternal–fetal history for additional risk factors that may cause increased hemolysis and circulating levels of unconjugated bilirubin (Rh, ABO, spherocytosis, bruising). Assess feeding method and intake and voiding and stooling patterns.	Monitor bilirubin (transcutaneous and/or serum) and note risk zone on hour-specific nomogram (see Figure 26.10).
Feeding difficulties	Assess ability to coordinate suck–swallow and breathing. Assess for respiratory distress, hypoglycemia, and thermal stability. Assess latch, milk transfer, and maternal comfort with feeding method. Determine weight loss (should be $\leq$10% of birth weight).	Initiate early feedings (human milk or, when medically indicated, formula). Ensure maternal knowledge of feeding method and of signs of inadequate feeding (sleepiness, lethargy, colour changes during feeding, apnea during feeding, decreased or absent urine output).
Neurodevelopmental issues	Assess for respiratory distress, neonatal jaundice, hypoglycemia, and thermal instability. Assess neurological status. Assess for seizure activity.	Perform newborn screening, including hearing test. Implement individualized developmental care. Encourage parents to keep follow-up appointments with primary health care provider for evaluation of growth and development (including cognitive function and achievement of appropriate milestones).
Infection	Evaluate maternal–fetal history for risk factors that may contribute to neonatal septicemia. Assess for signs and symptoms of neonatal infection (see Box 28.3).	Use routine practices, especially hand hygiene between infants and after contact with surfaces that may harbour bacteria (e.g., keyboards, telephones). Maintain thermal stability. Administer hepatitis B vaccine if required. Encourage breastfeeding and assist mother and baby with breastfeeding. Encourage parents to decrease infant exposure to respiratory viruses after discharge and to obtain vaccines as appropriate to prevent development of respiratory viruses (e.g., influenza).

IDM, Infant of diabetic mother; *IV,* intravenous.
*This is not an exhaustive list of nursing interventions; additional interventions include those discussed under the care of the high-risk infant in this chapter.
Portions adapted from Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN). (2014). *Assessment and care of the late preterm infant: Evidence-based clinical practice guideline.* Author.

expiratory grunting. Depending on the severity of respiratory distress and its cause, retractions may begin as subcostal, intercostal, or suprasternal. Increasing respiratory effort (e.g., paradoxical breathing patterns, retractions, nasal flaring, expiratory grunting, tachypnea, or apnea) indicates increasing distress. As a result of pulmonary immaturity, very-low-birth-weight (VLBW) and ELBW newborns may progress rapidly from respiratory distress to complete respiratory failure. Initially, a compromised newborn's colour may be cyanotic centrally or pale. Acrocyanosis is a normal finding in the newborn; however, central cyanosis indicates poor oxygenation.

Periodic breathing is a respiratory pattern commonly seen in preterm newborns and is manifested by 5- to 10-second respiratory pauses followed by 10 to 15 seconds of compensatory rapid respirations. Periodic breathing should not be confused with *apnea*—a cessation of respirations for 20 seconds or more, associated with hypoxia, bradycardia, or both. The nurse must be prepared to respond to an apneic infant by providing stimulation (e.g., gentle rubbing of back), ventilation, and supplemental oxygen as necessary.

Oxygen therapy. The goals of oxygen therapy are to provide adequate oxygen to the tissues and prevent lactic acid accumulation

resulting from **hypoxia**, yet avoid the potentially negative effects of oxygen therapy and barotrauma. Numerous methods are available to improve oxygenation in the newborn. All require that the oxygen be warmed and humidified before entering the respiratory tract.

The use of room air resuscitation has been associated with fewer complications related to oxidative stress and hyperoxemia (Paul, 2015). Studies of the resuscitation of compromised newborns with 21% oxygen, rather than 100% oxygen, have demonstrated no significant neurological morbidities at 18 to 24 months in newborns resuscitated with 21% oxygen. Current resuscitation guidelines advocate the use of room air, as the initial gas, for infants greater than 35 weeks' gestation and judicious use of oxygen when resuscitating preterm infants. Preterm infants, particularly ELBW infants, lack a sufficiently developed antioxidant defense system (Vento, 2017).

If the newborn does not require intubation and mechanical ventilation, oxygen can be supplied by nasal cannula or via nasal prongs in conjunction with continuous positive airway pressure (CPAP). If oxygen saturation of the blood cannot be maintained at a satisfactory level and the carbon dioxide level ($PaCo_2$) rises, the newborn likely requires ventilatory assistance. Because oxygen therapy has inherent risks, each newborn must be carefully monitored to prevent hyperoxemia and hypoxemia; minimizing fluctuations in oxygen saturation is desirable as alternating hypoxia and hyperoxia is known to be a proinflammatory stimulus.

Frequent assessments of respiratory status and oxygenation are required; the timing of assessments is based on the newborn's status. Oxygenation assessment includes continuous pulse oximetry and blood gases as ordered. Vital signs require monitoring to ensure adequacy of respiratory function, circulation, and perfusion of tissues. Current understanding of evidence encourages that ELBW infants' oxygen saturations be maintained at 90 to 95%, in the absence of pulmonary hypertension; continuous pulse oximetry guides the titration of oxygen being delivered (Vento, 2017).

Nasal cannula. Low-flow oxygen can be administered by nasal cannula, sometimes called *nasal prongs* (Figure 28.1). A *nasal cannula* consists of the tubing that connects to the gas source as well as the prongs that are inserted into the nares and is used for newborns who require low concentrations of supplemental oxygen; it is often used during the weaning process and for home oxygen administration. The newborn receives supplemental oxygen without compromising positioning, vision, or parental holding. Infants can also breastfeed or bottle-feed while receiving oxygen by this method. The nasal prongs must be inspected often to ensure that they remain in place, are patent, and do not cause skin irritation or excoriation.

