Neurological Conditions

Joley Johnstone

Originating US chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the various modalities for assessment of cerebral function.
2. Differentiate between the states of consciousness.
3. Formulate a care plan for the child with altered level of consciousness.
4. Distinguish between the types of head injuries and potential complications.
5. Describe the nursing care of a child with a tumour of the central nervous system.
6. Outline a care plan for the child with bacterial meningitis.
7. Differentiate between the various types of seizure characteristics.
8. Demonstrate an understanding of the manifestations of a seizure disorder and the management of a child with such a disorder.
9. Describe the preoperative and postoperative care of a child with hydrocephalus.

Most of the information about the status of the brain can be obtained by observation and indirect measurements. Some of these measurements are discussed elsewhere in relation to numerous aspects of child care (e.g., as part of the health assessment [Chapter 33], newborn status [Chapter 26], intellectual disability [Chapter 42], cerebral palsy [Chapter 54], and attainment of developmental milestones at each stage of development). Head trauma, increased intracranial pressure (ICP) and altered states of consciousness are common disorders of pediatric neurological dysfunction, thus they are described here, as well as techniques for neurological assessment and interpretation of diagnostic tests.

ASSESSMENT OF CEREBRAL FUNCTION

General Aspects

Children younger than 2 years of age require special evaluation for neurological assessment, as they are unable to respond to directions designed to elicit specific responses. Early neurological responses in infants are primarily reflexive. These responses are gradually replaced by meaningful movement in the characteristic **cephalocaudal** direction of development. This evidence of progressive maturation reflects more extensive myelination of the neurons and changes in neurochemical and electrophysiological properties.

Most information about infants and small children is gained by observing their spontaneous and elicited reflex responses as they develop increasingly complex locomotor and fine motor skills. In addition, valuable information is gained by eliciting progressively sophisticated communicative and adaptive behaviours. Delay or deviation from expected **developmental milestones** helps identify children at high risk for neurological issues or developmental delay. Persistence or reappearance of reflexes that normally disappear may indicate a pathological condition. In evaluating the infant or young child, it is also important to obtain the pregnancy and birth history to determine the possible impact of intrauterine environmental influences known to affect the maturation of the central nervous system (CNS). These influences could include maternal **infections**, cigarette or alcohol consumption, drug use, toxin exposure, **trauma**, and metabolic insults.

General aspects of assessment that provide clues to the etiology of a neurological condition include the following:

Family history—Identifies possible inherited genetic disorders with neurological manifestations

Health history—May provide valuable clues regarding the cause of dysfunction. Information should include Apgar scores, age of developmental milestones, trauma or injuries, acute and chronic illnesses, encounters with animals or insects, and ingestion or inhalation of neurotoxic substances.

Physical examination—Includes assessment of the following:

- Level of alertness
- Size and shape of the head, including presence of fontanels
- Sensory responses
- Motor function, including posture, tone, and muscle strength

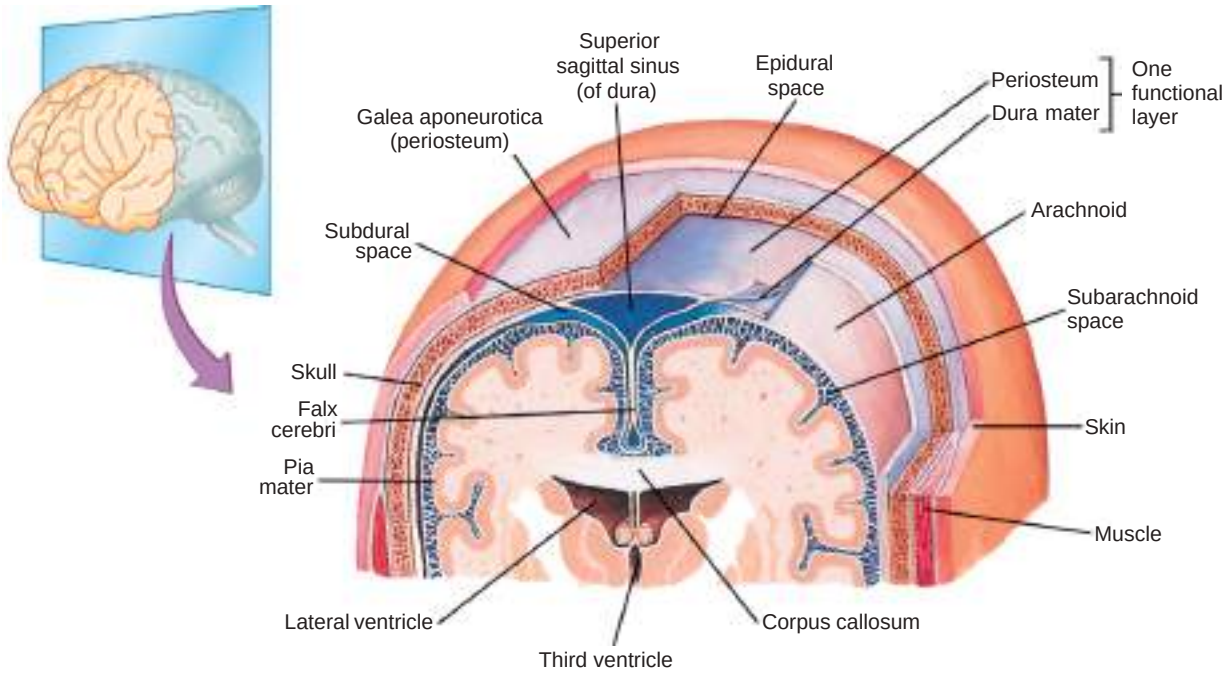

Fig. 50.1 Coronal section of the top of the head showing meningeal layers. (From Patton, K. T., & Thibodeau, G. A. [2010]. *Anatomy and physiology* [7th ed.]. Mosby.)

- Motility, including symmetry of movements and involuntary movements
- Respirations, including signs of prolonged apnea, ataxic breathing, paradoxical chest movement, or hyperventilation
- Dysmorphic facial features
- Behavioural cues, including consolability and habituation
- Primitive and deep tendon reflexes
- Cranial nerves, testing for function (see Chapter 33)

Increased Intracranial Pressure

The brain, tightly enclosed in the solid bony cranium, is well protected but highly vulnerable to pressure that may accumulate within the enclosure (Figure 50.1). The cranium's total volume—brain (80%), cerebrospinal fluid (CSF) (10%), and blood (10%)—must remain approximately the same at all times. A change in the proportional volume of one of these components (e.g., an increase or decrease in intracranial blood) must be accompanied by a compensatory change in another. In this way, the volume and pressure normally remain constant. Examples of compensatory changes are reduction in blood volume, decrease in CSF production, increase in CSF absorption, or shrinkage of brain mass by displacement of **intracellular fluid** and **extracellular fluid**.

Children with open fontanels compensate by skull expansion and widened sutures. However, at any age the capacity for spatial compensation is limited. An increase in ICP may be caused by tumours or other space-occupying lesions, accumulation of fluid within the ventricular system, bleeding, or **edema** of cerebral tissues. Once compensation is exhausted, any further increase in volume will result in a rapid rise in ICP.

Early signs and symptoms of increased ICP are often subtle and assume many patterns (Box 50.1). As ICP increases, signs and symptoms such as headache and vomiting become more pronounced and the level of consciousness (LOC) deteriorates.

Altered States of Consciousness

Consciousness implies awareness—the ability to respond to sensory stimuli and have subjective experiences. Consciousness has two components: *alertness*, an arousal-waking state, including the ability to respond to stimuli; and *cognitive power*, which includes the ability to process stimuli and produce verbal and motor responses.

An *altered state of consciousness* usually refers to varying states of unconsciousness that may be momentary or may extend for hours, for days, or indefinitely. *Unconsciousness* is depressed cerebral function—the inability to respond to sensory stimuli and have subjective experiences. *Coma* is defined as a state of unconsciousness from which the patient cannot be roused even with powerful stimuli.

Levels of Consciousness. Assessment of LOC remains the earliest indicator of improvement or deterioration in neurological status. LOC is determined by observations of the child's responses to the environment. When it is being assessed in young children, it is often useful to have a parent present to help elicit a response. An infant or child may not respond the same in an unfamiliar environment or to an unfamiliar voice as to a parent or close caregiver. Children older than 3 years of age should be able to give their name, although they may not be cognizant of place or time. Other diagnostic tests, such as motor activity, reflexes, and vital signs, are more variable and do not necessarily directly parallel the depth of the comatose state. The most consistently used terms are described in Box 50.2.

Coma Assessment. Several scales have been devised in an attempt to standardize the description and interpretation of the degree of depressed consciousness. The most popular of these is the Glasgow Coma Scale (GCS), which consists of a three-part assessment: eye opening, verbal response, and motor response (Figure 50.2).

Numeric values of 1 through 5 are assigned to the levels of response in each category. The sum of these numeric values provides an objective measure of the patient's LOC. A person with an unaltered LOC would score the highest, 15; a score of 8 or below is generally accepted as a definition of coma; the lowest score, 3, indicates severe head injury and deep, unresponsive coma or even brain death. A decrease in the GCS score indicates a deterioration in the patient's condition.

BOX 50.1 Clinical Manifestations of Increased Intracranial Pressure in Infants and Children

Infants
Tense, bulging fontanel
Separated cranial sutures
Macewen sign (cracked-pot sound on percussion)
Irritability and restlessness
Drowsiness, increased sleeping
High-pitched cry
Increased fronto-occipital circumference
Distended scalp veins
Poor feeding
Crying when disturbed
Setting-sun sign

Children
Headache
Nausea
Forceful vomiting
Diplopia, blurred vision
Seizures
Indifference, drowsiness
Decline in school performance
Diminished physical activity and motor performance
Increased sleeping
Inability to follow simple commands
Lethargy

Late Signs in Infants and Children
Bradycardia
Decreased motor response to commands
Decreased sensory response to painful stimuli
Alterations in pupil size and reactivity
Flexion or extension posturing
Cheyne-Stokes respirations
Papilledema
Decreased consciousness
Coma

BOX 50.2 Levels of Consciousness

Full consciousness—Awake and alert; oriented to person, place, and time; behaviour appropriate for age
Confusion—Impaired decision making
Disorientation—Disorientation to time and place, decreased level of consciousness
Lethargy—Limited spontaneous movement, sluggish speech, drowsy, falling asleep quickly
Obtundation—A severe reduction in LOC; the child arouses with very strong stimulus but is close to a comatose state
Stupor—Remaining in a deep sleep, responsive only to vigorous and repeated stimulation or moaning responses to stimuli
Coma—No motor or verbal response or extension posturing to noxious (painful) stimuli
Persistent vegetative state (PVS)—Permanently lost function of the cerebral cortex; eyes following objects only by reflex or when attracted to the direction of loud sounds, all four limbs spastic but can withdraw from painful stimuli, hands showing reflexive grasping and groping, face grimacing, some food may be swallowed, groaning or crying but without uttering any words

Neurological determination of death (NDD), previously known as *brain death*, is defined as the irreversible loss of the capacity for consciousness combined with the irreversible loss of all brainstem functions, including the capacity to breathe (Trillium Gift of Life Network, 2010). The criteria for NDD are listed in the Guidelines box: Neurological Determination of Death in Canada.

GUIDELINES

Neurological Determination of Death in Canada

The following minimum clinical criteria are required for neurological determination of death (NDD):

1. Proof of etiology that is capable of causing neurological death (in the absence of reversible conditions capable of imitating neurological death)
2. Absence of reversible causes of coma, or confounding factors including:
   a. Unresuscitated shock
   b. Low core body temperature <34°C (or <36°C for term newborns)
   c. Treatable metabolic/endocrine/electrolyte disturbances (including hypernatremia, hypoglycemia, severe hypophosphatemia, liver and/or renal dysfunction)
   d. Peripheral nerve or muscle dysfunction due to disease or neuromuscular blocking agents (e.g., pancuronium, succinylcholine)
   e. Central nervous system (CNS) depressants/significant drug intoxications (e.g., alcohol, barbiturates, sedatives)—Note that therapeutic levels of anticonvulsants, sedatives, and analgesics do not preclude the diagnosis.
3. Absence of brainstem reflexes/absence of bilateral movement, both spontaneous and in response to stimulation (including seizures). Spinal cord reflexes are exempt. Deep pain testing must include all extremities and above the clavicles.
4. Absence of respiratory effort, as established by apnea testing

Source: Trillium Gift of Life Network (TGLN). (2010). *Neurological determination of death (NDD).* https://www.giftoflife.on.ca/resources/pdf/Neurological%20Determination%20of%20Death%20New%20EN.pdf.

Neurological Examination

The purpose of the neurological examination is to establish an accurate, objective baseline of neurological information. It is essential that the neurological examination be documented in a fashion that can be reproduced by others. This allows for a comparison of the findings so the observer can detect subtle changes in the neurological status that might not otherwise be evident. Descriptions of behaviours should be simple, objective, and easily interpreted—for example: "Drowsy but awake and oriented to person, place, and time"; "Sleepy but arousable with vigorous physical stimuli. Pressure to nail base of right hand results in upper extremity flexion/lower extremity extension."

Vital Signs. Pulse, respiration, and blood pressure provide information regarding the adequacy of circulation and the possible underlying cause of altered consciousness. Altered autonomic activity occurs most significantly in cases of deep coma, encephalopathy, or brainstem lesions.

Body temperature is often elevated, and sometimes the elevation may be extreme. High temperature is most frequently a sign of an acute infectious process or heat stroke but may be caused by ingestion of some medications (especially salicylates, alcohol, and barbiturates) or

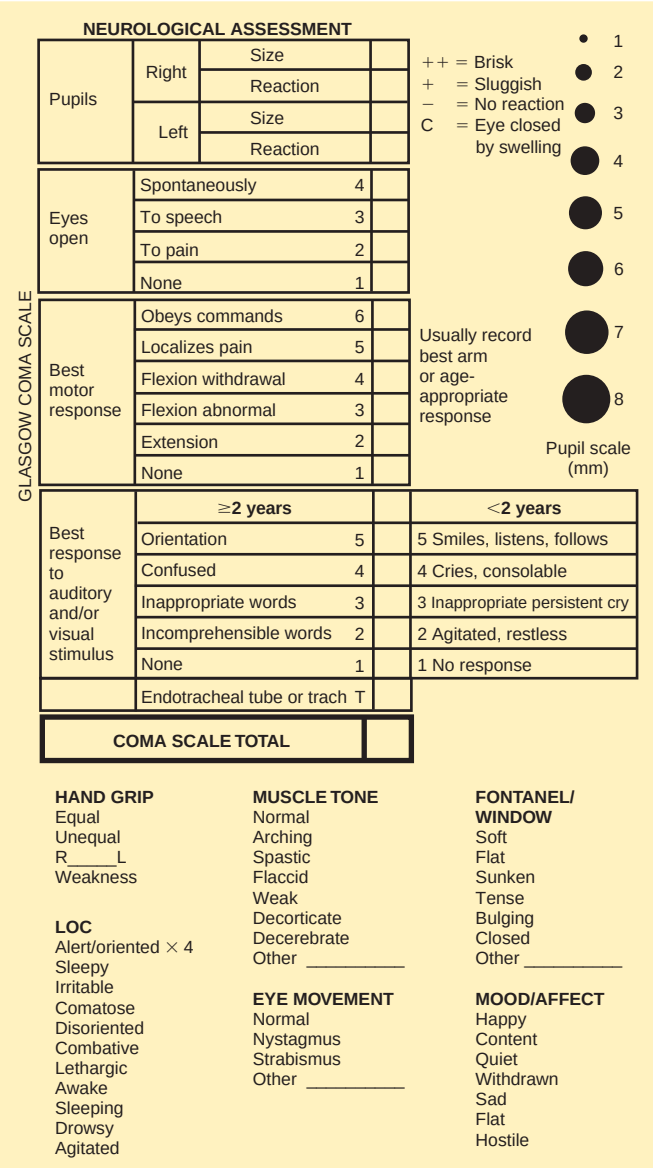

Fig. 50.2 Pediatric coma scale. *LOC,* Level of consciousness.

by intracranial bleeding, especially subarachnoid hemorrhage. Hypothalamic involvement may cause elevated or decreased temperature. Some infection may produce **hypothermia**.

The pulse varies and may be rapid, slow and bounding, or feeble. Blood pressure may be normal, elevated, or at shock levels. The Cushing reflex, or pressor response, causes a slowing of the pulse and an increase in blood pressure and is uncommon in children; when it occurs it is a very late sign of increased ICP. Medications may affect the vital signs. For assessment purposes, actual changes in pulse and blood pressure are more important than the direction of the change.

Slow, deep breathing is often seen in heavy sleep caused by sedatives, after seizures (postictal), or in cerebral infections. Slow, shallow breathing may result from use of sedatives or **opioids**. Hyperventilation with neurological compromise (deep and rapid respirations) is usually a result of metabolic acidosis or abnormal stimulation of the respiratory centre in the medulla caused by salicylate poisoning, hepatic coma, or Reye syndrome (RS).

Breathing patterns have been described with a number of terms (e.g., apneustic, cluster, ataxic, *Cheyne-Stokes*). However, it is better to describe what is being observed rather than placing a label on it because the traditional terms are often used and interpreted incorrectly. Periodic or irregular breathing is an ominous sign of brainstem (especially medullary) dysfunction that often precedes complete apnea. The odour of the breath may provide additional clues (e.g., the fruity, acetone odour of **ketosis**; the foul odour of uremia; the fetid odour of hepatic failure; or the odour of alcohol).

Skin. The skin should be evaluated for colour (such as pallor, cyanosis, erythema, or jaundice), temperature, and turgor. In addition, the skin may offer clues to the cause of unconsciousness. The body surface should be examined for signs of injury (lacerations, ecchymosis, or hematoma), needle marks, petechiae, bites, and ticks. Evidence of toxic substances may be found on the hands, face, mouth, and clothing—especially in small children.

Eyes. Pupil size and reactivity are assessed (Figure 50.3). Pupils either do or do not react to light. Pinpoint pupils are commonly observed in poisoning, such as opiate or barbiturate poisoning, or in brainstem dysfunction. Widely dilated and reactive pupils are often seen after seizures and may involve only one side. Dilated pupils may also be caused by eye trauma. Widely dilated and fixed pupils suggest paralysis of cranial nerve III secondary to pressure from herniation of the brain through the tentorium. A unilateral fixed pupil usually suggests a lesion on the same side. If pupils are fixed bilaterally for more than 5 minutes, it is usually assumed that there is brainstem damage. Dilated and nonreactive pupils are also seen in hypothermia, **anoxia**, ischemia, poisoning with atropine-like substances, or prior instillation of mydriatic medications.

! NURSING ALERT

The sudden appearance of a fixed and dilated pupil(s) is a neurosurgical emergency.

The description of eye movements should indicate whether one or both eyes are involved and how the reaction was elicited. The parents should be asked about pre-existing **strabismus**, which will cause the eyes to appear normal under compromise. Post-traumatic strabismus indicates cranial nerve VI damage.

Special tests, usually performed by qualified persons, include the following:

Doll's head manoeuvre—Elicited by rotating the child's head quickly to one side and then to the other. Conjugate (paired, or working together) movement of the eyes in the direction opposite to the head rotation is normal. Absence of this response suggests dysfunction of the brainstem or oculomotor nerve (cranial nerve III).

! NURSING ALERT

Any tests that require head movement should not be attempted until after cervical spine injury has been ruled out.

Caloric test, or oculovestibular response (RS)—Elicited with the child's head up (head of bed is elevated 30 degrees) by irrigating the external auditory canal with 10 mL of ice water for 20 seconds, which normally causes conjugate movement of the eyes toward the side of stimulation. This response is lost when the pontine centres are impaired, thus providing important information in assessment of the comatose patient.

Funduscopic examination—Reveals additional clues. **Papilledema** can occur with increased ICP, head injury, and encephalitis; this may be a later exam finding however. Papilledema is characterized

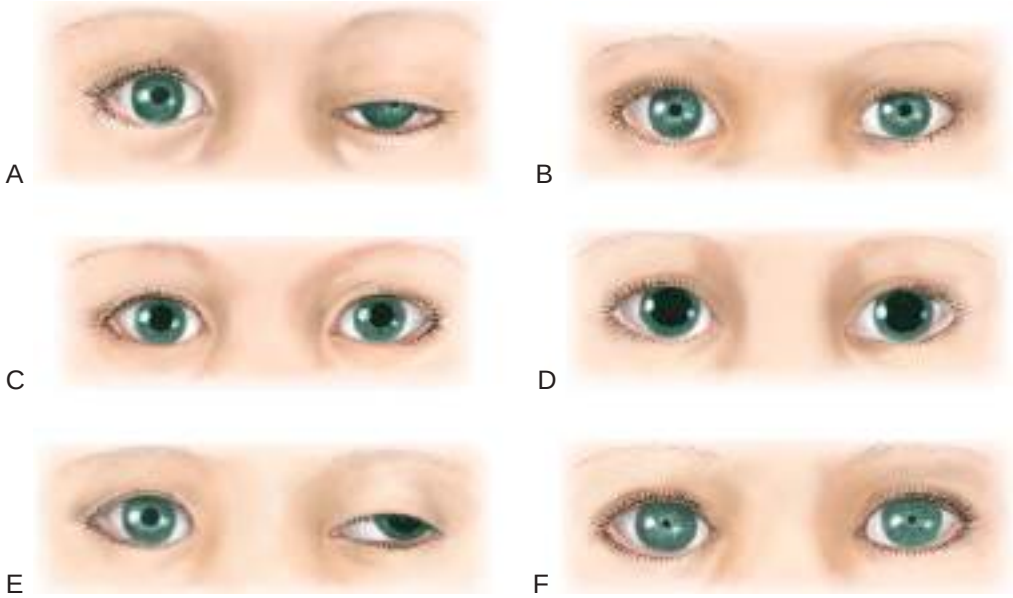

Fig. 50.3 Variations in pupil size with altered states of consciousness. **A:** Ipsilateral pupillary constriction with slight ptosis. **B:** Bilateral small pupils. **C:** Midposition, light fixed to all stimuli. **D:** Bilateral dilated and fixed pupils. **E:** Dilated pupils, left eye abducted with ptosis. **F:** Pinpoint pupils.

by optic disc swelling, indistinct optic disc margins, hemorrhage, tortuosity of vessels, and absence of venous pulsations. The presence of preretinal (subhyaloid) hemorrhages in children is almost invariably a result of acute trauma with intracranial bleeding, usually subarachnoid or subdural hemorrhage.

Motor Function. Observing spontaneous activity, posture, and response to painful stimuli provides clues to the location and extent of cerebral dysfunction. Even subtle movements (e.g., the outward rotation of a hip) should be noted and the child observed for other signs. Asymmetrical movements of the limbs or absence of movement suggests paralysis. In hemiplegia, the affected limb lies in external rotation and will fall uncontrollably when lifted and allowed to drop. In patients with cerebellum abnormalities, heel-to-toe walking is difficult. Patients with cerebellar ataxia have an unsteady, broad-based gait. These observations should be described rather than labelled.

In the deeper comatose states there is little or no spontaneous movement, and the musculature tends to be flaccid. There is considerable variability in the motor behaviour in lesser degrees of coma. For example, the child may be relatively immobile or restless and hyperkinetic; muscle tone may be increased or decreased. Tremors, twitching, and spasms of muscles are common observations. The child may display purposeless movements. Combative behaviour is common. Hyperactivity is more common in acute febrile and toxic states than in cases of increased ICP. Seizures are common in children and may be present from any cause. Any repetitive or seizure like movements should be described precisely.

! NURSING ALERT

Lack of response to painful stimuli is abnormal and should be reported immediately.

Posturing. Primitive postural reflexes emerge as cortical control over motor function is lost in brain dysfunction. These reflexes are evident in posturing and motor movements directly related to the area of the brain involved. Posturing reflects a balance between the lower exciting and the higher inhibiting influences, and strong muscles overcoming weaker ones. Decorticate or **flexion posturing** (Figure 50.4, *A*) is seen with severe dysfunction of the **cerebral cortex** or with lesions to corticospinal tracts above the brainstem. Typical flexion posturing includes rigid flexion, with arms held tightly to the body; flexed elbows, wrists, and fingers; plantar flexed feet; legs extended and internally rotated; and possibly fine tremors or intense stiffness. Decerebrate posture or **extension posturing** (see Figure 50.4, *B*) is a sign of dysfunction at the level of the midbrain or lesions to the brainstem. It is characterized by rigid extension and pronation of the arms and legs, flexed wrists and fingers, clenched jaw, extended neck, and possibly an arched back. Unilateral extension posturing is often caused by tentorial herniation.

Posturing may not be evident when the child is relaxed but can usually be elicited by applying painful stimuli, such as a blunt object pressed on the base of the nail. Noxious stimuli (e.g., suctioning) can elicit a response, as may turning or touching the patient. When the

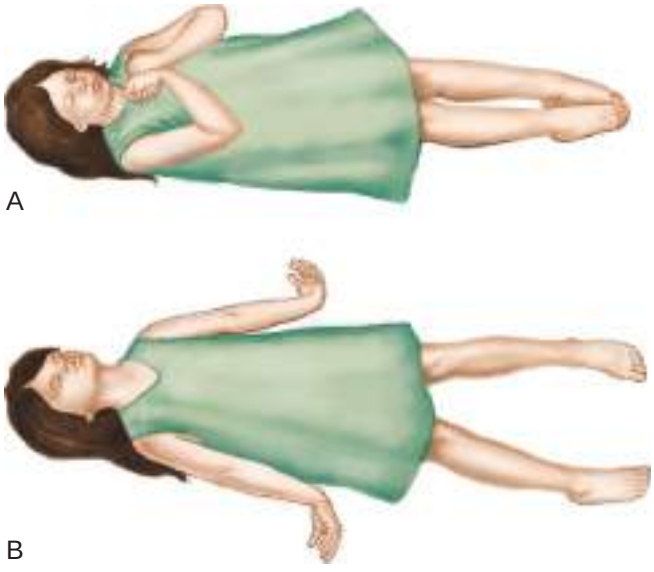

Fig. 50.4 **A:** Flexion posturing. **B:** Extension posturing.

nurse is describing posturing, the stimulus needed to provoke the response is as important as the reaction.

Reflexes. Testing of some reflexes may be of limited value. In general, the corneal, pupillary, muscle-stretch, superficial, and plantar reflexes tend to be absent in deep coma. The state of reflexes is variable in lighter grades of unconsciousness and depends on the underlying pathological process and the location of the lesion. Absence of corneal reflexes and presence of a tonic neck reflex are associated with severe brain damage. The Babinski reflex, in which the lateral portion of the foot is stroked, may be of value if it is found to be present consistently in children older than 1 year of age. A positive Babinski reflex is significant in assessment of pyramidal tract lesions when it is unilateral and associated with other pyramidal signs. A fluctuating Babinski reflex is often observed with seizures.

! NURSING ALERT

Three key reflexes that demonstrate healthy neurological status in young infants are the Moro, tonic neck, and withdrawal (to painful stimuli) reflexes.

Special Diagnostic Procedures

Numerous diagnostic procedures are used for assessment of cerebral function. Laboratory tests that may help delineate the cause of unconsciousness include blood glucose, urea nitrogen, and electrolyte (pH, sodium, potassium, chloride, calcium, and bicarbonate) tests; clotting studies, hematocrit, a complete blood count; liver function tests; blood cultures if there is fever; urine toxicology screen; and blood lead levels if clinically indicated.

An electroencephalogram (EEG) may provide important information. For example, generalized random, slow activity suggests suppressed cortical function, and localized slow activity suggests a space-occupying lesion such as a hematoma, tumour, or infectious process. A flat tracing is one of the criteria used as evidence of NDD.

Examination of spinal fluid is carried out when toxic encephalopathy or infection is suspected. Lumbar puncture is ordinarily delayed if intracranial hemorrhage is suspected and is contraindicated in the presence of ICP because of the potential for tentorial herniation.

Auditory and visual evoked potentials are sometimes used in neurological evaluation of very young children. Visual evoked potentials can aid in evaluating visual abnormalities from the retina to the visual cortex, and brainstem auditory evoked potentials are useful for assessing hearing acuity and brainstem function. Both are particularly useful for detecting demyelinating diseases such as pediatric multiple sclerosis and neoplasms.

Highly sophisticated tests are carried out with specialized equipment. Two imaging techniques, computed tomography (CT) and magnetic resonance imaging (MRI), assist in diagnosis by scanning both soft tissues and solid matter. Most of these tests are outlined in Table 50.1. Because such tests can feel threatening to children, the

TABLE 50.1 Neurological Diagnostic Procedures

Test	Description	Purpose	Comments
Lumbar puncture (LP)	Spinal needle is inserted between L3–L4 or L4–L5 vertebral spaces into subarachnoid space; CSF pressure is measured, and a sample is collected for examination.	*Diagnostic*—Measures spinal fluid pressure, obtains CSF for laboratory analysis *Therapeutic*—Injection of medication	Contraindicated in patients with increased ICP or infected skin over puncture site
Subdural tap	Needle is inserted into anterior fontanel or coronal suture (midline to pupil).	Helps rule out subdural effusions Removes CSF to relieve pressure	Place infant in semi-erect position after subdural tap to minimize leakage from site; prevent child from crying if possible. Check site frequently for evidence of leakage.
Ventricular puncture	Needle is inserted into lateral ventricle via coronal suture (midline to pupil).	Removes CSF to relieve pressure	Risk of intracerebral or ventricular hemorrhage
Electroencephalography (EEG)	EEG records changes in electrical potential of brain. Electrodes are placed at various points to assess electrical function in a particular area. Impulses are recorded by electromagnetic pen or digitally.	Detects spikes, or bursts of electrical activity that indicate the potential for seizures Used to determine neurological determination of death	Patient should remain quiet during procedure; may require sedation Minimize external stimuli during procedure.
Nuclear brain scan	Radioisotope is injected intravenously, then counted and recorded after fixed time intervals. Radioisotope accumulates in areas where blood–brain barrier is defective.	Identifies focal brain lesions (e.g., tumours, abscesses) Positive uptake of material with encephalitis and subdural hematoma Visualizes CSF pathways	Requires intravenous (IV) access; patient may require sedation In healthy children or children with noncommunicating hydrocephalus, no retrograde filling of ventricles occurs. Areas of concentrated uptake of material are termed *hot spots*.
Encephalography	Pulses of ultrasonic waves are beamed through head; echoes from reflecting surfaces are recorded graphically.	Identifies shifts in midline structures from their normal positions as a result of intracranial lesions May show ventricular dilation	Simple, safe, rapid procedure Fontanel must be patent.