Fig. 28.1 Infant with nasal cannula. (iStock.com/398147_441)

Heated, humidified high-flow nasal cannula (HHHFNC) therapy provides oxygen at flow rates ranging from 1.5 to 8L/minute, supplying some positive pressure and greater oxygen concentrations when compared to conventional low-flow therapy (Chauvin-Kimoff et al., 2018). Safety mechanisms do not exist on current HHHFNC interfaces to prevent very high pressure transmission to the lungs; thus cautious use of HHHFNC is encouraged (Chauvin-Kimoff et al., 2018; DiBlasi & Gallagher, 2017).

Continuous distending pressure. Newborns who are unable to maintain adequate oxygenation (Pao_2) despite administration of oxygen by nasal cannula may require the use of CPAP. CPAP provides a positive pressure during both inspiratory and expiratory phases while the newborn spontaneously breathes and is delivered noninvasively using nasal prongs, nasopharyngeal tube, or face mask (Figure 28.2). Nasal CPAP increases the functional residual capacity, improves the diffusion of pulmonary gases, and can decrease pulmonary vascular resistance and intrapulmonary shunting. By preventing alveolar collapse, CPAP may eliminate the need for endotracheal intubation and avoid the trauma and inherent complications associated with mechanical ventilation (Gardner, Enzman-Hines, et al., 2021). Newborns who require noninvasive respiratory support need to be monitored closely for signs of nasal damage and skin breakdown (Fraser, 2017). An orogastric tube may be needed to decompress the stomach during the use of CPAP.

Mechanical ventilation. Mechanical ventilation must be implemented if other methods of therapy cannot correct abnormalities in gas exchange. Its use is indicated whenever blood gas values reveal severe hypoxemia or severe **hypercapnia**. Mechanical ventilation may be required for the newborn with apnea, **meconium aspiration syndrome (MAS)**, respiratory distress syndrome (RDS), or congenital malformations. Ventilator settings are individualized: the ventilator is set to provide a predetermined amount of oxygen during spontaneous respirations and to provide assisted ventilation in the absence of spontaneous respirations. Newer technologies allow oxygen to be delivered at lower pressures and in assist modes. This decreases barotrauma and

Fig. 28.2 Infant on nasal continuous positive airway pressure (CPAP) with father's finger in hand. (Courtesy E. Jacobs, Texas Children's Hospital.)

associated complications such as pneumothorax and pulmonary interstitial emphysema (Fraser, 2012). Table 28.2 outlines the types of mechanical ventilation used in newborns.

Weaning from ventilatory support. When a newborn is mature and strong enough to breathe spontaneously, every effort should be made to wean the ventilation support to the point of extubation. Even ELBW infants may successfully extubate to other forms of support. Signs of readiness include blood gas results within an acceptable range and oxygen saturation levels maintained within normal limits. A spontaneous, adequate respiratory effort must be present, and the infant must show sustained muscle tone during spontaneous respirations. Weaning of volume and pressure support is done in a stepwise, gradual manner. The infant may be extubated, placed on noninvasive respiratory support, and then weaned to oxygen alone. Throughout the weaning process, the infant's work of breathing is observed, oxygen levels are monitored by pulse oximetry, and blood gas analysis for trends in carbon dioxide clearance is evaluated.

Some infants are not able to be weaned from oxygen by the time of discharge and may require home oxygen therapy. Parents require education about the trajectory of their infant's chronic lung disease, the importance of regular follow-up appointments with their pediatric health care provider, as well as the technical aspects around managing oxygen delivery in their home.

Cardiovascular Support. Evaluation of heart rate and rhythm, skin colour, blood pressure, perfusion, peripheral pulses, oxygen saturation, and acid–base status provides information regarding cardiovascular status. The nurse must be prepared to intervene if symptoms of **hypovolemia**, shock, or both are found. These symptoms include prolonged capillary refill (longer than 3 seconds), pale colour (pallor), poor muscle tone, lethargy, initial tachycardia then bradycardia, and continued respiratory distress despite the provision of adequate oxygen and ventilation. Hypotension may initially be present or may occur in some infants as a late sign of shock.

Blood pressure is monitored routinely in the sick newborn by either internal or external means. Direct recording with arterial catheters is often used but carries the risks inherent in any procedure in which a catheter is introduced into an artery. An umbilical venous catheter may also be used to monitor the newborn's central venous pressure.

Thermoregulation. After or concurrent with the establishment of respiration, the most crucial need of LBW newborns is delivery of external warmth. Preventing heat loss in distressed newborns is essential for their survival, and maintaining a **neutral thermal environment (NTE)** is a challenging aspect of neonatal intensive nursing care. Heat production is a complex process that involves the cardiovascular, neurological, and metabolic systems; immature newborns have all of the issues related to heat production that are faced by full-term newborns (see Chapter 25, Thermogenic System). However, LBW infants are placed at further disadvantage by a number of additional complications. They have an even smaller muscle mass and fewer deposits of brown fat for producing heat, lack insulating subcutaneous fat, and have poor reflex control of skin capillaries.

Because overheating produces an increase in oxygen and calorie consumption, newborns are also jeopardized in a hyperthermic environment. Apnea and flushed colour may indicate hyperthermia. Unlike an older child, the preterm infant is not able to sweat and thus dissipate heat. An NTE is one that permits the newborn to maintain a normal core temperature with minimum oxygen consumption and calorie expenditure (Gardner & Cammack, 2021). Studies indicate that

TABLE 28.2 Common Methods for Assisted Ventilation in Neonatal Respiratory Distress