Continued

TABLE 50.1 Neurological Diagnostic Procedures—cont'd

Test	Description	Purpose	Comments
Real-time ultrasonography (RTUS)	RTUS is similar to CT but uses ultrasound instead of ionizing radiation.	Allows high-resolution anatomical visualization in variety of imaging planes	Produces images similar to CT scan Especially useful in newborn central nervous system issues Anterior fontanel must be patent.
Radiography	Skull films are taken from different views—lateral, posterolateral, axial (submentoventricular), half-axial.	Shows fractures, dislocations, spreading suture lines, craniosynostosis Shows degenerative changes, bone erosion, calcifications	Simple, noninvasive procedure
Computed tomography (CT) scan	Pinpoint X-ray beam is directed on horizontal or vertical plane to provide series of images that are fed into a computer and assembled in an image displayed on a video screen. CT uses ionizing radiation.	Visualizes horizontal and vertical cross section of brain in three planes (axial, coronal, sagittal) Distinguishes density of various intracranial tissues and structures—congenital abnormalities, hemorrhage, tumours, demyelinating and inflammatory processes, calcification	Requires IV access if contrast agent is used Patient may require sedation. Rapid
Magnetic resonance imaging (MRI)	MRI produces radiofrequency emissions from elements (e.g., hydrogen, phosphorus), which are converted to visual images by computer.	Permits visualization of morphological feature of target structures Permits tissue discrimination unavailable with many techniques	MRI is a noninvasive procedure except when IV contrast agent is used. No exposure to radiation occurs. Patient may require sedation. Parent or attendant can remain in room with child. MRI does not visualize bone detail or calcifications. No metal can be present in scanner.
Positron emission tomography (PET)	PET involves IV injection of positron-emitting radionucleotide; local concentrations are detected and transformed into visual display by computer.	Detects and measures blood volume and flow in brain, metabolic activity, biochemical changes within tissue	Requires lengthy period of immobility Minimum exposure to radiation occurs. Patient may require sedation.
Digital subtraction angiography (DSA)	Contrast dye is injected intravenously; computer "subtracts" all tissues without contrast medium, leaving clear image of contrast medium in vessels studied.	Visualizes vasculature of target tissue Visualizes finite vascular abnormalities	Safe alternative to angiography Patient must remain still during procedure; may require sedation.
Single-photon emission computed tomography (SPECT)	SPECT involves IV injection of photon-emitting radionuclide; radionuclides are absorbed by healthy tissue at a different rate than by diseased or necrotic tissue; data are transferred to a computer, which converts the image to film.	Provides information regarding blood flow to tissues; analyzing blood flow to organ may help determine how well it is functioning	Requires lengthy period of immobility Minimum exposure to radiation occurs. Patient may require sedation.

nurse needs to prepare patients for the tests and provide support and reassurance during the tests (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44). Children who are old enough to understand require careful explanation of the procedure, the reason for the procedure, what they will experience, and how they can help. School-age children usually appreciate a more detailed description of procedures and an explanation of why contrast material is injected.

Children unfamiliar with the machines can be shown a picture beforehand. Although radiographic examinations are not painful, the machinery is often so frightening in appearance that the child protests out of anxiety. It is important to stress to the child the importance of lying still for tests. This is especially true for CT and MRI, both of which require that the child's head be placed within a special immobilizing device. Chin and cheek pads are sometimes used to prevent the slightest head movement, and straps are applied to the body to prevent a slight change in body position. The nurse can explain these events to a frightened child by comparing them to an astronaut's preparation for a space flight. It is important to emphasize to the child that at no time is the procedure painful.

Physical preparation for the diagnostic test may involve administration of a sedative. Many different agents are used for sedation of children undergoing neurological diagnostic procedures. Chloral hydrate or benzodiazepines have been used for decades as short-term sedative agents and remain safe methods in pediatric outpatient sedation

(Arlachov & Ganatra, 2012). Other sedative agents have been used safely, alone and in combination, for children and include intravenous (IV) sodium pentobarbital (Nembutal), IV fentanyl (Sublimaze), IV midazolam (Versed), and intranasal midazolam (Bhatt et al., 2015). Some adverse outcomes of pediatric outpatient sedation that have been reported include bradycardia, asystole, pulmonary aspiration, permanent neurological injury, and death (Bhatt et al., 2015). Propofol is a good sedation agent for diagnostic procedures because of its short induction and recovery time, but this medication should be used with caution because it can cause respiratory depression and apnea with little warning (Arlachov & Ganatra, 2012).

Children scheduled to undergo sedation should be helped through the preparation and administration and be assured that someone will remain with them (if possible). Children need continual support and reinforcement during procedures in which they remain conscious. Vital signs and physiological responses to the procedure should be monitored throughout. Many diagnostic procedures performed on an outpatient basis require sedation, and children need recovery time and observation. The nurse should review written instructions with the parents before discharge. Children who have undergone a procedure with a general anaesthetic require postanaesthesia care, including positioning to prevent aspiration of secretions and frequent assessment of vital signs and LOC. In addition, other neurological functions such as pupillary responses, motor strength, and movement are tested at regular intervals. Any surgical wound resulting from the test should be checked for bleeding, CSF leakage, and other complications. Children who undergo repeated subdural taps should have their hematocrit level monitored to detect excessive blood loss from the procedure.

NURSING CARE OF THE UNCONSCIOUS CHILD

The unconscious child requires nursing observation, recording, and evaluation of changes in objective signs. These observations provide valuable information regarding the patient's progress and often serve as a guide to diagnosis and treatment. Therefore, careful and detailed observations are essential for the patient's welfare. In addition, vital functions must be maintained and complications prevented through conscientious and meticulous nursing care. The outcome of unconsciousness is variable and ranges from early and complete recovery, to death within a few hours or days, or persistent and permanent unconsciousness, or recovery with varying degrees of residual cognitive or physical disability. The outcome and recovery of the unconscious child may depend on the level of nursing care and observational skills.

Emergency measures are directed toward ensuring a patent airway, breathing, and circulation; stabilizing the spine when indicated; treating shock; and reducing increased ICP. Delayed treatment often leads to increased damage. As soon as emergency measures have been implemented—and in many cases concurrently—therapies for specific causes are begun. Because nursing care is closely related to medical management, both are considered here.

Continual observation of LOC, pupillary reaction, and vital signs is essential in the care of CNS disorders. The assessment frequency depends on the cause of unconsciousness and the progression of cerebral involvement. Intervals may be as short as every 15 minutes or as long as every 2 hours. Significant alterations should be reported immediately.

Vital signs provide important information about the status of the unconscious child. The temperature is taken every 2 to 4 hours. Fevers can indicate an infective process, heat stroke, or brainstem or hypothalamic regulatory abnormalities. Tachycardia is common with fevers, hypovolemic shock, or heart failure, whereas increased ICP or myocardial injury can cause bradycardia. Tachypnea is associated with lung pathology, but quiet tachypnea indicates acidosis that can be associated with diabetic ketoacidosis or some poisonings (Sharma et al., 2010). The LOC is assessed periodically and includes evaluating pupillary size, equality, and reaction to light. Signs of meningeal irritation such as nuchal rigidity are assessed. Assessment of LOC includes response to vocal commands, spontaneous behaviour, resistance to care, and response to painful stimuli. Abnormal movement, changes in muscle tone or strength, and body position are noted. Seizure activity is described according to the duration and body areas involved.

Pain management for the comatose child requires astute nursing observation and management. Signs of pain include changes in behaviour (e.g., increased agitation and rigidity, alterations in physiological parameters); increased heart rate, respiratory rate, and blood pressure; and decreased oxygen saturation. Since these findings are not specific for pain, the nurse should observe for their appearance during times of induced or suspected pain and their disappearance after the end of the inciting procedure or the administration of analgesia. A pain assessment record should be used to document indications of pain and the effectiveness of interventions (see Pain Assessment, Chapter 34).

The use of opioids, such as morphine, to relieve pain is controversial because they may mask signs of altered consciousness or depress respirations. However, unrelieved pain activates the stress response, which can elevate ICP. To block the stress response, some health care providers advocate the use of **analgesics**, sedatives, and, in some cases such as head injury, paralyzing agents via continuous IV infusion. A frequently used combination is fentanyl, midazolam, and vecuronium (Norcuron). Acetaminophen (Tylenol) may also be an effective analgesic for mild to moderate pain. Regardless of which medications are used, adequate dosage and regular administration are essential to provide optimal pain relief.

Other measures to relieve discomfort include providing a quiet, dimly lit environment; limiting visitors; preventing any sudden, jarring movements, such as banging into the bed; and preventing an increase in ICP. This last effort is most effectively achieved by proper positioning and prevention of the patient's straining, such as during coughing, vomiting, suctioning, and defecating. Antiepileptic medications may be ordered for control of seizure activity.

! NURSING ALERT

When opioids are used, bowel elimination must be closely monitored because of the potential constipating effect. Stool softeners should be given with laxatives as needed to prevent constipation (see Chapter 34).

Respiratory Management

Respiratory effectiveness is the primary concern in the care of the unconscious child, and establishing an adequate airway is always the first priority. Carbon dioxide has a potent vasodilating effect and will increase cerebral blood flow (CBF) and ICP. Cerebral hypoxia that lasts longer than 4 minutes nearly always causes irreversible brain damage.

! NURSING ALERT

Respiratory obstruction and subsequent compromise lead to cardiac arrest. Maintaining an adequate, patent airway is of critical importance.

Children in lighter states of coma may be able to cough and swallow, but those in deeper states are unable to handle secretions, which tend to pool in the throat and pharynx. Dysfunction of cranial nerves IX and X places the child at risk for aspiration and cardiac arrest; the child needs

to be positioned to prevent aspiration of secretions and the stomach emptied to reduce the likelihood of vomiting. In infants, blockage of air passages from secretions can happen in seconds. In addition, upper airway obstruction from laryngospasm is a frequent complication in comatose children.

An oral airway can be used for the child who has a temporary loss of consciousness, such as after a contusion, seizure, or anaesthesia. For children who remain unconscious for a longer time, a nasotracheal or orotracheal tube is inserted to maintain the open airway and facilitate removal of secretions. Insertion of an endotracheal tube (ET) should be considered when a child has a GCS of less than 8, evidence of herniation, apnea, or inability to maintain an airway. A tracheostomy is performed in cases in which laryngoscopy for introduction of an ET would be difficult or for a child who needs long-term ventilator support. Suctioning is used only as needed to clear the airway, exerting care to prevent increasing ICP. Signs of respiratory distress may be an indication for ventilatory assistance.

When the respiratory centre is involved, mechanical ventilation is usually indicated (see Chapter 45). Blood gas analysis is performed regularly, and oxygen is administered when indicated. Moderately severe hypoxia and respiratory acidosis are often present but are not always evident from clinical manifestations. Hyperventilation frequently accompanies unconsciousness and may lead to respiratory alkalosis, or it may represent the body's attempt to compensate for metabolic acidosis. Thus blood gas and pH determinations are essential guides for therapy. Chest physiotherapy is carried out on a regular basis, and the child's position is changed at least every 2 hours to prevent pulmonary complications.

Intracranial Pressure Monitoring

An acute rise in ICP can cause secondary brain injury; the management of the child with increased ICP is a complex and important task. ICP monitoring is used to guide therapy and provides information on intracranial compliance, cerebrovascular status, and cerebral infusion. Nonetheless, ICP monitoring is an invasive procedure that has associated risks, including infections, hemorrhage, malfunction, and obstruction. More research is needed to provide further evidence of the efficacy of early detection of raised ICP and to develop treatment interventions that would improve cerebral perfusion and reduce brain injury (Forsyth et al., 2015). When a CSF obstruction causes increased ICP, a ventricular tap to drain excess CSF will provide relief quickly and effectively decrease the ICP. Evacuation of a hematoma reduces pressure from this source.

Indications for inserting an ICP monitor are as follows:

- GCS evaluation of less than 8
- GCS evaluation greater than 8 with respiratory assistance
- Deterioration of condition
- Subjective judgement regarding clinical appearance and response (Bhalla et al., 2012)

Four major types of ICP monitors are as follows:

1. Intraventricular catheter with fibroscopic sensors attached to a monitoring system
2. Subarachnoid bolt (Richmond screw)
3. Epidural sensor
4. Anterior fontanel pressure monitor

Direct ventricular pressure measurement with an intraventricular catheter remains the gold standard of ICP monitoring. Placement of the intraventricular catheter and subarachnoid bolt occurs through a burr hole in the skull. The intraventricular catheter is introduced into the lateral ventricle on the nondominant side, if known. The subarachnoid bolt is placed in the subarachnoid space, and the epidural sensor is placed between the dura and the skull. The intraventricular catheter has the advantage of providing a means for recalibration when measurement drift occurs; both the catheter and the bolt can be used for therapeutic CSF drainage to reduce pressure. A drainage bag attached to the system is kept at the level of the ventricles and can be lowered to decrease ICP.

The placement of the bolt is not adjusted by anyone except the neurosurgeon who placed the device. The neurosurgeon should be notified if a satisfactory waveform is not observed.

! NURSING ALERT

The bolt is stabilized with dressings, but these are not changed or disturbed, even to check the site. However, they can be reinforced.

An epidural sensor provides a readout of the ICP with a stopcock assembly and transducer. In infants, a fontanel transducer can be used to detect impulses from a pressure sensor and convert them to electrical energy. The electrical energy is then converted to visible waves or numeric readings on an oscilloscope. ICP measurement from the anterior fontanel is noninvasive but may prove to be inaccurate if the equipment is poorly placed or inconsistently recalibrated.

ICP can be increased by instilling solutions; therefore, antibiotics are administered intravenously if a positive CSF culture is obtained. CSF is a body fluid, thus routine precautions are implemented according to institutional policy.

Nurses caring for patients with intracranial monitoring devices must be acquainted with the system, assist with insertion, interpret the monitor readings, and be able to distinguish between danger signals and mechanical dysfunction. Because systematic blood pressure, ICP, and therefore **cerebral perfusion pressure** (CPP) are normally lower in children, the child's age must be considered when deciding what constitutes an abnormally high ICP or abnormally low ICP.

Managing Intracranial Pressure. In cases of high levels of increased ICP, procedures tend to trigger reactive pressure waves in many patients. For example, increased intrathoracic or abdominal pressure will be transmitted to the cranium. Particular care should be taken in positioning these patients to avoid neck vein compression, which may further increase ICP by interfering with venous return.

The child can be propped to one side or the other, and the use of an alternating-pressure mattress reduces the chance of prolonged pressure to vulnerable areas. Frequent clinical assessment of the child cannot be replaced by an ICP monitoring device.

! NURSING ALERT

The head of the bed is elevated to 15 to 30 degrees, and the child is positioned so that the head is maintained in midline to facilitate venous drainage and avoid jugular compression.

It is important to avoid activities that may increase ICP by causing pain or emotional stress. Clustering nursing activities together and minimizing environmental stimuli by decreasing noxious procedures help to control ICP. Gentle range-of-motion exercises can be carried out but should not be performed vigorously. Nontherapeutic touch can cause an increase in ICP. Any disturbing procedures to be performed should be scheduled to take advantage of therapies that reduce ICP, such as osmotherapy and sedation. Environmental noise should be minimized or eliminated to the degree possible. Assessment and intervention to relieve pain are important nursing actions to decrease ICP.

Suctioning and chest percussion are poorly tolerated and are contraindicated unless concurrent respiratory issues exist. **Hypoxia** and the

Valsalva manoeuvre associated with cough both acutely elevate ICP. Vibration, which does not increase ICP, accomplishes excellent results and should be tried first if treatment is needed. If suctioning is necessary, it should be brief and preceded by hyperventilation with 100% oxygen, which can be monitored during suctioning with pulse oximetry to determine oxygen saturation.

Several medical measures are available to treat increased ICP resulting from cerebral edema. Osmotic diuretics may provide rapid relief in emergency situations. Although their effect is transient, lasting only about 6 hours, they can be lifesaving in emergencies. These substances are rapidly excreted by the kidneys and carry with them large quantities of sodium and water. Mannitol or hypertonic saline (3% solution) or both measures are administered intravenously and are the most frequently used for rapid reduction (Kochanek & Bell, 2020). The infusion is generally given slowly but may be pushed rapidly in cases of herniation or impending **cerebral herniation**. Because of the profound diuretic effect of the medication, an in-dwelling catheter is inserted to ensure bladder emptying. Adrenocorticosteroids are not recommended for cerebral edema secondary to head trauma. Arterial carbon dioxide ($Paco_2$) should be maintained at 25 to 30 mm Hg to produce vasoconstriction, which reduces CSF, thereby decreasing ICP.

Nutrition and Hydration

In the unconscious child, fluids and calories are supplied initially via the IV route (see Chapter 44). An IV infusion is started early, and the type of fluid administered is determined by the patient's general condition. Fluid therapy requires careful monitoring and adjustment based on neurological signs and electrolyte determinations. The goal of fluid therapy is *euvolemia* (normal blood volume). Often, comatose children are unable to cope with the same amounts of fluid they could tolerate at other times, and overhydration must be avoided to prevent fatal cerebral edema. When cerebral edema is a threat, fluids may need to be restricted to reduce the chance of fluid overload. Skin and mucous membranes need to be examined for signs of dehydration. Adjustments to fluid administration are based on urinary output, serum electrolytes and osmolarity, blood pressure, and arterial filling pressure. Observation for signs of altered fluid balance related to abnormal pituitary secretions is also a part of nursing care.

Long-term nutrition is provided with a balanced formula via a nasogastric or gastrostomy tube.

Altered Pituitary Secretion. An altered ability to handle fluid loads is attributed in part to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus (DI) resulting from hypothalamic dysfunction (see Chapter 51, Syndrome of Inappropriate Antidiuretic Hormone). SIADH frequently accompanies CNS diseases such as head injury, meningitis, encephalitis, brain abscess, brain tumour, and subarachnoid hemorrhage. In the patient with SIADH, scant quantities of urine are excreted, electrolyte analysis reveals hyponatremia and hyposmolality, and manifestations of overhydration are evident. It is important to evaluate all parameters, since the reduced urine output might be erroneously interpreted as a sign of dehydration. The treatment of SIADH consists of restriction of fluids until serum electrolytes and osmolality return to normal levels.

DI may occur after intracranial trauma. In DI there are large amounts of diluted urine and the accompanying danger of dehydration. Adequate replacement of fluids is essential, and observation of electrolyte balance is necessary to detect signs of hypernatremia and hyperosmolality. Exogenous vasopressin may be administered.

Medications

The cause of unconsciousness determines specific medication therapies. Children with infectious processes such as meningitis or encephalitis may be given antibiotics appropriate to the disease and the infecting organism. Corticosteroids are prescribed for inflammatory conditions, CNS demyelinating diseases, and edema. Cerebral edema is an indication for osmotherapy with osmotic diuretics. Sedatives or antiepileptics are prescribed for seizure activity.

MEDICATION ALERT

Sedation in the combative child provides amnesic and anxiolytic properties in conjunction with a paralytic agent. The combination decreases ICP and allows treatment of cerebral edema. Usual medications include morphine, midazolam, and pancuronium (Pavulon). Midazolam is attractive because of its short half-life.

The management of increased ICP using a barbiturate-induced deep coma is debated among practitioners. Barbiturates are currently reserved for the reduction of increased ICP when all else has failed. Barbiturates decrease the cerebral metabolic rate for oxygen and protect the brain during times of reduced CPP. Barbiturate comas require extensive monitoring, cardiovascular and respiratory support, and ICP monitoring to assess response to therapy. Paralyzing agents such as pancuronium also may be needed to aid in performing diagnostic tests, improving effectiveness of therapies, and reducing risks of secondary complications. Elevation of ICP or heart rate of patients who are being given paralyzing agents or are under sedation may indicate the need for another dose of either or both medications.

Thermoregulation

Hyperthermia often accompanies cerebral dysfunction; if it is present, measures should be implemented to reduce the temperature to prevent brain damage and to reduce metabolic demands generated by the increased body temperature. Medically induced hypothermia assists in controlling ICP and may result in an improved outcome. Antipyretic agents are the method of choice for fever reduction; cooling devices should be used for hyperthermia. Laboratory tests and other methods are used in an attempt to determine the cause of the hyperthermia.

Elimination

A urinary catheter is usually inserted during the acute phase, although diapers may be used and weighed to record urine output. The child who formerly had bowel and bladder control is generally incontinent. If the child remains comatose for a long period, the in-dwelling catheter may be removed and periodic bladder emptying accomplished by intermittent catheterization. Stool softeners are usually sufficient to maintain bowel function, but suppositories or enemas may be needed occasionally for adequate elimination and to prevent fecal impaction. The passage of liquid stool after a period of no bowel activity is usually a sign of an impaction. To avoid this preventable condition, daily recording of bowel activity is essential.

Hygienic Care

Routine measures for cleansing to maintain skin integrity are an integral part of nursing of the unconscious child. The child who is unable to move is prone to developing tissue breakdown. To help prevent this, the child can be placed on an alternating-pressure or water-filled mattress, which alleviates pressure on vulnerable areas. Assessment of pressure ulcer risk can be calculated using the modified pediatric Braden QD Scale (see Additional Resources).

Mouth care should be performed at least twice daily, because the mouth tends to become dry or coated with mucus. The teeth should be carefully brushed with a soft toothbrush or cleaned with gauze saturated with saline. Commercially prepared cleansing devices, such as Toothettes, are convenient for cleansing the mouth and teeth. Lips can be coated with ointment or other water-based preparations to protect them from drying, cracking, or blistering. Glycerin swabs should not be used, as they break down tooth enamel.

The deeply comatose child is also prone to eye irritation. The corneal reflexes are absent; thus the eyes are easily irritated or damaged by linen, dust, or other substances that may come in contact with them. There is excessive dryness as a result of incomplete closure of the eyes or decreased secretions, especially if the child is undergoing osmotherapy to reduce or prevent brain edema.

! NURSING ALERT

The eyes should be examined regularly and carefully for early signs of irritation or **inflammation**. Artificial tears (methylcellulose) are placed in the eyes every 1 to 2 hours. Eye dressings may sometimes be needed to protect the eyes from possible damage.

Positioning and Exercise

The unconscious child needs to be positioned to prevent aspiration of saliva, nasogastric secretions, and vomitus and to minimize ICP. The head of the bed is elevated, and the child is placed in a side-lying or semiprone position. A small, firm pillow is placed under the head, and the uppermost limbs are flexed and supported with pillows. In the semiprone position, the child lies with the dependent arm at the side behind the body, the opposite side supported on pillows, and the uppermost arm and leg flexed and resting on the pillows. This position prevents undue pressure on the dependent extremities. The dependent position of the face encourages drainage of secretions and prevents the flaccid tongue from obstructing the airway.

Normal range-of-motion exercises help maintain function and prevent contractures of joints. Exercises should be done gently and with full range of motion. A small rolled pad can be placed in the palms to help maintain proper position of the fingers; footboards or boots can be used to help prevent footdrop; and splinting may be needed to prevent severe contractures of the wrist, knee, or ankle in decerebrate children. Extremity splints and the child's position should be changed every 1 to 2 hours.

Stimulation

Sensory stimulation is important in the care of the unconscious child. It helps arouse the temporarily unconscious or semiconscious child to the conscious state and orient the child in terms of time and place. Auditory and tactile stimulation are especially valuable. Tactile stimulation is not appropriate for the child in whom it may elicit an undesirable response. However, for other children, tactile contact often has a relaxing and calming effect. When the child's condition permits, holding or rocking has a soothing effect and provides body contact needed by young children. Involving family members with the sensory stimulation can create a positive effect on the child and allows the family to participate in their care.

The auditory sense is often present in a state of coma. Hearing is the last sense to be lost and the first one to be regained, thus the child should be spoken to as any other child. Conversation around the child should not include thoughtless or derogatory remarks. Soft music is used frequently to provide auditory stimulation. Singing the child's favourite songs or reading a favourite story can help the child maintain contact with a familiar world. Playing songs or stories recorded in the parents' voices can also provide a continuous source of familiar stimulation.

Regaining Consciousness

Awakening from a coma is a gradual process; however, sometimes children regain consciousness within a short time. Regaining orientation involves knowing person, place, and time, in that order.

Certain behaviours have been observed when children awaken from the unconscious state. The stress and anxiety they appear to feel in a strange and unfamiliar environment are consistently expressed in silent and withdrawn behaviour. Children respond to basic questioning but usually do not display their prehospitalization personality and social behaviour until they are transferred from the critical care area.

Family Support

Helping the parents of an unconscious child cope with the situation can be especially difficult. They may demonstrate all the guilt, fear, hostility, and anxiety of any parent of a seriously ill child (see Chapter 43). In addition, these parents are faced with the uncertain outcome of the cerebral dysfunction. The fear of death, intellectual disability, or other permanent disability is present. Nursing intervention with parents depends on the nature of the pathological condition, the parents' personality, and the parent–child relationship before the injury or illness.

The most difficult situations involve children who never regain consciousness. Unlike losing a child through death, these situations lack finality, which often leaves family members in a state of prolonged grief and searching for signs of hope. An awareness of these behaviours and coping mechanisms can help nurses support the parents as they grieve.

Superimposed on the process of grieving for the "lost" child, parents may be faced with difficult decisions. When the child's brain is so severely damaged that vital functions must be maintained by artificial means, the parents, along with guidance from the health care team, must make the final decision of whether to remove life support systems. During this time nurses continue to provide specialty care that maintains the child's physiological status while addressing informational and psychological needs of the family. While the decision to remove life support is difficult for parents, having an open and honest discussion about the child's medical condition and prognosis can help parents make a decision based on their child's care and status (de Vos et al., 2015). Parent's cultural, religious, and language needs, coupled with their intellectual level, decision-making preferences, and emotional state, should be considered during this discussion (Allen, 2014). Sometimes parents may choose to refuse or not initiate treatment if they believe that is best for the child and the family (informed dissent). At other times parents request that "everything possible" be done for the child.

When the child has survived the cerebral insult and is not comatose, but physical or mental capacity is limited, either minimally or severely, families must cope with the long rehabilitation process and the uncertain outcome. The drain on financial, emotional, and social resources can be enormous. For parents who choose to care for their child at home, planning for home care begins early in the recovery process (see Chapter 41). The family should become involved with the child's care as soon as they indicate an interest and ability to do so. They need education and support in learning to care for the child, regular follow-up observation and assessment of home management, and planning for respite care. Parents need to understand that it is important to plan for periodic relief from the continual care of the child (see Family-Centred Care box: Preparation for Discharge, in Chapter 41).

CEREBRAL TRAUMA

Head Injury

Head injury is a pathological process involving the scalp, skull, meninges, or brain as a result of mechanical force. In Canada, pediatric injuries are the most common cause of death and disability (Pike et al., 2015). Traumatic brain injuries in the pediatric population can have a lasting and permanent impact on brain function. Among children aged 10 to 19 years, 40% of head injuries occur during sports (Parachute, 2021b).

Etiology. Important causes of brain damage in children include falls, motor vehicle injuries, bicycle injuries, and sports-related injuries. Neurological injury accounts for the highest mortality rate, with boys affected twice as often as girls. In motor vehicle accidents, children younger than 2 years of age are almost exclusively injured as passengers, whereas older children may be injured as pedestrians or cyclists. The majority of deaths from brain trauma caused by bicycle injuries occur in children between the ages of 5 and 19 years. Bicycle helmet laws have been effective in reducing the risk of head injury; helmets have been estimated to reduce the risk of head and brain injuries by 69%, severe brain injuries by 74%, and facial injuries by 65%, with similar effects for cyclists in collisions with motor vehicles and across all age groups (Hagel et al., 2013/2020). However, provincial and territorial legislation on the use of bicycle helmets varies from province to province. To date, legislation mandating helmet use for all cyclists, or for cyclists under a given age (for example, 18 years), has been implemented throughout Canada except in Saskatchewan, Quebec, and the territories. Individual municipalities such as Whitehorse have instituted helmet laws.

Many of the physical characteristics of children predispose them to craniocerebral trauma. For example, infants who are left unattended on beds, in high chairs, and in other places can fall. Because the head of an infant or toddler is proportionately larger and heavier in relation to other body parts, it is the most likely to be injured. Incomplete motor development contributes to falls at young ages, and children's natural curiosity and exuberance can also increase their risk of injury.

Pathophysiology. Primary head injuries are those that occur at the time of trauma and include skull fracture, contusions, intracranial hematoma, and diffuse injury. Subsequent complications include hypoxic brain damage, increased ICP, infection, and cerebral edema. The predominant feature of a child's brain injury is the amount of diffuse swelling that occurs. Hypoxia and **hypercapnia** threaten the energy requirements of the brain and increase CBF. The added volume across the **blood–brain barrier**, along with the loss of **autoregulation**, exacerbates cerebral edema. Pressure inside the skull that is greater than arterial pressure results in inadequate perfusion.

The pathology of brain injury is directly related to the force of impact. Intracranial contents (brain, blood, CSF) are damaged because the force is too great to be absorbed by the skull and musculoligamentous support of the head. The elastic, pliable skull of the infant and young child absorbs much of the direct energy of physical impact to the head and affords some protection to intracranial structures. Although nervous tissue is delicate, it usually requires a severe blow to cause significant damage.

A child's response to head injury is different from that of an adult. The larger head size and insufficient musculoskeletal support render the very young child particularly vulnerable to head injuries. Physical forces act on the head through acceleration, deceleration, or deformation. Acceleration or deceleration is more descriptive of the circumstances responsible for most head injuries. When the stationary head receives a blow, the sudden acceleration causes deformation of the skull and mass movement of the brain. Continued movement of the intracranial contents allows the brain to strike parts of the skull (e.g., the sharp edges of the sphenoid or the irregular surface of the anterior fossa) or the edges of the tentorium. The very young child's larger head size and insufficient musculoskeletal support render these children particularly vulnerable to acceleration–deceleration injuries.

Although the brain volume remains unchanged, significant distortion takes place as the brain changes shape in response to the force of impact to the skull. This movement can cause bruising at the point of impact (*coup*) or at a distance as the brain collides with the unyielding surfaces far removed from the point of impact (*contrecoup*) (Figure 50.5). Thus a blow to the occipital region can cause severe injury to the frontal and temporal areas of the brain. Children with an acceleration–deceleration injury demonstrate diffuse generalized cerebral swelling produced by increased blood volume or a redistribution of cerebral blood volume (cerebral hyperemia) rather than by increased water content (edema), as seen in adults. Sudden deceleration, such as takes place during a fall, causes the greatest cerebral injury at the point of impact.

Another effect of brain movement is shearing stresses, which may tear small arteries and cause subdural hemorrhages (Figure 50.6). Although shearing forces are maximum at the cerebral surface and extend toward the centre of rotation within the brain, the most serious effects are often in the area of the brainstem. Damage can also occur when severe compression of the skull causes the brain to be forced through the tentorial opening. This can produce irreparable damage to the brainstem.

The clinical manifestations of acute head injury are listed in Box 50.3.

Concussion. The most common head injury is *concussion*, a transient disturbance of brain function often traumatically induced that involves a complex pathophysiological process (Liebig & Congeni, 2020). Concussion may result from a direct impact to the head, neck, or face, or to somewhere else on the body that transmits an impulsive force to the head (Purcell & Canadian Paediatric Society [CPS], Healthy

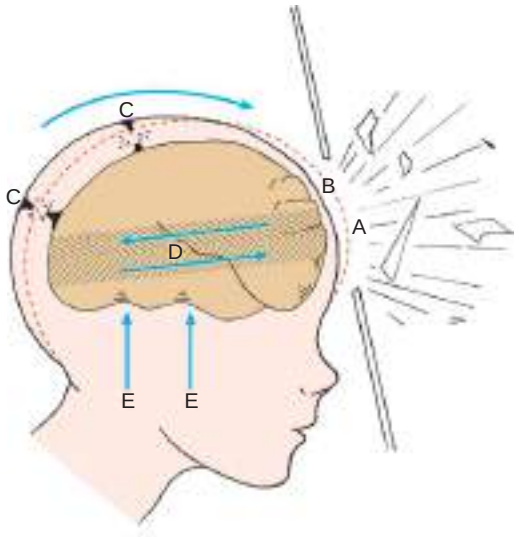

Fig. 50.5 Mechanical distortion of cranium during closed-head injury. **A:** Preinjury contour of skull. **B:** Immediate postinjury contour of skull. **C:** Torn subdural vessels. **D:** Shearing forces. **E:** Trauma from contact with floor of cranium. (Redrawn from Grubb, R. L., & Coxe, W. S. [1974]. Central nervous system trauma: Cranial. In S. G. Eliasson, A. L. Presky, & W. B. Hardin, Jr. [Eds.], *Neurological pathophysiology*. Oxford University Press.)