Method	Description	How Provided
Conventional Methods		
Continuous positive airway pressure (CPAP)	Provides constant distending pressure to airway in a spontaneously breathing infant	Nasal cannula Face mask Nasal cannula
Intermittent mandatory ventilation (IMV)	Allows infant to breathe spontaneously at own rate but provides mechanical cycled respirations and pressure at regular preset intervals	Endotracheal intubation and ventilator
Synchronized intermittent mandatory ventilation (SIMV)	Mechanically delivered breaths are synchronized to onset of spontaneous patient breaths; assist/control mode facilitates full inspiratory synchrony; involves signal detection of onset of spontaneous respiration from abdominal movement, thoracic impedance, and airway pressure or flow changes Pressure support ventilation provides inspiratory pressure assistance when spontaneous breathing is detected to decrease infant's work of breathing.	Patient-triggered infant ventilator with signal detector and assist/control mode; endotracheal tube
Volume guarantee ventilation	Delivers a predetermined volume of gas using inspiratory pressure that varies according to infant's lung compliance (often used in conjunction with SIMV)	Volume-guarantee ventilator with flow sensor; endotracheal tube
Alternative Methods		
High-frequency oscillation (HFO)	Application of high-frequency, low-volume, sine-wave flow oscillations to airway at rates between 480 and 1 200 breaths/min	Variable-speed piston pump (or loudspeaker, fluidic oscillator); endotracheal tube
High-frequency jet ventilation (HFJV)	Uses a separate, parallel, low-compliant circuit and injector port to deliver small pulses or jets of fresh gas deep into airway at rates between 250 and 900 breaths/min	May be used alone or with low-rate IMV; endotracheal tube

optimum thermoneutrality cannot be predicted for every high-risk infant's needs. In healthy term newborns it is recommended that axillary temperatures be maintained at 36.5° to 37.5°C (97.7° to 99.5°F). Normal axillary temperatures in the preterm or at-risk newborn may range between 36.3° and 37.2°C (Gardner & Cammack, 2021).

VLBW and ELBW infants, with thin skin and almost no subcutaneous fat, can control body heat balance within a limited range of environmental temperatures. Heat loss from radiation, evaporation, and transepidermal water loss is three to five times greater than in larger newborns, and a decrease in body temperature is associated with an increase in mortality. Extremely premature infants may require environmental temperatures equal to or greater than skin and core temperature to achieve thermoneutrality (Boulton et al., 2021).

The consequences of cold stress that produce additional hazards to newborns are (1) hypoxia, (2) metabolic acidosis, and (3) hypoglycemia. Increased metabolism in response to hypothermia creates a compensatory increase in oxygen and calorie consumption. If available oxygen is not increased to accommodate this need, arterial oxygen tension is decreased. This is further complicated by a smaller lung volume in relation to the metabolic rate, which creates diminished oxygen in the blood and concurrent pulmonary disorders. A small advantage is gained by the presence of fetal hemoglobin because its increased capacity to carry oxygen allows the newborn to exist for longer periods in conditions of lowered oxygen tension.

High-risk newborns may need an external heat source to achieve an NTE. A probe applied to the newborn is attached to the external heat source supplied by a radiant warmer or a servocontrolled isolette. To delay or prevent the effects of cold stress, at-risk newborns are placed in a prewarmed isolette immediately after birth, where they remain until they are able to maintain thermal stability (i.e., the capacity to balance heat production and conservation with heat dissipation). ELBW newborns may be placed in a polyethylene bag (or wrap) to decrease heat and water loss during resuscitation and the immediate postpartum period. Skin-to-skin contact between the preterm newborn and parent can help the newborn maintain body temperature.

Care of the hypothermic infant. Rapid changes in body temperature may cause changes to cerebral blood flow and contribute to intraventricular hemorrhage in ELBW infants (Morassutti et al., 2015). Clear, validated guidelines for rewarming a preterm infant are not available; however, gradual rewarming is prudent in an effort to protect the brain of the vulnerable preterm infant. If the newborn's condition allows, skin-to-skin contact is an effective method to regulate or increase body temperature. Extreme hypothermia may require more rapid rewarming to avoid prolonged metabolic acidosis or hypoglycemia (Gardner & Cammack, 2021).

Transition from the isolette. Infants who are medically stable and gaining weight, tolerating enteral feedings, and weigh 1 300 to 1 500 g may be transitioned from the isolette. The following guidelines may be followed to wean the infant from the isolette:

- Disconnect the servocontrol probe (if still in use).
- Dress the infant in a diaper, shirt, and cap.
- Lower the isolette temperature by 0.5°C every 2 hours.
- Record the temperature of the infant and the isolette.
- Assess the infant's responses to the changes every hour until four stable readings are obtained.
- Monitor the infant's temperature and other vital signs.

This procedure is repeated until the isolette temperature is the same as the room temperature and the infant's body temperature consistently remains within normal limits. The infant is then placed in an open bed (away from any drafts) and reassessed during routine care. If the infant is unable to maintain their temperature, the infant is returned to the isolette and the weaning process restarted once the infant is able to regulate their temperature. Consistent weight gain and absence of any clinical distress signs (poor feeding, respiratory distress, and temperature instability) are measures of effective weaning to an open bed.

Neurological Support. The preterm infant's central nervous system (CNS) is susceptible to injury as a result of the following:

- Birth trauma with damage to immature intracranial structures
- Bleeding from fragile capillaries
- Impaired coagulation process, including prolonged prothrombin time
- Recurrent hypoxic and hyperoxic episodes
- Predisposition to hypoglycemia
- Fluctuating systemic blood pressure with concomitant variation in cerebral blood flow and pressure

In the preterm newborn, neurological function depends on gestational age, illness factors, and predisposing factors (i.e., in utero hypoxic events). Clinical signs of neurological dysfunction may be subtle, nonspecific, or overt. A neurological assessment including an evaluation of tone, symmetry and quality of movements, reflexes, and cranial nerves provides insight into the integrity of the CNS (Heaberlin, 2019). Preterm infants require evaluation for seizure activity, hyperirritability, CNS depression, elevated intracranial pressure, and abnormal movements. Many primitive and tendon reflexes are present in preterm infants by 28 weeks' gestation and form part of the neurological examination. Astute clinical examinations by the nurse play an important part in assisting the health care team in identifying abnormalities or changes in condition. Postnatal neuroprotection practice guidelines for LBW and ELBW infants include neutral (midline) head positioning and elevation of the head of the bed to 30° during the first 72 hours of life (Ryan et al., 2019).

Nutritional Support. Optimum nutrition is critical in the management of LBW and preterm infants, yet providing for their nutritional needs is difficult. The various systems and mechanisms for ingestion and digestion of foods are not fully developed; the more immature the newborn, the greater the challenge. In addition, the nutritional requirements for this group of infants are not known with certainty (Brown et al., 2021). Preterm infants are at risk for nutritional compromise because of limited nutritional stores as well as physical (immaturity of the gastrointestinal tract) and developmental characteristics (lack of coordinated suck, swallow, and breathe reflexes).

Some sucking and swallowing activities are demonstrated in utero in the preterm fetus. Coordination of these mechanisms occurs at approximately 32 to 34 weeks of gestation although may not be fully synchronized until 36 to 37 weeks. Consequently, preterm infants may experience aspiration and complications thereof. The amount and method of feeding are determined by the newborn's maturity and general health condition. Nutrition can be provided by either the parenteral or enteral route or by a combination of the two. Total parenteral nutrition (TPN) support of acutely ill infants provides intravenous (IV) combinations of protein, amino acids, trace minerals, vitamins, carbohydrates (dextrose), and fat (lipid emulsion).

Early introduction of small amounts of breast milk via enteral feedings in metabolically stable preterm newborns is beneficial and has been shown to stimulate the newborn's gastrointestinal tract, preventing mucosal atrophy and subsequent enteral feeding difficulties; improve developmental outcome; and prevent growth failure (American Academy of Pediatrics [AAP], 2014; Ditzenberger, 2015). Minimal enteral feedings (10 to 15 ml/kg/day) of breast milk may be given by gavage within the first 24 hours of life, with particular caution paid to growth-restricted or ELBW infants (Ditzenberger, 2015; Dutta

et al., 2015). An allowance of 24 to 48 hours for the availability of the mother's own milk or donor milk with consent is encouraged before considering introducing formula-based feeds. Parenteral hydration and nutrition continue until the infant is able to tolerate an amount of enteral feeding sufficient to sustain growth.

Type of nourishment. Human milk is the best source of nutrition for term and preterm newborns. Studies indicate that even small preterm infants are able to breastfeed, if they have adequate sucking and swallowing reflexes and no other contraindications. Breastfed preterm infants have fewer oxygen desaturations; warmer skin temperature; and better coordination of breathing, sucking, and swallowing than bottle-fed newborns (Gardner, Lawrence, et al., 2021). Mothers who wish to breastfeed their preterm infants are encouraged to regularly pump their breasts and establish a milk supply until their newborns are stable enough to trial breastfeeding. Guidelines for the storage of expressed mother's milk should be followed to decrease the risk of milk contamination and destruction of its beneficial properties (see Chapter 27). Because of the significant number of mothers who do not continue to breastfeed preterm newborns, mothers of preterm or unwell infants need additional support and frequent encouragement to continue pumping until their newborn is able to breastfeed; early connection to lactation consultants is encouraged.

When the mother's own or donor breast milk is not a viable option, preterm formula is used, which is cow's milk based and whey predominant, with a higher concentration of protein, calcium, and phosphorus than in term formulas, to meet the unique needs of the preterm infant (AAP, 2014). Most preterm formulas are either 22 or 24 kcal/30 mL. Powdered infant formula is not recommended for premature and LBW infants under 2 months of age. If it is used, the preparation of powdered formula for preterm infants should be performed under strict aseptic technique, preferably in a pharmacy, and the formula refrigerated for up to 24 hours (Government of Canada, 2012). Preterm infants fed human milk with fortifier (protein, phosphorus, and calcium) have increased weight gain and improved bone mineralization; therefore, human milk fortifier is recommended for LBW preterm infants (Lawrence & Lawrence, 2016). Supplementation with iron, vitamin D, and multivitamins may be considered in exclusively breastfed LBW infants.

Gavage feeding. Gavage feeding is a method of providing breast milk or formula through a nasogastric or orogastric tube (Figure 28.3). It can be done either intermittently (bolus) or continuously through an in-dwelling feeding tube. Human milk or formula can be supplied intermittently using a syringe with gravity-controlled flow or can be given continuously using an infusion pump. The type and amount of fluid are recorded with every feed or syringe change. The volume of the continuous feedings is recorded hourly.

Measuring gastric residual volumes as an indicator for feeding tolerance is no longer standard care, although it may be a routine that remains in NICUs. Residuals, even green ones, and particularly when feed volumes are small, often reflect the early state of immature transit in preterm infants (Torrazza et al., 2015). Assessing gastric aspirate pH as part of determining naso/orogastric feeding position and observing feeding residuals creates a conundrum for frontline nurses. Interpreting the significance of gastric residual volumes that may represent 5 mL/kg or greater than 50% of the previous feed volume warrants a closer examination of the abdomen and review of vital signs to observe for changing trends in overall condition, followed by consultation with other members of the health care team (Dutta et al., 2015).

The nourishment given by gavage feedings is increased as tolerated by the newborn, and the parenteral fluids are decreased. Feedings are advanced gradually, in a stepwise progression. If feedings are advanced too rapidly, apnea, abdominal distension, vomiting, and diarrhea may

Fig. 28.3 Gavage feeding. **A:** Measurement of gavage feeding tube from tip of nose to earlobe and to midpoint between end of xiphoid process and umbilicus. Tape may be used to mark correct length on tube. **B:** Insertion of gavage tube using orogastric route. **C:** In-dwelling gavage tube, nasogastric route. After feeding by orogastric or nasogastric tube, the infant is propped on their right side or placed prone (preterm infant) for 1 hour to facilitate emptying of the stomach into the small intestine. Note rolled towel for support. (*A* and *B*, Courtesy Marjorie Pyle, RNC, Lifecircle.)

result. For newborns who are growth restricted, are ELBW, have undergone abdominal surgery, or are born with congenital heart defects, additional caution is warranted when feed volume and caloric concentration advancements are being considered, because of the potential increased risk of developing necrotizing enterocolitis (NEC).