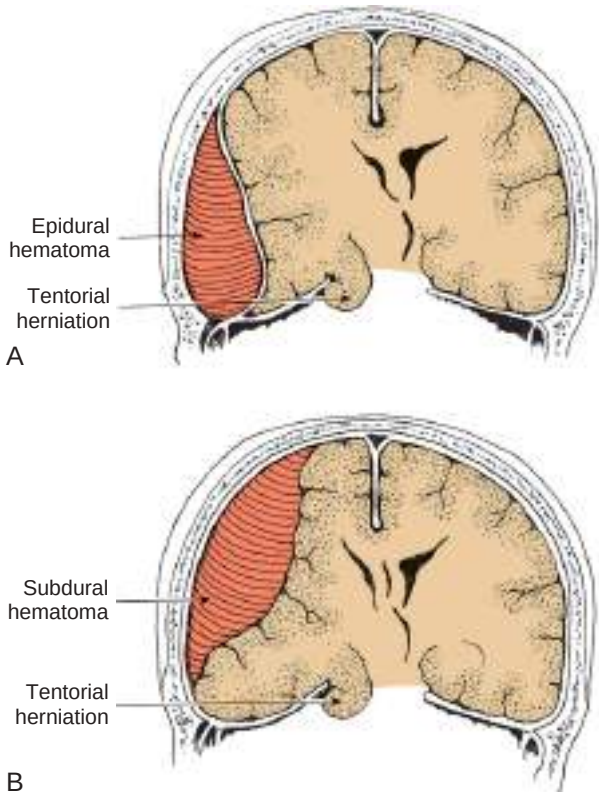

Fig. 50.6 **A:** Epidural (extradural) hematoma and compression of temporal lobe through tentorial hiatus. **B:** Subdural hematoma.

Active Living and Sports Medicine Committee, 2014/2016). Confusion and amnesia after head injury are the hallmarks of concussion; however, loss of consciousness is not an accurate indicator for the presence of a concussion. Concussions usually resolve in 1 to 3 weeks without complications, but the child should be encouraged to carry out light activity, while taking care to stay below their cognitive and physical symptom-exacerbation threshold. Rest for more than a few days may not hasten recovery and may lead to prolonged symptoms (Liebig & Congeni, 2020).

The pathogenesis of concussion is still unclear but may be a result of shearing forces that cause stretching, compression, and tearing of nerve fibres, particularly in the area of the central brainstem, the seat of the reticular activating system. It has also been suggested that the anatomical alterations of nerve fibres cause the release of large quantities of acetylcholine into the CSF and a reduction in oxygen consumption with increased lactate production.

Contusion and laceration. The terms *contusion* and *laceration* are used to describe visible bruising and tearing of cerebral tissue. Contusions represent petechial hemorrhages along the superficial aspects of the brain at the site of impact or a lesion remote from the site of direct trauma. In serious accidents there may be multiple sites of injury.

The major areas of the brain susceptible to contusion or laceration are the occipital, frontal, and temporal lobes. Also, the irregular surfaces of the anterior and middle fossae at the base of the skull are capable of producing bruises or lacerations on forceful impact. Contusions may cause focal disturbances in strength, sensation, or visual awareness. The degree of brain damage in the contused areas varies according to the extent of vascular injury. Signs will vary from mild, transient weakness of a limb to prolonged unconsciousness and paralysis. However, the signs and symptoms may be clinically indistinguishable from those of concussion.

The lower incidence of cerebral contusion in infancy has been attributed to the infant's pliable skull with less convolutional markings of the inner space between brain tissue and bone. In addition, the infant's brain tissue has a softer consistency, which also reduces surface injury. However, infants who are roughly shaken (traumatic head injury) can sustain profound neurological impairment, seizures, retinal hemorrhages, and intracranial subarachnoid or subdural hemorrhages. In addition to these classic injuries, high cervical spinal cord hemorrhages and contusions can occur (Mian et al., 2015).

Cerebral lacerations are generally associated with penetrating or depressed skull fractures. However, they may occur without fracture in small children. When brain tissue is torn, with bleeding into and around the tear, more severe and prolonged unconsciousness and paralysis occur, leaving permanent scarring and some degree of disability.

Traumatic head injury due to child maltreatment. Traumatic head injury due to child maltreatment (THI-CM), previously known as *shaken baby syndrome* or *abusive head trauma*, is violent shaking that may occur as a result of the inconsolable infant crying (Public Health Agency of Canada [PHAC], 2020). In Canada, THI-CM comprises a small proportion of child maltreatment. Many of these children have lifelong complications including neurological, visual, cognitive, behavioural, and sleep abnormalities (Hinds et al., 2015).

It is important to understand what happens in THI-CM. Infants have a large head-to-body ratio, weak neck muscles, and a large amount of water in the brain. Violent shaking causes the brain to rotate within

BOX 50.3 Clinical Manifestations of Acute Head Injury

Minor Injury
May or may not lose consciousness
Transient period of confusion
Somnolence
Listlessness
Irritability
Pallor
Vomiting (one or more episodes)

Signs of Progression
Altered mental status (e.g., difficulty rousing child)
Mounting agitation
Development of focal lateral neurological signs
Marked changes in vital signs

Severe Injury
Signs of increased intracranial pressure (see Box 50.1)
Bulging or full fontanel (infant)
Retinal hemorrhage
Extraocular palsies (especially cranial nerve VI)
Hemiparesis
Quadriplegia
Elevated temperature
Unsteady gait (older child)
Papilledema (older child)

Associated Signs
Scalp trauma
Other injuries (e.g., to extremities)

the skull, resulting in shearing forces that tear blood vessels and neurons. The characteristic injuries that occur are intracranial bleeding (subdural hematoma) and, in approximately 80% of cases, retinal hemorrhages, which are classic results of repetitive acceleration–deceleration head trauma (Maguire et al., 2013). Injuries may also include fractures of the ribs and long bones; however, most often there are no signs of external injury. Health care providers base an abusive diagnosis on patterns of injuries to the infant, but this can be subjective.

THI-CM is often not an isolated event. Victims can be seen with a variety of symptoms. Many of the presenting symptoms such as vomiting, irritability, poor feeding, and listlessness are often mistaken for common infant and childhood ailments. In more severe forms, presenting symptoms may include seizures, posturing, alterations in LOC, apnea, bradycardia, or death. Nurses can take an active role in preventing THI-CM by teaching caregivers about care for infants and techniques to cope with inconsolable crying (Barr, 2012) (see Chapter 26, Interpretation of Crying).

Fractures. Skull fractures result from a direct blow or injury to the skull and are often associated with intracranial injury. Falls are the most common cause of head injury. Many of the falls that result in a skull fracture in children younger than 2 years of age involve short distances, such as falls from a caregiver's arms. Hajiaghamemar et al. (2019) note that infant falls from 0.3 metres or less had a low probability of resulting in parietal skull fracture, particularly with carpet impact. Head-first falls from 0.9 metre had a high probability of fracture with concrete impact and a moderate probability with carpet impact. The probability of fracture from a 0.6-metre fall is dependent on impact surface.

The types of skull fractures that occur are linear, depressed, comminuted, basilar, open, and growing. As a rule, the faster the blow, the greater the likelihood of a depressed fracture; a low-velocity impact tends to produce a linear fracture.

Linear fractures comprise a single fracture line that starts at the point of maximal impact but does not cross suture lines. Linear fractures constitute the majority of childhood skull fractures. Most linear skull fractures are associated with an overlying hematoma or soft-tissue swelling, particularly in infants younger than 1 year of age and in the parietal or temporal region.

Depressed fractures are those in which the bone is broken locally, usually into several irregular fragments that are pushed inward. Depressed skull fractures may be associated with direct underlying parenchymal damage and should be suspected when a child's head appears misshapen. In infants and very young children, the soft, malleable bone may become dented in with a peculiar rounded or "ping-pong ball" depression, without laceration of either skin or dura. Surgery may be needed to elevate the depressed bone fragment if there is an associated intracranial hematoma or pressure.

Comminuted fractures consist of multiple associated linear fractures. They usually result from intense impact. These types of fractures often result from repeated blows against an object and may suggest child maltreatment.

Basilar fractures involve the bones at the base of the skull in either the posterior or anterior region. The bones involved are the ethmoid, sphenoid, temporal, or occipital bones and usually result in a dural tear. Because of the proximity of the fracture line to structures surrounding the brainstem, a basal skull fracture is a serious head injury. Approximately 80% of cases may include clinical features such as subcutaneous bleeding over the mastoid process (battle sign), bleeding around the orbit ("raccoon eyes"), bleeding behind the tympanic membrane (hemotympanum), or CSF leakage from the nose or ear (Perheentupa et al., 2010).

Open fractures cause communication between the skull and the scalp or the surfaces of the upper respiratory tract. Open fractures increase the risk of CNS infection when the fracture creates an opening in the paranasal sinuses or middle ear that causes CSF leakage. They may have a skin laceration overlying the bone fracture, called a *compound fracture*. Open fractures can also create an opening in the paranasal sinuses or middle ear that can lead to CSF rhinorrhea or otorrhea. Antibiotics are recommended to prevent osteomyelitis.

Growing fractures are skull fractures with an underlying dural tear that fails to heal properly. The enlargement may be caused by a leptomeningeal cyst, dilated ventricles, or a herniated brain. Neurological symptoms include headache, seizures, and asymmetrical cranial growth. The majority of growing skull fractures (90%) occur before 3 years of age (Le Fournier et al., 2015). Physical examination can reveal the development of a pulsatile mass or enlarged and sunken skull defect. Clinical neurological symptoms may be delayed for months to years after the initial skull fracture.

Complications. The major complications of trauma to the head are hemorrhage, infection, edema, and herniation through the brainstem. Infection is always a hazard in open injuries, and edema is related to tissue trauma. Vascular rupture may occur even in minor head injuries, causing hemorrhage between the skull and cerebral surfaces. Compression of the underlying brain produces effects that can be rapidly fatal or insidiously progressive.

! NURSING ALERT

Post-traumatic meningitis should be suspected in children with increasing drowsiness and fever who also have basilar skull fractures.

Epidural hemorrhage. An *epidural hemorrhage* is bleeding between the dura and the skull to form a hematoma. This bleeding causes the dura to be stripped from the bone, forcing the underlying brain contents downward and inward as the brain expands (see Figure 50.6, *A*). Because bleeding is generally arterial, brain compression occurs rapidly. Most often the expanding hematoma is located in the parietal and temporal regions. The lower incidence of epidural hematoma in childhood has been attributed to the fact that the middle meningeal artery is not embedded in the bone surface of the skull until approximately 2 years of age. Thus a fracture of the temporal bone is less likely to lacerate the artery. Also, the dura closely adheres to the inner table of the skull, especially at the level of the sutures, making separation from bleeding less likely. However, a child's skull can be indented with sufficient force to tear the middle meningeal artery and rebound intact without causing a fracture. Hemorrhage can also derive from dural veins or the dural sinuses, especially in infants and small children, in whom fracture is less likely to occur. In 20 to 40% of children a skull fracture is not detectable.

The classic clinical picture of epidural hemorrhage consists of momentary unconsciousness followed by a normal period, and then followed with lethargy and coma due to blood accumulation in the epidural space and compression of the brain (see Box 50.3 for clinical manifestations). Frequently, the period of impaired consciousness is lacking, and the symptom-free period is atypical because of nonspecific symptoms such as irritability, headache, and vomiting. Physical findings can include pallor with anemia and cephalohematoma, with infants exhibiting additional findings of hypotonia and a bulging fontanel. If the severity of the child's signs and symptoms are not recognized, herniation and death will occur.

Subdural hemorrhage. A *subdural hemorrhage* is bleeding between the dura and the arachnoid membrane, usually as a result of the rupture of cortical veins that bridge the subdural space (see Figure 50.6, *B*). Subdural hematomas are more common than epidural hematomas, occurring most often in infancy, frequently as a result of birth trauma, falls, or THI-CM.

Unlike epidural hemorrhage, which develops inwardly against the less resistant brain tissue, subdural hemorrhage tends to develop more slowly and spreads thinly and widely until it is limited by the dural barriers—the falx and tentorium. The small subdural space and dura firmly attached to the skull in this area are highly vulnerable to increased ICP.

! NURSING ALERT

Children with a subdural hematoma and retinal hemorrhages should be evaluated for the possibility of child maltreatment, especially THI-CM.

Presenting signs can include irritability, vomiting, increased head circumference, bulging fontanels in infants, lethargy, or seizures. In infants with open fontanels, large amounts of intracranial blood may accumulate, causing hemorrhagic shock or fever before there are any changes in the neurological examination. Hemiparesis, hemiplegia, and unequal pupils are signs of brainstem compression and increased ICP. A child with a GCS of 12 or less requires emergency consultation with the neurosurgeon.

Cerebral edema. Some degree of brain edema is expected after craniocerebral trauma. Cerebral edema peaks at 24 to 72 hours after injury and may account for changes in a child's neurological status. Cerebral edema associated with traumatic brain injury may be caused by direct cellular injury leading to intracellular swelling or vascular injury, which in turn creates increased intracellular fluid. Either mechanism can cause increased ICP as a result of the increased intracranial volume and changes in cerebral blood flow.

! NURSING ALERT

If a child loses consciousness or vomits more than three times following a head injury, medical attention should be sought.

Post-traumatic syndromes. Post-traumatic syndromes include post-concussion syndrome, post-traumatic seizures, and structural complications after a head injury.

There is increasing evidence that concussions in some children will persist longer with a post-concussion syndrome. One study reported that 11.8% of children presenting to the emergency room with a concussion remained symptomatic at 3 months postinjury. In addition, although most children reported a reduction in symptoms over time, 10% of children developed symptoms even though they initially had a good outcome (Barlow et al., 2015). The manifestations vary with the child's age and include nausea, dizziness, headache, photophobia, fatigue, irritability, restlessness, difficulty concentrating, and memory impairment (Purcell & CPS, Healthy Active Living and Sports Medicine Committee, 2014/2016). The duration of manifestations can vary from several days to several months.

Post-traumatic seizures occur in a number of children who survive a head injury, often within 24 hours after the injury, but they can occur up to 1 week after the trauma (O'Neill et al., 2015). In comparison to children with no brain injury, seizures are two times more likely to take place in children with mild traumatic brain injury and seven times more likely in children with severe head injury (O'Neill et al., 2015).

Structural complications (e.g., hydrocephalus) may occur as a result of a head injury. Clinical sequelae include cognitive deterioration, motor deficits, optic atrophy, cranial nerve palsies, and aphasia. The type of residual effect depends on the location and nature of the trauma.

Diagnostic Evaluation. A detailed health history, both past and present, is essential in evaluating the child with a craniocerebral trauma. Certain disorders, such as medication allergies, hemophilia, diabetes mellitus, or epilepsy, may produce similar symptoms. Even minor traumatic injury can aggravate a pre-existing disease process, thereby producing neurological symptoms out of proportion to the injury. Events surrounding the injury often supply significant data. It must be determined whether the infant or child exhibited alterations in consciousness; any other abnormal signs and behaviours exhibited by the child must be noted. Because head injuries are frequently accompanied by injuries in other areas, the examination needs to be performed with care to avoid further damage.

! NURSING ALERT

Stabilize a child's spine after head injury until a spinal cord injury is ruled out.

Initial assessment. Priorities in the initial stabilization phase of a child with a head injury include assessment of circulation, airway, and breathing; evaluation for shock; and assessment for spinal cord injuries and a neurological examination, focusing on mental status, pupillary responses (symmetry and response to light), and motor responses. The assessment needs to be carried out quickly in relation to vital signs (see Emergency box: Head Injury). Some children may have a rapid pulse, hyperventilate, appear pale, act excited or irritable, and feel clammy shortly after an injury.