A study in Canada found no consensus on the use of orogastric versus nasogastric tubes in infants. Most of the 28 centres (75%) surveyed used nasogastric tubes the vast majority (more than 90%) of the time (Birnbaum & Limperopoulos, 2009). Smaller flexible feeding tubes (e.g., 5 Fr) may be inserted via the nasal route without interfering with the infant's breathing. The procedure for inserting a gavage feeding tube is shown and described in Figure 28.3. Complications of in-dwelling tubes include aspiration, obstructed nares, mucous plugs, purulent rhinitis, epistaxis, infection, and possible stomach perforation. Current best practice is use of a radiograph as the only certain way to determine nasogastric tube placement in the stomach. Methods such as auscultation of an air bubble, neck-ear-xiphoid (NEX) measurements for insertion depth, or pH measurements are considered imprecise when used as the only method for determining feeding tube placement in infants. Aside from X-ray confirmation, reliable bedside evaluation of nasogastric tube placement is not available (Dias et al., 2017). As the era of point-of-care ultrasound progresses in neonatology, there may be opportunities for implementation in determining nasogastric position prefeeds.

To begin the feeding, the nurse connects the barrel of a syringe to the gavage tube. While clamping (or pinching) the feeding tube, the nurse pours the specified amount of breast milk or formula into the syringe. The clamp is then released and the feeding allowed to flow by gravity at a rate that approximates that of an oral feeding (about 1 mL/min). The infant may be held during gavage feedings by the caregiver or parent. If necessary, oxygen may be supplied via nasal cannula to facilitate handling. It is not recommended that the infant be removed from a primary source of oxygen for feedings because doing so decreases oxygen availability.

Once the prescribed volume has been delivered, the tube is clamped or pinched and the syringe either removed or left in place. If the gavage tube is to be left in situ, it is flushed with sterile water (1–2 mL) or air. If it is to be taken out, the gavage tube is capped (or the nurse continues to pinch it) and is removed in one steady motion. Capping or pinching the tube prevents breast milk or formula from leaking from the tube and being aspirated during removal of the tube.

Documentation of the procedure includes size of the feeding tube, type and quantity of fluid instilled, and the infant's tolerance of the procedure.

Gastrostomy feeding. Gastrostomy feeding involves surgical placement of a tube through the skin of the abdomen into the stomach. With percutaneous gastrostomy insertion, feedings may be started within hours of insertion. Feedings by gravity are done slowly over 20 to 30 minutes, depending on the volume. Special care must be taken to avoid a rapid bolus of the fluid because this may lead to respiratory compromise, abdominal distension, reflux into the esophagus, or diarrhea with malabsorption. Meticulous skin care at the tube insertion site is necessary to prevent skin breakdown and infection. Intake and output should be carefully monitored to ensure adequate fluid and calorie intake and adequate renal function. Unless there are contraindications, non-nutritive sucking can be offered with feeds to help the newborn associate satiation with suckling.

Non-nutritive sucking. For the infant who requires gavage or parenteral nutrition, non-nutritive sucking on a pacifier during the procedure may improve oxygenation and facilitate earlier transition to nipple feeding (Figure 28.4). Unless contraindicated, mothers of preterm newborn may be encouraged to let their infant start sucking at the breast during kangaroo care. Proposed benefits of non-nutritive sucking include improved weight gain, improved milk intake, more stable heart rate and oxygen saturation, earlier age at full oral feeds, and improved behavioural state.

Fig. 28.4 Non-nutritive sucking by infant. (iStock.com/metinkiyak)

Infant led oral feeding. Feedings are advanced from passive (parenteral and gavage) to active (nipple and breastfeeding) on the basis of the newborn's readiness for and ability to tolerate feedings. The newborn's sucking patterns and demonstration of a quiet, alert state signal readiness to nipple feed. The newborn may be fed by both nipple and gavage feeding during this transition; this ensures intake of the prescribed volumes of both fluid and nutrients. Providing an elevated side-lying position, co-regulated pacing and resting during feeding to aid in swallowing and breathing, and avoiding prodding mechanisms provide support as infant-guided interventions (Shaker, 2013). Parents are encouraged to interact with their baby by holding, making eye contact with, and talking to the newborn during feedings.

Because preterm infants may be discharged weighing as little as 1 500 g, close monitoring of nutritional intake and growth continues after discharge.

Hydration. High-risk newborns often receive supplemental parenteral fluids to supply additional calories, electrolytes, or water. Adequate hydration is particularly important in preterm infants because their extracellular water content is higher (70% in term newborns and up to 90% in preterm infants), their body surface is larger, their skin barrier is immature and unable to prevent transepidermal water loss (TEWL) losses. In addition, glomerular immaturity decreases the ability to concentrate urine. Therefore, preterm newborns are vulnerable to fluid depletion, fluid volume overload, and electrolyte abnormalities.

Newborns who are ELBW, tachypneic, receiving phototherapy, or cared for on a radiant warmer have increased insensible water losses that require fluid administration adjustments. Methods to decrease insensible fluid losses include placement of the ELBW infant in a highly humidified (60 to 90%) microenvironment (isolette) and use of plastic wrap, a polyethylene bag, or emollient to decrease TEWL. Concern about the increased incidence of infection associated with the use of emollients has led to a decrease in their use.

Nurses monitor fluid status closely, which includes weighing the newborn, often on a daily basis, and ensuring accurate intake and output of all fluids, including medications and blood products. Urine-specific gravity and dipstick measurements are monitored per unit protocol. Serum electrolytes are obtained as warranted by the newborn's condition. ELBW infants may require more frequent monitoring of

these parameters because of their TEWL, immature renal function, and propensity for dehydration or overhydration. Glucose intolerance, even at low concentrations, is not uncommon in the ELBW infant, with subsequent glycosuria and osmotic diuresis. Alterations in behaviour, alertness, or activity level in these newborns may signal an electrolyte imbalance, hypoglycemia, or hyperglycemia. Observation of tremors or seizures may signal electrolyte imbalance, including hypoglycemia, hyponatremia, or hypernatremia. Weight gain from fluid overload in the sick preterm infant may occur as a result of fluid retention (renal failure), inappropriate fluid administration (parenteral), or heart failure. Growing preterm infants, especially those with bronchopulmonary dysplasia (BPD) and those on oral electrolyte supplements, require careful monitoring for rapid weight gain that may result in pulmonary congestion, patent ductus arteriosus (PDA), and electrolyte imbalance. See Box 28.2 for calculation of a weight loss or gain.

Renal Support. The preterm infant's immature renal system is unable to (1) adequately excrete metabolites and medications, (2) concentrate urine, or (3) maintain acid–base, fluid, or electrolyte balance. Therefore, intake and output, as well as specific gravity, are assessed. Laboratory tests are performed to assess acid–base and electrolyte balance. Medication levels (e.g., gentamycin) are also monitored in preterm infants because metabolism via renal and hepatic routes is often hindered. Because of great variability in medication metabolism, serum levels are obtained to ensure adequate therapeutic range for treatment and to prevent toxicity.

Hematological Support. The preterm infant is predisposed to hematological challenges because of the following conditions:

- Increased capillary fragility
- Increased tendency to bleed (prolonged prothrombin time and partial thromboplastin time)
- Decreased production of red blood cells (RBCs) resulting from physiological rapid decrease in erythropoiesis after birth
- Large amount of fetal hemoglobin (up to 80% of total volume)
- Loss of blood attributable to frequent blood sampling for laboratory tests
- Decreased RBC survival related to the increased size of the RBC and its increased permeability to sodium and potassium
- Decreased levels of circulating albumin

BOX 28.2 Calculation of a Weight Loss or Gain

Net Weight Gain/Loss	Percentage Weight Gain/Loss
Current weight − previous weight = net weight gain (+) or weight loss (−)	$\frac{\text{Net weight gain or loss}}{\text{previous weight}} \times 100$ = percentage weight gain (+) or loss (−)
Example 1	
Weight day 1 = 1 750 g (birth weight)	−70 g/1 750 g
Weight day 2 = 1 680 g	−.04 × 100 (%) = 4.0% weight loss
Net gain/**loss**: 1 680 − 1 750 = −70g	
Example 2	
Weight day 3 = 1 680 g	40 g/1 680 g
Weight day 4 = 1 720 g	0.24 × 100 = 2.4% weight gain
Net **gain**/loss: 1 720 − 1 680 = +40 g	

The nurse needs to assess infants for any evidence of bleeding from puncture sites, the gastrointestinal tract, and pulmonary system or signs of anemia (e.g., decreased hemoglobin and hematocrit levels, pale skin or pallor, apnea, lethargy, tachycardia, and poor weight gain). In high-risk infants, the amount of blood withdrawn for laboratory testing may be monitored and documented.

Protection From Infection. While protection from infection is an integral part of all newborn care, preterm and sick infants are particularly susceptible to infectious organisms. As with all aspects of care, strict hand hygiene is the single most important measure to prevent health care–associated infections. Personnel and family members of the preterm newborn with known infectious disorders should be excluded from the unit until they are no longer infectious.

Newborns are highly susceptible to infection as a result of diminished nonspecific (inflammatory) and specific (humoral) **immunity** and impaired phagocytosis, delayed chemotactic response, decreased complement levels, and minimal or absent immune globulins (Ig) A and M. Because of the newborn's diminished response to pathogenic agents, there may be no local inflammatory reaction to signal an infection. Consequently, diagnosis and treatment may be delayed. Preterm and term newborns exhibit various nonspecific signs and symptoms of infection (Box 28.3). Early identification and treatment of sepsis are essential.

BOX 28.3 Signs and Symptoms of Newborn Infection

Signs and symptoms are subtle and nonspecific and include the following:

Temperature instability
- Hypothermia—most common
- Hyperthermia—rarely

Central nervous system changes
- Lethargy
- Irritability
- Altered level of consciousness

Changes in colour
- Cyanosis, pallor
- Mottling
- Jaundice

Cardiovascular instability
- Poor perfusion
- Prolonged capillary refill (>3 seconds)
- Hypotension
- Bradycardia or tachycardia

Respiratory distress
- Tachypnea or bradypnea
- Apnea
- Retractions, nasal flaring, grunting
- Gastrointestinal issues
- Feeding intolerance, increased residuals (when gavage fed)
- Abdominal distension
- Vomiting
- Diarrhea
- Bloody stools (frank or occult positive)
- Metabolic instability
- Glucose instability
- Metabolic acidosis

Other
- Electrolyte imbalance
- Decreased urine output

Skin Care. The skin of preterm infants is immature relative to that of term newborns. In most preterm infants the skin barrier properties mature and resemble those of the term newborn by 2 to 4 weeks' postnatal age, regardless of gestational age at birth. Because of its increased sensitivity and fragility, no alkaline-based soap that might destroy the acid mantle of the skin is used. The increased permeability of the skin facilitates absorption of ingredients. All skin products (e.g., alcohol, chlorhexidine, povidone-iodine) should be used with caution; the skin is rinsed with water afterward because these substances may cause severe irritation and chemical burns in VLBW and ELBW infants.

The skin of VLBW and ELBW infants is easily excoriated and denuded; care must be taken to avoid damage to the delicate structure. The total skin is thinner than that of full-term newborns and lacks rete pegs, appendages that anchor the epidermis to the dermis. Therefore, there is less cohesion between the thinner skin layers. The use of adhesive tape or bandages may excoriate the skin or adhere to the skin surface so well that the epidermis can be separated from the dermis and pulled away with the tape, thus altering skin barrier function. Pectin barriers and hydrocolloid adhesives may be useful because these products mould well to skin contours and adhere in moist conditions. Recommendations for protecting the integrity of the skin of preterm infants include minimal use of adhesive tape, backing the tape with cotton, and delaying adhesive and pectin barrier removal until adherence is reduced (Lund & Kuller, 2020).

Emollients such as Eucerin or Aquaphor have been used to promote skin integrity and prevent dry, cracking, and peeling skin in newborns at risk for skin breakdown. Emollients may also reduce TEWL and protect newborns from health care–associated infection (Witt, 2015). However, in some studies these agents have been shown to increase the risk for coagulase-negative infections in preterm infants and therefore should be used with caution. The use and effectiveness of emollients in high-risk newborns is controversial, and further studies are needed (Telofski et al., 2012).

Using scissors to remove dressings or tape from the extremities of very small and immature infants can lead to inadvertent injuries. Two-person procedure principles and vigilance need to be implemented. Use of solvents to remove tape should be avoided because they tend to dry and burn the skin.