EMERGENCY

Head Injury

For head injuries requiring resuscitation:
C—Circulation
A—Airway (with cervical-spine immobilization)
B—Bleeding
Stabilize neck and spine immediately. Use jaw thrust, not chin lift, to open airway if required.
Keep NPO (nothing by mouth) until instructed otherwise.
Assess for the following:

- Loss of consciousness
- Amnesia
- Discomfort (crying) more than 10 minutes after injury
- Headache that is severe, worsening, interferes with sleep
- Fluid leaking from ears or nose
- Blackened eyes
- Vomiting three or more times, beginning after injury, or continuing 4 to 6 hours after injury
- Swelling in front of or above earlobe or increased swelling
- Confusion or abnormal behaviour

Symptoms in a child difficult to arouse from sleep:

- Difficulty speaking
- Blurred vision or diplopia
- Unsteady gait
- Difficulty using extremities, weakness, or incoordination
- Neck pain or stiffness
- Pupils dilated, unequal, or fixed
- Infant with full or bulging fontanel
- Seizures

Do not give analgesics or sedatives.
Check pupil reaction every 4 hours (including twice during night) for 48 hours.
Interventions and treatment:

- Clean any abrasions with soap and water.
- Apply clean dressing.
- If bleeding, apply ice to relieve pain and swelling and to decrease blood flow.

Awaken twice during the night to check level of consciousness.

! NURSING ALERT

Signs of brainstem involvement include deep, rapid, periodic, or intermittent and gasping respirations; wide fluctuations or noticeable slowing of the pulse; and widening pulse pressure or extreme fluctuations in blood pressure. Marked hypotension may represent internal injuries.

Ocular signs such as fixed and dilated unequal pupils, fixed and constricted pupils, and pupils that are poorly reactive or nonreactive to light and accommodation indicate increased ICP or brainstem involvement. It is important to remain with the child who demonstrates fixed and dilated pupils, since these are ominous signs, with the high probability of respiratory arrest. Dilated, nonpulsating blood vessels indicate increased ICP before the appearance of papilledema. Retinal hemorrhages are seen in acute head injuries, including THI-CM.

Less urgent but important additional assessments include examination of the scalp for lacerations, widely separated sutures, and the size and tension of fontanels, which indicate intracranial hemorrhage or rapidly developing cerebral edema. A significant amount of blood loss can occur from scalp lacerations. An underlying skull fracture should be ruled out by CT scan.

! NURSING ALERT

Bleeding from the nose or ears needs further evaluation, and a watery discharge from the nose (rhinorrhea) that is positive for glucose (as tested with Dextrostix) suggests leaking of CSF from a skull fracture.

An accurate assessment of clinical signs provides baseline information. Serial evaluations, preferably by a single observer, help to detect changes in the neurological status. Alterations in mental status, evidenced by increased difficulty in rousing the child, mounting agitation, development of focal lateral neurological signs, or marked changes in vital signs, usually indicate extension or progression of the basic pathological process.

Special tests. After a thorough clinical examination, a variety of diagnostic tests are helpful in providing a more definitive diagnosis of the type and extent of the trauma. The severity of a head injury may not be apparent on clinical examination of a child, but it will be detectable on a CT scan. Whenever the child has a history consistent with a serious head injury (e.g., unrestrained occupant in a severe motor vehicle accident or a fall from a significant height), it is important that a scan be performed even if the child initially appears alert and oriented. All children with head injuries who have any alteration of consciousness, headache, vomiting, skull fracture, seizure, or a predisposing medical condition should also undergo CT scanning.

After a head injury, an MRI may be useful in detecting and evaluating cerebral edema or structural brain abnormalities. A neurobehavioural assessment can assist in identifying any cognitive impairments. Other radiographic tests may be indicated, depending on the severity or cause of the trauma. EEG is not helpful for diagnosis of head injury but is useful for defining seizure activity. Lumbar puncture is rarely used in craniocerebral trauma and is contraindicated in the presence of increased ICP because of the possibility of herniation. See Table 50.1 for a description of tests.

Therapeutic Management

Concussion management. According to the Canadian Paediatric Society (CPS), concussion signs and symptoms may develop within minutes to hours and sometimes even days following an injury. Any child with a head injury should be observed specifically for the signs and symptoms of possible concussion outlined in Table 50.2 (Purcell & CPS, Healthy Active Living and Sports Medicine Committee, 2014/2016). Knowing the signs and symptoms associated with concussions is especially pertinent when determining the status of a young child or infant, who lacks the ability to express their current state.

TABLE 50.2 Signs and Symptoms of Concussion

Physical Signs	Change in Behaviour	Cognitive Impairment (Difficulties Thinking)	Trouble With Sleep
Headache	Irritability	Slowed reaction times	Drowsiness
Nausea/vomiting	Sadness	Confusion	Trouble falling asleep
Changes in sight	Anxiety	Difficulty concentrating	Sleeping more than usual
Loss of consciousness (passing out)	Inappropriate emotions	Difficulty remembering	Sleeping less than usual
Irritation from light			
Irritation from loud sounds			
Loss of balance/ poor coordination			
Amnesia			
Decreased playing ability			

Adapted from Purcell, L. K., & Canadian Paediatric Society, Healthy Active Living and Sports Medicine Committee. (2014). Sport-related concussion: Evaluation and management. *Paediatrics & Child Health, 19*(3), 153–158. Updated 2016. https://www.ncbi.nlm.nih.gov/pmc/articles/PMC3959977/.

Initial concussion management begins with recognition of the injury and the hallmark treatment of rest until the patient is asymptomatic. Clinical manifestations of concussion can be subtle and easily missed by athletes, coaches or trainers, parents, and even health care providers. Often, injured athletes do not recognize the signs or symptoms of a concussion or choose not to get medical treatment. Any child who sustains a concussion needs to be removed from play immediately and undergo a medical assessment as soon as possible. Cognitive and physical rest are recommended to allow symptoms to resolve. Cognitive rest may require a temporary school absence, as well as modified class work or homework. As well, parents should be advised to limit their child's activities, such as reading, texting, watching television, doing computer work, and playing electronic games. After symptoms have entirely resolved at rest, a child can return to school with a medically supervised, stepwise exertion program to return to play (Purcell & CPS, Healthy Active Living and Sports Medicine Committee, 2014/2016).

Most children with mild to moderate concussion who have not lost consciousness can be cared for and observed at home after careful examination reveals no serious intracranial injury. Nurses should provide parents with clear explanations and instructions and should encourage them to ask questions both before and after leaving the medical facility if clarification is needed (see Family-Centred Care box: Maintaining Contact).

FAMILY-CENTRED CARE

Maintaining Contact

Maintaining contact with parents for continued observation and re-evaluation of the child, when indicated, facilitates early diagnosis and treatment of possible complications from head injury, such as hematoma, hydrocephalus, cysts, and post-traumatic seizures. Children are generally hospitalized for 24 to 48 hours' observation if their family lives far from medical facilities or lacks transportation or a telephone that would provide access to immediate help. Other circumstances such as language or other communication barriers, or even emotional trauma, may hinder learning and make it difficult for families to feel confident in caring for their child at home.

The parents should be instructed to check the child every 2 hours to determine any changes in responsiveness. The sleeping child should be wakened to see if they can be roused normally. Parents need to maintain contact with the health care provider, who will usually wish to examine the child again in 1 or 2 days. The manifestations of epidural hematoma in children do not generally appear until 24 hours or more after injury.

Management of severe injuries. Children with severe injuries, those who have lost consciousness for more than a few minutes, and those with prolonged and continued seizures or other focal or diffuse neurological signs must be hospitalized until their condition is stable and their neurological signs have diminished. The child is maintained on nothing by mouth (NPO) or restricted to clear liquids, if able to take fluids by mouth, until it is determined that vomiting will not occur. IV fluids are indicated in the child who is comatose or displays dulled sensorium and in the child with persistent vomiting. The volume of IV fluid is carefully monitored to minimize the possibility of overhydration in cases of SIADH and cerebral edema. However, damage to the hypothalamus or pituitary gland may produce DI with its accompanying hypertonicity and dehydration. Fluid balance is monitored closely by daily weights, accurate intake and output measurements, and serum osmolality to detect early signs of water retention.

Sedating medications are commonly withheld in the acute phase of head injuries. Headaches are usually controlled with acetaminophen, although opioids may be needed. Antiepileptics are used for seizure control. Antibiotics may be administered if lacerations, CSF leakage, or excessive cerebral tissue damage is present. Prophylactic tetanus toxoid is given as appropriate. Cerebral edema is managed as described for the unconscious child.

Surgical therapy. Scalp lacerations are sutured after the underlying bone is carefully examined. Depressed fractures require surgical reduction and removal of bone fragments. Torn dura is sutured. Ping-pong ball skull fractures in very young infants ordinarily correct themselves within a few weeks; however, some larger depressions may require further surgical intervention.

The need for surgical evacuation of the hematoma depends on the physical examination, size of the hematoma, and CT scan abnormalities. Various surgical options to treat subdural hematomas include transfontanel percutaneous aspiration, subdural drains, placement of a burr hole, or craniotomy.

Prognosis. The outcome of craniocerebral trauma depends on the extent of injury and complications. In general, the prognosis is more favourable for children than for adults. More than 90% of children with concussions or simple linear fractures recover without symptoms after the initial period. The prognosis for recovery for more complicated head trauma is primarily related to the duration of coma and the degree of injury. The combination of impaired consciousness and skull fracture carries the highest risk of complication. Outcomes in children with brain injuries are focused increasingly on long-term cognitive, emotional, and emotional issues.

True coma (not obeying commands, eyes closed, and not speaking) usually does not last more than 2 weeks. A child's eventual outcome can range from NDD to a persistent vegetative state to complete recovery. However, even the best recovery may be associated with personality changes, including mood lability and loss of confidence; impaired short-term memory; headaches; and subtle cognitive impairments. Many children are left with significant disabilities after a head injury that appear months later as learning difficulties, behavioural changes, or emotional disturbances (Barlow et al., 2015).

Nursing Care. The hospitalized child requires careful neurological assessment and evaluation (including vital signs) repeated at frequent intervals to provide information needed to establish a correct diagnosis, identify signs and symptoms of increased ICP, determine clinical management, prevent complications, and provide support to the child and family during the recovery phases.

Frequent examinations of vital signs, neurological signs, and LOC are extremely important nursing observations. When possible, they should be performed by a single observer to better detect subtle changes that may indicate worsening neurological status. Pupils are checked for size, equality, reaction to light, and accommodation. After the initial elevations usually seen following injury, the vital signs generally return to normal unless there is brainstem involvement. An axillary measurement of temperature is the safest method, since seizures are not uncommon and vomiting is a frequent response in children, especially when the child is disturbed.

The child is placed on bed rest, usually with the head of the bed slightly elevated and the child's head in a midline position. Appropriate safety measures, such as keeping side rails raised and maintaining seizure precautions, need to be implemented. A quiet environment helps reduce restlessness and irritability and when left undisturbed, many children will fall asleep. For the extremely restless child, hard surfaces may have to be padded and restraints used to prevent the possibility of further injury. Shining bright lights directly into the child's face is irritating and often aggravates the child, making assessment of ocular responses difficult. Care should be individualized according to the child's specific needs.

The most important nursing observation is assessment of the child's LOC. Alterations in consciousness appear earlier in the progression of an injury than alterations of vital signs or focal neurological signs. Some expected responses may be misinterpreted as deviations from normal. Frequent examinations of alertness are fatiguing to the child; thus the child will often want to fall asleep, which may be confused with depressed consciousness. It is not uncommon to observe ocular divergence through the partially closed eyelids.

A key nursing role is to provide sedation and analgesia for the child. The conflict between the need to promote comfort and relieve anxiety in the child versus the need to assess for neurological changes presents a dilemma for the nurse. However, both goals can be achieved with close observation of the child's LOC and response to analgesics, use of a pain assessment record, and effective communication with the health care provider. Decreasing restlessness after administration of an analgesic most likely reflects pain control rather than a declining LOC.

Observations of position and movement provide additional information. Any abnormal posturing should be noted, as well as whether it occurs continuously or intermittently. Questions nurses might consider include the following:

- Are the child's handgrips strong and equal in strength?
- Are there any signs of flexion or extension posturing?
- What is the child's response to stimulation?
- Is movement purposeful, random, or absent?
- Are movement and sensation equal on both sides or restricted to one side only?

The child may communicate having a headache or other discomfort. The child who is too young to describe a headache will be fussy and resist being handled. The child who has vertigo will often assume a position of comfort. Forcible movement causes the child to vomit and display spontaneous **nystagmus**. Seizures, relatively common in children with craniocerebral trauma, may be of any type but are more often generalized, regardless of the type of injury. Any seizure activity should be carefully observed, described in detail, and recorded. Children in postictal (postseizure) states are lethargic, with sluggish pupils.

Drainage from any orifice should be noted. Bleeding from the ear suggests the possibility of a basal skull fracture. Clear nasal discharge suggests an anterior basal skull fracture. The amount and characteristics of drainage should be observed, recorded, and reported.

! NURSING ALERT

Suctioning through the nares is contraindicated because of the risk of the catheter entering the brain parenchyma through a fracture in the skull.

Head trauma is frequently accompanied by other undetected injuries; thus any bruises, lacerations, or evidence of internal injuries or fractures of the extremities need to be noted and reported. Associated injuries should be evaluated and treated appropriately.

The child with normal LOC is usually allowed clear liquids unless fluid is restricted. If the child has an IV infusion, it should be maintained as prescribed. The diet is advanced to that appropriate for the child's age as soon as their condition permits. Intake and output need to be measured and recorded. Any incontinence of bowel or bladder needs to be noted in the child who has achieved toilet independence.

The child should be observed for any unusual behaviour, but it should be interpreted in relation to the child's normal behaviour. For example, urinary incontinence during sleep would be of no consequence for a child who routinely wets the bed but would be highly significant for one who is always dry. Parents are valuable resources in evaluating objective behaviour of their child (e.g., the ease with which the child is roused normally, the usual sleeping position and patterns, motor activities [rolling over, sitting up, climbing], hearing and visual acuity, appetite, and manner of eating [spoon, bottle, cup]).

Family support. The emotional and educational support of the family of children who have suffered head injury presents a challenging aspect to nursing care. The nurse can encourage the family to be involved in the child's care, to bring in familiar belongings, or to make a recording of familiar voices and sounds. Parents may need a demonstration on how to touch or cuddle their child while being connected to monitoring equipment in a critical care unit. They may want to talk about their grief. The nurse can listen attentively, reinforce what is being done to assist the child, and direct parents toward signs and symptoms of recovery. A common phenomenon is for families to seek information from all health care providers, asking, "What will my child be like? What do you know?" as they search for some clue that the child is recovering. Honesty and kindness, along with competent care, can help families through this difficult time.

When the child is discharged, the parents should be advised of probable post-traumatic symptoms that may be expected, such as behavioural changes, sleep disturbances, phobias, and seizures. They should understand observations they need to make and how to contact the health care provider with follow-up questions or concerns. The importance of follow-up evaluation should be emphasized.

Rehabilitation. The rehabilitation and management of the child with acquired brain injury are essential aspects of care. Rehabilitation begins as soon as feasible and usually involves the family and a rehabilitation team. Careful assessment of the child's capabilities, limitations, and potential needs should be made as early as possible and appropriate interventions implemented to maximize the residual capacities. The Rancho Los Amigos Scale provides a **systematic assessment** of the possible progress a child may achieve after a severe head injury (see Additional Resources).

The child with a disability resulting from head trauma requires assessment on a physical, cognitive, emotional, and social level. The child has likely experienced separation, pain, sensory deprivation and overload, changes in circadian cycle, and fear of unfamiliar procedures and environment. Recovery and transition require new coping strategies at the same time that regressive and acting-out behaviour may start. A rehabilitation facility or home rehabilitation is advocated when the child has progressed beyond what can be provided in the hospital setting. The Brain Injury Association of Canada provides information and listings of rehabilitation services and support groups throughout the country (see Additional Resources at the end of this chapter).

Prevention. Tremendous strides have been made in the prevention of cerebral damage after head injury in children. The greatest benefit lies in preventing head injuries from occurring in the first place. Nurses can play a key role in promoting injury prevention. The reason many head injuries continue to occur is that unnecessary risks go unchecked; inadequate supervision combined with a child's natural sense of indestructibility and exploration can lead to lethal results. Nurses are in the unique position to educate caregivers about growth and development expectations and risk management. Public education, coupled with legislative support, can help prevent childhood injuries. (For extensive discussions of childhood injuries and prevention, see Chapter 35.)

One example of proactive legislation regarding prevention of childhood head injury is *Rowan's Law*, which came into effect on July 1, 2019 in Ontario to improve concussion safety in amateur competitive sports. Concussion awareness resources are directed at amateur athletes, parents, coaches, and team trainers, and officials are required to be reviewed by these groups (Government of Ontario, 2019/2020).

Submersion Injury

The term **submersion injury** has replaced the term *near-drowning* and should be used to describe injury occurring up until the time of drowning-related death. This term includes any person who experiences distress from near-drowning submersion or immersion in liquid that results in death (*drowning*) or survival at least 24 hours after submersion (*near-drowning*) (Mott & Latimer, 2016). Submersion injury is a major cause of accidental death in children over 1 year of age. Drowning is the second leading cause of injury-related death for children in Canada. Every year, approximately 60 children drown, and another 140 children must stay in the hospital because they have a submersion injury that can result in long-term health effects (Parachute, 2021a). (See Chapter 35 for more information on water safety.)

Most cases of submersion injury are accidental and usually involve the following situations:

- Children who are helpless in water, such as inadequately attended children in or near swimming pools or infants in bathtubs or containers of fluid
- Small children who fall into ponds, streams, and flooded excavations, usually near home
- Occupants of pleasure boats who fail to wear life preservers
- Children who have diving accidents
- Children who are able to swim but overestimate their endurance
- Accidental drowning occurs five times more often among boys than among girls, almost 40% of children are younger than age 5, and 87% of pool drownings occur in private swimming pools (Lifesaving Society Canada, 2019).
- New immigrants or visitors to Canada, especially those who have been in Canada for less than 5 years, may be more likely to be unable to swim than those born in Canada (Lifesaving Society Canada, 2019).
- Preschoolers are at risk for drowning in swimming pools, and drowning among school-age children and adolescents most commonly occurs in natural bodies of water, such as lakes, ponds, and rivers (Thomas & Caglar, 2020).
- Pools, hot tubs, or whirlpool spas have suction created at the outlet that is strong enough to trap any child, even larger children, underwater.

Pathophysiology. Physiologically most organ systems are affected, especially pulmonary, cardiovascular, and neurological systems. Cerebral hypoxia is the major component of morbidity and mortality with submersion events. Within minutes of a submersion, a lack of oxygen leads to loss of consciousness and progressive decreased cardiac output and ultimately apnea and cardiac arrest (Thomas & Caglar, 2020). Recovery depends on the timeliness and effectiveness of initial resuscitation and subsequent supportive care measures.

Physiological features in submersion injuries are hypoxia, aspiration, and hypothermia. Hypoxia is related to the duration of anoxia and asphyxia. Different cells tolerate variable lengths of anoxia, causing variations of cell damage. Neurons, especially cerebral cells, sustain irreversible damage after 4 to 6 minutes of submersion. The heart and lungs can survive up to 30 minutes. Regardless of the amount of water aspirated, there is arterial hypoxemia (resulting from atelectasis with shunting of blood through the nonventilated alveoli) and a combined respiratory acidosis (resulting from retained carbon dioxide) and metabolic acidosis (caused by buildup of acid metabolites from anaerobic metabolism). Aspiration of fluid occurs in most drownings and is quickly absorbed in the pulmonary circulation, resulting in pulmonary edema, atelectasis, airway spasm, and pneumonitis, which aggravates the hypoxia. Approximately 10% of drowning victims die without aspirating fluid but succumb due to acute asphyxia as a result of prolonged reflex laryngospasm.

Children are at an increased risk of hypothermia because of their large surface area relative to body mass, decreased subcutaneous fat, and limited thermoregulation and partly as a result of the cold water itself (Thomas & Caglar, 2020). Cold water decreases metabolic demands and activates the diving reflex, which causes blood to be shunted away from the periphery and concentrated to the brain and heart. However, prolonged submersion in cold liquids can impair cognition, coordination, and muscle strength, ultimately resulting in a loss of consciousness, decreased cardiac output, and cardiac arrest. Profound hypothermia is usually evidence of lengthy submersion (Thomas & Caglar, 2020).

Therapeutic Management. The outcome of children after a submersion event depends on the circumstances and duration of the submersion and the speed and effectiveness of resuscitation efforts (Thomas & Caglar, 2020). Resuscitative measures should begin at the scene, and the victim should be transported to the hospital with maximal ventilatory and circulatory support. In the hospital critical care is implemented and continued according to the patient's needs.

In general, the management of the submersion injury victim is based on the degree of cerebral insult. The first priority is to restore oxygen delivery to the cells and prevent further hypoxic damage. A spontaneously breathing child does well in an oxygen-enriched atmosphere; the more severely affected child will require endotracheal intubation and mechanical ventilation. Blood gases and pH are monitored frequently as a guide to oxygen, fluid, and electrolyte therapies. Seizures may occur due to hypoxia and cerebral edema.

! NURSING ALERT

All children who have had a submersion injury should be admitted to the hospital for observation. Almost half of asymptomatic or minimally symptomatic alert children experience complications (e.g., respiratory compromise, cerebral edema) during the first 24 hours after the incident (Thomas & Caglar, 2020).

Aspiration pneumonia is a frequent complication that occurs about 48 to 72 hours after the episode. Bronchospasm, alveolocapillary membrane damage, atelectasis, abscess formation, and acute respiratory distress syndrome are other complications that occur after aspiration of fluid.

Prognosis. Studies report that the best predictors of a good outcome are length of submersion for less than 5 minutes and the presence of sinus rhythm, reactive pupils, and neurological responsiveness at the scene. The worst prognoses—death or severe neurological impairment—are for children submerged for more than 10 minutes and not responding to advanced life support within 25 minutes. Most children without spontaneous, purposeful movement and normal brainstem function 24 hours after a submersion injury have sustained severe neurological deficits or death (Thomas & Caglar, 2020).

Nursing Care. Nursing care depends on the child's condition. A child who survives may need intensive respiratory nursing care with attention to vital signs, mechanical ventilation or tracheostomy or both, blood gas determination, and IV infusion. Frequently the child is comatose for an indefinite period and requires the same care as an unconscious child. A difficult aspect in the care of the child victim of submersion injury is helping the parents cope with severe guilt. The magnitude of the event is so great that efforts to provide comfort and support may provide little solace. Parents need to hear that everything possible is being done to treat the child, and this message needs to be repeated often.

The parents of the child who is saved from death are also faced with the anxiety of not knowing what the outcome will be. It is important for these families to know that they are not alone. They need to be reminded frequently that there are caring people to assist them both during the crisis and later. Additional sources of support can include psychiatric and social work consultants, community services, and religious support. Support groups may be beneficial if these are available in the community.

Nurses often have difficulty relating to the parents if obvious neglect has precipitated the accident and subsequent complications. It is important for those who care for these children and their families to assess their own feelings about the situation, as well as the family's coping abilities and resources.

Prevention. Most drownings, particularly of infants or small children, can be prevented with adequate supervision. Water safety and survival training should be required for all school-age children, and nurses can be active advocates for such training in their communities. Nurses are also in a position to emphasize the importance of continuous adult supervision when children are near water. Aquatic programs for infants and toddlers do not decrease the risk of drowning; young children should *never* be left unattended when in or near the water (Parachute, 2021a). Parents with pools should know **cardiopulmonary resuscitation (CPR)** techniques. Pool fencing, pool covers, and personal floatation devices (PFD) are additional ways to protect children (see also Injury Prevention, Chapter 35).

NERVOUS SYSTEM TUMOURS

Brain tumour and neuroblastoma are two major forms of childhood cancer derived from neural tissue. CNS tumours account for approximately 20% of all childhood cancers and occur most often in children under 15 years of age (Canadian Cancer Society [CCS], 2021a). Both of these tumours are difficult to treat and have not demonstrated the dramatic improvements in survival seen in other forms of childhood cancer.

Brain Tumours

Brain tumours are the most common solid tumours in children and are the second most common type of childhood cancer. The CCS (2021a) reported that, from 2012 to 2016, 745 Canadian children aged 0 to 14 years were diagnosed with childhood brain and spinal cord cancer. About 60% of the tumours are infratentorial (below the tentorium cerebelli), which means they occur in the posterior part of the brain, primarily in the cerebellum or brainstem. This anatomical distribution accounts for the frequency of symptoms resulting from increased ICP.

Because the neoplasms can arise from any cell within the cranium, it is possible to have tumours originating from the glial cells, nerve cells, neuroepithelium, cranial nerves, blood vessels, pineal gland, and hypophysis. Within each of these structures, specific cells may be involved to provide a histological classification of the major tumours found in children. Astrocytes, cells that form most of the supportive tissue for the neurons, may form astrocytomas, which is the most common glial tumor (Parsons et al., 2016). Brain tumours may be benign or malignant, although the designation of any tumour in the brain as "benign" should be done cautiously given the vital functions the brain controls.

Clinical Manifestations. The signs and symptoms of brain tumours are directly related to their anatomical location and size and, to some extent, the child's age. For instance, in infants whose sutures are still open, a bulging fontanel indicates hydrocephalus. Head circumference measurements allow for detection of increased head size. In infants and very young children whose cranial sutures are still open, initial signs and symptoms of increased ICP (headache, vomiting, and lethargy) may not be evident and symptoms may include irritability, failure to thrive, and loss of developmental milestones. Even in older children, clinical manifestations may be nonspecific. However, the most common symptoms of infratentorial brain tumours are headache, especially on awakening, and vomiting that is not related to feeding. Tumours in this area of the brain often obstruct the flow of CSF, causing increased ICP and the symptoms mentioned earlier. In addition, patients may have symptoms related to the specific structure involved. Tumours of the cerebellum often cause nystagmus, ataxia, dysarthria, and dysmetria. Supratentorial symptoms more commonly include seizures, personality or behavioural changes, visual disturbances, and hemiparesis. Tumours involving the structures of the midbrain, including the hypothalamus and pituitary gland, may cause endocrinopathies, such as diabetes insipidus, delayed or precocious puberty, and growth failure.

Diagnostic Evaluation. Diagnosis of a brain tumour is based subjectively on presenting clinical signs, objectively on neurological tests, and histological diagnosis via surgery. Because the signs and symptoms are vague and easily overlooked, early diagnosis relies on a high index of suspicion during history taking. A number of tests may be used in the neurological evaluation, but the gold standard diagnostic procedure is MRI, which enables early diagnosis of brain tumours and assessment of tumour growth during or after treatment. Other tests include CT, angiography, electroencephalography, and lumbar puncture (see Table 50.1). The definitive diagnosis is based on brain tissue specimens obtained during surgery. Occasionally, special techniques are required for determining the cell type. This period of waiting is one of anxiety for family members who are aware of the link between cell type and prognosis. Because of the location of some brain tumours (e.g., brainstem tumours), a biopsy is not possible and the diagnosis is made by imaging findings alone.

Therapeutic Management. Treatment may involve the use of surgery, radiotherapy, and chemotherapy or a combination of these treatment modalities, depending on the type of tumour. The optimal treatment is total removal of the tumour without residual neurological damage. Patients with the most complete tumour removal have the greatest chance of survival. Radiation therapy is used to treat most tumours and to shrink the size of the tumour before attempting surgical removal but can cause significant neurocognitive adverse effects and endocrinopathies. Because rapid brain development occurs during the first few years of life, radiation therapy, particularly craniospinal radiation, is avoided in children younger than 3 years of age. Radiation therapy is delayed until patients are older and may experience fewer neurocognitive adverse effects. Chemotherapy may be used as primary treatment or in combination with surgery and/or radiation. One of the challenges in using chemotherapy for CNS tumours is the blood–brain barrier, which is a natural barrier that significantly influences the penetration of substances into the CNS. Chemotherapy is also used as adjunct therapy for residual tumour, nonresectable tumour, or recurrent tumour.

Prognosis. The prognosis for a child with a brain tumour varies greatly and depends on the type of brain tumour, the size of the tumour, the extent of the disease, the child's age, and surgical resectability. Recent advances in surgical instrumentation allowing aggressive surgical intervention (e.g., stereotactic surgery, radiosurgery), modifications in radiation (e.g., hyperfractionation, brain mapping), and use of chemotherapy (e.g., intrathecal, intratumoural) have increased the long-term survival rates for many children with brain tumours (Parsons et al., 2016). Currently, the overall survival rate for children with CNS tumours who are younger than 15 years of age is approximately 72% (CCS, 2021a). Despite an improvement in overall survival, children with brain tumours, particularly those who are very young at diagnosis, may have significant physical, cognitive, and endocrinological sequelae because of their tumour and associated treatment.

Nursing Care. If a brain tumour is suspected in a child admitted to the hospital for cerebral dysfunction, establishing baseline data with which to compare preoperative and postoperative changes is an essential step. It also allows the nurse to assess the degree of physical incapacity and the family's reaction to the diagnosis.

Vital signs, including pulse pressure (the difference between systolic and diastolic pressures), need to be taken routinely and more often when any change is noted. Any sudden variations should be reported immediately. Observation for symptoms of Cushing triad (i.e., hallmark sign of increased ICP, which includes bradycardia, hypertension, and irregular respirations) is a crucial role of the nurse. It is especially important to note a change in vital signs during or after diagnostic procedures. A routine neurological assessment is performed at the same time as taking vital signs, and head circumference is measured on infants and very young children. The child should be observed for evidence of headache, vomiting, and any seizure activity. The location, severity, and duration of the headache need to be noted, as well as its relationship to activity and time of day and any associated factors noted. Behaviours such as lying flat and facing away from light or refusing to engage in play are clues to discomfort in the nonverbal child. The child's gait should be observed at least once daily. Head tilt while talking or performing an activity and other changes in posturing are always noted.

Preventing postoperative complications. Usually the surgeon will prescribe specific orders for vital signs, neurological checks, positioning, fluid regulation, and medication. These vary somewhat, depending on the location of the craniotomy. The following discussion addresses general principles of care for infratentorial or supratentorial surgery. Additional aspects of care that are discussed elsewhere may include care of the child with seizures and neurological assessment of the unconscious child.

Assessment. Vital signs should be taken as frequently as every 15 to 30 minutes until the child is stable. Temperature measurement is particularly important because of hyperthermia resulting from surgical intervention in the hypothalamus or brainstem and from some types of general anaesthesia. To prepare for this reaction, a cooling blanket should be placed on the bed before the child returns to the unit so that it is ready for use if required. The temperature needs to be monitored carefully when any cooling measures are taken because hypothermia can occur suddenly. Recognizing signs of other complications such as increased ICP, meningitis, and respiratory tract infection is imperative.

Dressings need to be observed for evidence of drainage. If soiled, the dressing is not removed but is reinforced with dry sterile gauze. The approximate amount of drainage should be estimated and recorded. A drain may be placed in the operative site. The presence of colourless drainage should be reported immediately, since it most likely is CSF from the incisional area. A foul odour from the dressing may indicate an infection. Such a finding should be reported, and the nurse should anticipate that a culture will be taken from the site. The most likely types of infection are meningitis and respiratory tract infection. The probable cause of meningitis is wound contamination. The risk for respiratory tract infections is high because of the imposed immobility, danger of aspiration, and possible depression from the brainstem. The usual precautions of deep breathing and turning as allowed are instituted. Regular pulmonary assessments are performed to identify adventitious sounds or any areas of diminished or absent breath sounds.

As soon as possible, the nurse should begin testing reflexes, handgrip, and functioning of the cranial nerves. Muscle strength is usually less after surgery because of general weakness but should improve daily. Ataxia may be significantly worse with cerebellar intervention, but it slowly improves. Edema near the cranial nerves may depress important functions, such as the gag, blink, or swallowing reflex.

Neurological checks are an essential aspect of care and include pupillary reaction to light, LOC, sleep patterns, and response to stimuli. Although children may be less responsive for a few days after surgery, when they regain full consciousness there should be a steady increase in alertness. Regression to a lethargic, irritable state indicates increasing pressure, possibly caused by hemorrhage, meningitis, or cerebral edema.