Guidelines for skin care are listed in the Guidelines box. It is recommended that a validated skin assessment tool such as the Neonatal Skin Condition Score be used daily to evaluate the high-risk infant's skin condition in order to implement interventions aimed at minimizing skin breakdown (Lund & Osborne, 2004) (see Additional Resources at the end of the chapter).

GUIDELINES

Newborn Skin Care

General Skin Care

Assessment

- Assess skin frequently for redness, dryness, flaking, scaling, rashes, lesions, excoriation, or breakdown. An ideal time to assess the skin integrity and condition is during the bath and with diaper changes, but assessment can be performed during taking of vital signs and repositioning.
- Identify risk factors for skin injury: gestational age less than 30 weeks, infant being unwell, intravenous and/or adhesive use, use of assisted ventilation devices, medications that compromise tissue perfusion (i.e., vasopressors).
- Use a valid assessment tool to provide reliable and objective measurement of skin condition (e.g., Neonatal Skin Condition Score).
- Evaluate and report abnormal skin findings and assess for possible causes.
- Intervene according to cause or health care provider order.

Bathing

Initial Bath

- Assess for stable temperature a minimum of 2 to 4 hours before the first bath.
- Use cleansing agents with neutral pH. Avoid using agents with dyes or scents.
- Use routine practices; wear gloves.
- Do not completely remove vernix; allow vernix to wear off with care and handling.
- Use warm water only to bathe preterm infants (less than 32 weeks' gestation) for the first week.

Routine

- Decrease frequency of baths to every second or third day; continue daily cleansing of eyes, mouth, diaper areas, and pressure points, if present.
- Use cleanser or soaps no more than two or three times a week.
- Avoid rubbing skin during bathing or drying.
- Immerse stable infants fully (except head) in an appropriate-sized tub.
- Use swaddled immersion bathing technique: slow unwrapping after gently lowering into water for infants needing assistance with motor system reactivity (Fig. 26.29).

Emollients

- Apply sparingly to dry, flaking, fissured areas as needed.
- Choose petrolatum-based products that are free of preservatives, dyes, and fragrances.
- Observe newborns who weigh less than 750 g receiving emollient therapy for increased risk of coagulase-negative *Staphylococcus* infections.
- Use emollients from the hospital pharmacy that are dispensed in a unit dose or patient-specific container. Follow hospital protocol or consider applying emollient as needed to infants older than 32 weeks for dry, flaking skin.

Adhesives

- Decrease use as much as possible.
- Use semipermeable transparent adhesive dressings to secure intravenous lines (IVs), nasogastric or orogastric tubes, silicone catheters, and central lines.
- Use hydrogel or limb electrodes.
- Consider pectin barriers beneath adhesives to protect skin.
- Secure pulse oximeter probe or electrodes with elasticized dressing material (carefully to avoid restricting blood flow).
- Do not use adhesive remover, solvents, or bonding agents.
- Avoid removing adhesives for at least 24 hours after application.
- Facilitate adhesive removal using water, mineral oil, or petrolatum.
- Remove adhesives or skin barriers slowly, supporting the skin underneath with one hand and gently peeling away the product from the skin with the other hand.*

Antiseptic Agents

- Apply before invasive procedures.
- Consider the potential for skin breakdown or irritation with disinfectant.
- No specific disinfectant is recommended for all newborns; remove completely with sterile water or saline after use. Follow instructions for use of chosen disinfectant.
- Avoid use of isopropyl alcohol for skin preparation or removal of other disinfectants.

Transepidermal Water Loss (TEWL)

Minimize TEWL and heat loss in preterm infants less than 29 weeks of gestation by doing the following:

- Apply an occlusive food-grade polyethylene bag or wrap at birth; remove it once the infant's temperature is stable.
- Supply and measure ambient humidity during the first weeks of life (isolette).
- Maintain the humidity in the microenvironment (isolette) between 60 and 90% for the first 7 days and at 50% for the first 28 days (or according to hospital policy).
- Use supplemental conductive heat and reduce radiant heat source.
- Apply semipermeable transparent dressings to skin surfaces on the infant's chest, abdomen, and back.

Skin Breakdown

Prevention

- Decrease pressure from externally applied forces using water, air, or gel mattresses; sheepskin; or cotton bedding.
- Provide adequate nutrition, including protein, fat, and zinc.
- Apply transparent adhesive dressings to protect arms, elbows, and knees from friction injury.
- Use tracheostomy and gastrostomy dressings for drainage and relief of pressure from a tracheostomy or gastrostomy tube.
- Use emollient in the diaper area (groin and thighs) to reduce urine irritation.

Treating Skin Breakdown

- Irrigate wound gently every 4 to 8 hours with warm, half-strength normal saline.
- Culture wound and treat if signs of infection are present (excessive redness, swelling, pain on touch, heat, or resistance to healing).
- Use a transparent adhesive dressing for uninfected wounds.
- Apply hydrogel with or without antibacterial or antifungal ointments (as ordered) for infected wounds.
- Use hydrocolloid for deep, uninfected wounds (leave in place for 5 to 7 days) or as an ostomy barrier and to improve appliance adhesion: warm barrier in your hand for several minutes to soften it before applying it to the skin.
- Avoid use of antiseptic solutions for wound cleansing (use for intact skin only).

Treating Diaper Dermatitis

- Maintain clean, dry skin; use absorbent diapers and change them often.
- If mild irritation occurs, use petrolatum barrier.
- For dermatitis, apply a generous quantity of zinc-oxide barrier; when cleaning, remove only the soiled layer of barrier, as excessive friction can cause skin irritation and hinder healing.
- For severe dermatitis, identify the cause and treat (e.g., frequent stooling from spina bifida, severe opiate withdrawal, malabsorption syndrome).
- Treat *Candida albicans* with antifungal ointment or cream.
- Avoid use of powders and antibiotic ointments. (See Chapter 26, Bathing and Umbilical Cord Care, and Care of the Newly Circumcised Newborn.)

Other Skin Care Concerns

Use of Substances on Skin

- Evaluate all substances that come in contact with infant's skin.
- Before using any topical agent, analyze its components and:
  - Use sparingly and only when necessary.
  - Confine use to the smallest possible area.
  - Whenever possible and appropriate, wash off with water.
  - Monitor infant carefully for signs of toxicity and systemic effects.

Use of Thermal Devices

- Avoid use of heat lamps because of the increased potential for burns. If needed, measure temperature of the exposed skin every 15 minutes.
- When using heated mattresses:
  - Refer to the manufacturer's instruction manual for proper use.
  - Change the infant's position every 15 minutes initially and then every 1 to 2 hours.
  - Preset temperature of the mattress to less than 40°C.
- When using transcutaneous electrodes, set at the lowest possible temperature.
  - Change the location of the probe frequently.
  - Use pulse oximetry rather than transcutaneous monitoring whenever possible.
- If prewarming the infant's heel before phlebotomy, avoid temperatures over 40°C.
- Provide warm ambient humidity, directed away from the infant; use aerosolized sterile water and maintain ambient temperature so as to not exceed 40°C.
- Document use and temperature, if known, of all heating devices.

Use of Fluid Therapy and Hemodynamic Monitoring

- Be certain that fingers or toes are visible whenever an extremity is used for peripheral IV or arterial line.
- Secure catheter or needle with transparent dressing and tape for easy visualization of site.
- Assess site hourly for signs of ischemia, infiltration, and inadequate perfusion (check capillary refill, pulses, colour).
- Avoid use of restraints (e.g., arm boards); if used, ensure that they are secured safely and not restricting circulation or movement (check for pressure areas).
- Use commercial IV protector (e.g., I.V. House) with minimal tape.

*Caution: Scissors should be used with caution for tape or dressing removal because of the hazard of cutting skin or amputating tiny digits.

Nurturing Environment. Infants in NICUs are exposed to high levels of auditory input from the various machine alarms (Figure 28.5). Continuous noise levels of 7 to 120 decibels (dB) are common in the NICU, often exceeding the maximum acceptable level of 45 dB (Almadhoob & Ohlsson, 2020). Each piece of life-support equipment adds to the background noise. The infant's hearing may be damaged if exposed to a constant decibel level of 90 dB or frequent decibel levels higher than 110 dB. Personnel are encouraged to reduce noise-generating activities, such as slamming doors (including isolette portholes), listening to radios, talking loudly, and handling equipment (e.g., trash containers). Monitoring sound levels in the nursery has been shown to reduce ambient noise (Almadhoob & Ohlsson, 2020; Wang et al., 2014).

Twenty-four-hour surveillance of sick infants requires appropriate visibility and often bright lights. However, newborns benefit from regular sleep periods with cycled lighting (Figure 28.6), whereby the isolettes are covered with blankets, and the newborns are not disturbed for handling (Altimier & Holditch-Davis, 2020). Clustering of care and

Fig. 28.5 Neonatal intensive care unit (NICU) equipment, although necessary, contributes to environmental noise. Note radiant warmer, gas outlets, suction apparatus, monitor, ventilator, and pumps, all of which contribute to the auditory environment of the NICU. (Chassenet/Science Source.)

assessments to enable undisturbed sleep periods is encouraged. Shielding newborns' eyes from bright lights (e.g., procedure lighting) aids in preventing potential harm. Neonatal experts suggest that the human face, especially a parent's, is the best visual stimulus and that other visual stimuli be kept to a minimum.

Nurses can modify the environment to protect the newborn from sensory overload and provide a neurodevelopmentally supportive milieu whereby neurobehavioural, growth, and physiological needs can be optimized.

Developmental Care. *Developmental care* is a comprehensive term that encompasses strategies and interventions that are designed to reduce the effects of negative stress experienced by the newborn and optimize neurobehavioural development. The atmosphere and activities of the NICU produces multiple exposures to noxious stimuli that may lead to functional and structural changes in the preterm infant's brain (Coughlin McNeil & D'Agata, 2020). Nursing care activities, such as taking vital signs, weighing, repositioning, and suctioning, have been associated with periods of hypoxia, oxygen desaturation, and elevated intracranial pressure. The more immature the newborn, the less able they are to habituate to a single procedure. The caregiver needs to use the infant's own behavioural and physiological responses as the basis for planning care and providing interventions. Through observation, caregivers can identify the newborn's strengths, thresholds for disorganization, and areas of vulnerability.

Developmental care can be tailored to each newborn on the basis of a comprehensive behavioural assessment. During the early stages of development (especially before 33 weeks' gestation), external stimulation produces uncoordinated, random activity (jerky limb extension, hyperflexion) and irregular vital signs. At this stage, the newborn needs to have minimal environmental stimulation. Using the developmental model of supportive care, the nurse can closely monitor physiological and behavioural signs to foster organization and well-being of the high-risk newborn during handling. Softly calling the newborn by name and then gently placing a hand on the body signal that care is beginning. The newborn can be handled with slow, controlled movements. The newborn's random movements can be controlled and limbs held flexed close to the newborn's body during turning or other position changes. This containment or facilitated tucking may also be used before doing invasive procedures, such as a heel stick, to alleviate distress. Blanket swaddling and nesting or containment has been shown to decrease physiological and behavioural stress during routine care procedures. A nest constructed by placing blanket rolls underneath the bed sheet helps the newborn maintain flexion when prone or side-lying.

Skin-to-skin contact (kangaroo care) helps reduce stress and supports brain adaptability to form neural connections in preterm infants (Altimier & Phillips, 2016) (Figure 28.7). The undressed (except for diaper) newborn is placed in a vertical position on the parent's bare chest to permit direct eye contact, skin-to-skin sensations, and close proximity. In addition to being a safe and effective method for infant–parent acquaintance, skin-to-skin contact between parent and newborn can have a positive healing effect for the mother with a high-risk pregnancy. Mothers may experience psychological healing and regain the mothering role through early skin-to-skin contact with their VLBW infants. Additional benefits of skin-to-skin care include earlier contact for