! NURSING ALERT

Sluggish, dilated, or unequal pupils need to be reported immediately because they may indicate increased ICP and potential brainstem herniation, a medical emergency.

! NURSING ALERT

To keep an accurate account of drainage, the soiled area is circled with a pen approximately every hour. In this way, continuous bleeding is easily recognized.

Positioning. Correct positioning after surgery is critical to prevent pressure against the operative site, reduce ICP, and avoid the danger of aspiration. If a large tumour was removed, the child should not be placed on the operative side, since the brain may suddenly shift to that cavity, causing trauma to the blood vessels, linings, and the brain itself. The nurse should confer with the surgeon to be certain of the correct position, including degree of neck flexion. The first 24 to 48 hours after brain surgery are critical. If the child's position is restricted, notice of this should be posted above the head of the bed. When the child is turned, every precaution should be taken to prevent jarring or malalignment and to prevent undue strain on the sutures. Two nurses are needed for repositioning the child—one supporting the head and the other supporting the body. The use of a turning sheet may facilitate turning a heavy child.

The child with an infratentorial procedure is usually positioned on either side with the bed flat. When a supratentorial craniotomy is performed, the head of the bed is elevated 20 to 30 degrees with the child on either side or on their back. In a supratentorial craniotomy the head elevation facilitates CSF drainage and decreases excessive blood flow to the brain to prevent hemorrhage. Pillows should be placed against the child's back, not head, to maintain the desired position. Ordinarily the head and neck are kept in midline with the body, and the neck should not be flexed to support venous drainage.

! NURSING ALERT

The Trendelenburg position is contraindicated in both infratentorial and supratentorial surgeries because it increases ICP and the risk of hemorrhage. If shock is impending, a primary health care provider knowledgeable of the child's condition should be notified immediately, before the head is lowered.

Fluid regulation. With an infratentorial craniotomy, the child is allowed nothing by mouth for at least 24 hours, or longer if the gag and swallowing reflexes are depressed or the child is comatose. With a supratentorial operation, cranial neuropathy is less likely, and clear fluids may be resumed soon after the child is alert, sometimes within 24 hours. If the child vomits, oral liquids are stopped. Vomiting not only predisposes the child to aspiration but also increases ICP and the potential for incisional rupture.

IV fluids should be continued until oral fluids are well tolerated or enteral feeding is established. Because of the postoperative cerebral edema and danger of increased ICP, fluid status needs to be carefully monitored. A hypertonic solution such as mannitol may be necessary to remove excess fluid. These medications cause rapid diuresis. Urinary output is monitored after administration of these medications to evaluate their effectiveness.

Comfort measures. Headache may be severe and is largely a result of cerebral edema. Measures to relieve some of the discomfort include providing a quiet, dimly lit environment; limiting visitors; preventing any sudden jarring movements, such as banging into the bed; and preventing an increase in ICP. Avoiding increased ICP is most effectively achieved by proper positioning and prevention of straining, such as during coughing, vomiting, or defecating.

The use of opioids, such as morphine, to relieve pain is controversial because they may mask signs of altered consciousness or depress respirations. However, they can be given safely, since naloxone can be used to reverse opioid effects, such as sedation or respiratory depression. Acetaminophen is also an effective analgesic for mild to moderate pain. The nurse must be aware that acetaminophen can mask a fever, which could indicate postoperative infection. Regardless of the medications used, adequate dosage and regular administration are essential to providing optimal pain relief (see also Pain Assessment; Pain Management, Chapter 34).

Constipation is a common postoperative issue because of anaesthesia and immobility, and the use of opioids for pain control may further contribute to constipation. Patients should be given a bowel regimen during the postoperative period until normal bowel function returns.

Brain edema may severely depress the gag reflex, necessitating suctioning of oral secretions. Facial edema may also be present, thus eye care is required if the lids remain partially open. Ice compresses applied to the eyes for short periods help relieve the edema. A depressed blink reflex also predisposes the corneas to ulceration. Irrigating the eyes with saline drops and covering them with eye dressings are important steps in preventing this complication.

Supporting the child and family. The family's emotional needs are immense when the diagnosis is a brain tumour; feelings can be influenced by the extent of surgery, any neurological deficits, the expected prognosis, and additional therapy. Since few definitive answers can be given before surgery, the surgeon's report is a significant finding that can vary from a completely benign, resected neoplasm to a highly malignant, invasive, and only partially removed tumour. Although parents often try to prepare themselves for the worst possible scenario, being given the news that their child has a potentially fatal tumour or may have significant neurological impairment from the necessary treatment is always devastating.

Parents should be encouraged to express their feelings about the diagnosis. During this period, the nurse should also discuss with parents what they plan to tell the child. If the child was prepared honestly, the diagnosis can be expressed in an age-appropriate manner. During recovery the child will need additional explanation about the treatment and the reason for any residual neurological effects, such as ataxia or blindness. Hair loss is a normal concern for the child, and its regrowth will be delayed, depending on the length of therapy. The increasing availability of child life specialists has served as a useful resource in explaining diagnoses such as brain tumours to children and helping them cope with hospitalization and necessary treatment and to understand physical sequelae they may experience.

Neuroblastoma

Neuroblastomas are the most common malignant extracranial solid tumours in children and account for 8 to 10% of all childhood cancers (Harrison & Ater, 2020). In Canada, from 2012 to 2016, there were 160 children and youths ages 0 to 14 years who were newly diagnosed with an endocrine system cancer, of which neuroblastoma is considered (CCS, 2021b). Approximately 90% of children with neuroblastoma manifest the disease before 5 years of age, with a median age of occurrence at 22 months (Harrison & Ater, 2020). The incidence is slightly higher in boys and in White populations.

These tumours originate from embryonic neural crest cells that normally give rise to the adrenal medulla and the sympathetic ganglia. Consequently, most tumours develop in the abdomen along the adrenal gland or the retroperitoneal sympathetic chain. Other sites may be in the head, neck, chest, or pelvis.

Clinical Manifestations. The signs and symptoms of neuroblastoma depend on the location and stage of the disease. Neuroblastoma is commonly referred to as a "silent" tumour because approximately half of the patients present with localized disease and display few symptoms. Children with advanced disease, by contrast, are ill appearing, with symptoms of periorbital ecchymoses, proptosis, bone pain, and irritability caused by extensive tumour metastasis usually in the lymph nodes, bone marrow, skeletal system, skin, or liver (Harrison & Ater, 2020).

Opsoclonus-myoclonus-ataxia syndrome (OMAS) syndrome is a rare neurological syndrome that can affect 2 to 3% of patients with neuroblastoma. This paraneoplastic syndrome can cause symptoms of abnormal eye movements (opsoclonus), brief muscle jerks (myoclonus), cerebellar ataxia, irritability, and speech issues. Treatment includes resection of the tumour and anti-inflammatory therapies for the associated OMAS syndrome treatment.

Diagnostic Evaluation. The objective of diagnosis is to locate the primary site and areas of metastasis. A CT scan of the abdomen, pelvis, or chest is the preferred imaging modality to locate the primary tumour. A bone scan and metaiodobenzylguanidine (MIBG) scan are performed to evaluate for the presence of skeletal metastases. Examination of the bone marrow with bilateral aspirates and biopsies should be performed on all patients. Neuroblastomas, particularly those arising in the adrenal glands or from a sympathetic chain, excrete the catecholamines epinephrine and norepinephrine. Urinary excretion of catecholamines is detected in approximately 95% of children with adrenal or sympathetic tumours. Amplification of proto-oncogene, known as the *N-Myc* gene, and chromosomal abnormalities correlate strongly with advanced-stage disease, rapid tumour progression, and a poor prognosis (Brodeur et al., 2016).

Staging and Prognosis. The child's age and the stage of the disease (Box 50.4) at diagnosis are important prognostic factors. Because of the frequency of invasiveness, the prognosis for neuroblastoma is generally poor. Survival is inversely correlated with age. If all stages are grouped together, the survival rates are approximately 80% for children younger than 1 year of age and less than 50% for children older than 1 year of age (Brodeur et al., 2016). This marked difference in survival rates by age is partly accounted for by the larger proportion of very young children with stage I, II, or IV-S disease and the absence of the *N-Myc* gene amplification.

Infants who remain free from disease for 1 year after treatment are usually cured, but older children have experienced relapses several years after cessation of treatment. Surgical resection of the tumor in stage I appears to be greater than 90% curative (Brodeur et al., 2016). Stage IV-S neuroblastoma is one of the few tumors that demonstrate spontaneous regression, possibly as a result of maturity of the embryonic cell or development of an active immune system.

Therapeutic Management. Accurate clinical staging is important for establishing initial treatment. Therefore, the purpose of surgery is used both to remove as much of the tumour as possible and to obtain biopsies. In early stages, complete surgical removal of the tumour is the treatment of choice. If the tumour is large, partial resection is attempted, with a course of irradiation postoperatively to shrink the

BOX 50.4 Staging of Neuroblastoma

Stage I: Localized tumour that is confined to the area of origin capable of complete gross excision; representative ipsilateral lymph nodes negative for tumour microscopically (nodes that are attached to and removed with the primary tumour may be positive)

Stage II-A: Unilateral tumour with incomplete gross resection; representative ipsilateral nonadherent lymph nodes and contralateral lymph nodes negative for tumour microscopically

Stage II-B: Unilateral tumour with or without complete gross excision, with ipsilateral nonadherent lymph nodes positive for tumour; enlarged contralateral lymph nodes must be negative microscopically

Stage III: Tumour infiltrating across the midline, with or without regional lymph node involvement; or localized unilateral tumour with contralateral regional lymph node involvement; or midline tumour with bilateral lymph node involvement

Stage IV: Dissemination of tumour to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs

Stage IV-S: Localized primary tumour (as defined for stage I, II-A, or II-B) with dissemination limited to liver, skin, or bone marrow but not to bone

tumour in the hope of complete removal at a later date. Surgery is usually limited to biopsy in stages III and IV because of the extensive metastasis.

The precise role of radiotherapy is unclear. It does not appear to be of any benefit in children with stage I and II disease. It is can be used with stage III disease, although it may not improve survival expectancy. Radiotherapy for paraspinal neuroblastoma is no longer recommended because the radiation therapy has long-term morbidity, and chemotherapy is a safe and effective initial treatment modality (Brodeur et al., 2016).

Chemotherapy is the mainstay of therapy for extensive local or disseminated disease. The medications are administered in a variety of combinations according to specific protocols. In addition, the use of consolidative myeloablative therapy using autologous marrow or peripheral stem cells followed by retinoic acid has improved the outcomes of patients with high-risk disease.

Nursing Care. Nursing considerations are similar to those discussed for leukemia and brain tumours, including psychological and physical preparation for diagnostic and operative procedures; prevention of postoperative complications for abdominal, thoracic, or cranial surgery; and explanation of chemotherapy, radiotherapy, and their adverse effects (see Chapter 48).

Because this tumour carries a poor prognosis for many children, the family should be assessed for how they are coping with a life-threatening illness. Because of the sometimes high degree of metastasis at the time of diagnosis, many parents suffer substantial guilt for not having recognized signs earlier. Parents need much support in dealing with these feelings and expressing them to the appropriate people.

INTRACRANIAL INFECTIONS

The CNS is subject to infection by the same organisms that affect other organs of the body. However, the nervous system is limited in the ways in which it responds to injury. Laboratory studies are needed to identify the causative agent. The inflammatory process can affect the meninges (meningitis) or brain (encephalitis), causing a variety of neurological symptoms, including behavioural changes, changes to LOC, and seizures.

While meningitis can be caused by a variety of organisms, the three main types are (1) bacterial, or pyogenic, caused by pus-forming bacteria, especially meningococci, pneumococci, and *Haemophilus* organisms; (2) viral, or aseptic, caused by a wide variety of viral agents; and (3) tuberculous, caused by the *tuberculin bacillus*. Most children with acute febrile intracranial infections have either bacterial meningitis or viral meningitis as the underlying cause.

Bacterial Meningitis

Bacterial meningitis causes acute inflammation of the meninges and CSF. Suspected bacterial meningitis is a medical emergency, and immediate action must be taken to identify the causative organism and to initiate prompt treatment. It remains a significant cause of illness in the pediatric age groups because of the residual damage caused by undiagnosed and untreated or inadequately treated cases. Overall, the incidence rate is highest among children less than 1 year of age and then declines as age increases, except for a smaller peak in the 15- to 19-year age group, with an increased mortality risk in the adolescent and young adult. Invasive meningococcal disease is found worldwide. An average of almost 200 cases per year occur in Canada (Government of Canada, 2014).

Bacterial meningitis can be caused by a variety of bacterial agents, although the epidemiology of meningitis in Canada has been influenced dramatically by universal immunization programs delivering conjugate vaccines for *Haemophilus influenzae* type b (Hib), *Neisseria meningitidis*, and *Streptococcus pneumoniae* (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2020). The advent of antimicrobial therapy has had a significant effect on the overall clinical course and prognosis of children with bacterial meningitis.

Despite the dramatic decline in incidence of bacterial meningitis, this disease can still result in death, with a fatality rate of approximately 6.9% in children. The incidence is highest among patients younger than 2 months of age, with group B streptococcus (GBS) being the most common causative organism. In Canada, meningococcal outbreaks are almost exclusively due to serogroup C *Neisseria meningitidis*. Other causative organisms include beta-hemolytic streptococci, *Staphylococcus aureus*, and *Escherichia coli*.

Meningococcal meningitis occurs in epidemic form and is the only type readily transmitted by droplet infection from nasopharyngeal secretions. Although this condition may develop at any age, the risk of meningococcal infection increases with the number of contacts; therefore, it occurs predominantly in school-age children and adolescents. Postsecondary students, especially those living in dormitory residences, are at moderately increased risk for meningococcal disease compared with other people their age. There appear to be some seasonal variations in etiology. Meningitis caused by *H. influenzae* occurs primarily in autumn or early winter. Pneumococcal and meningococcal infections can occur at any time but are more common in later winter or early spring.

Pathophysiology. The most common route of infection is vascular dissemination from a focus of infection elsewhere. For example, organisms from the nasopharynx invade the underlying blood vessels, cross the blood–brain barrier, and multiply in the CSF. Invasion by direct extension from infections in the paranasal and mastoid sinuses is less common. Organisms also gain entry by direct implantation after penetrating wounds, skull fractures that provide an opening into the skin or sinuses, lumbar puncture or surgical procedures, anatomical abnormalities such as spina bifida, or foreign bodies such as an internal

ventricular shunt or an external ventricular device. After implanting, the organisms spread into the CSF, by which the infection spreads throughout the subarachnoid space.

The infective process is like that seen in any bacterial infection: inflammation, exudation, white blood cell accumulation, and varying degrees of tissue damage. The brain becomes hyperemic and edematous, and the entire surface of the brain is covered by a layer of purulent exudate that varies with the type of organism. For example, meningococcal exudate is most marked over the parietal, occipital, and cerebellar regions; the thick, fibrinous exudate of pneumococcal infection is confined chiefly to the surface of the brain, particularly the anterior lobes; and the exudate of streptococcal infections is similar to that of pneumococcal infections, but thinner. As infection extends to the ventricles, thick pus, fibrin, or adhesions may occlude the narrow passages and obstruct the flow of CSF.

Clinical Manifestations. The onset of illness may be abrupt and rapid, or it may develop progressively over 1 day or several days, and may be preceded by a febrile illness. Most children with meningitis present with fever, chills, headache, and vomiting that are quickly followed by alterations in the sensorium; however, some may present only with lethargy and irritability. The child is extremely irritable and agitated and may develop seizures, photophobia, confusion, hallucinations, drowsiness, stupor, or coma (Box 50.5). Nuchal rigidity is manifested by inability to flex the neck and place the chin on the chest and by the presence of Kernig and Brudzinski signs. The Kernig sign is present if the patient, in the supine position with the hip and knee flexed at 90 degrees, cannot extend the knee more than 135 degrees and pain is felt in the hamstrings. Flexion of the opposite knee may also occur. The Brudzinski sign is present if the patient, while in the supine position, flexes the lower extremities if passive flexion of the neck is attempted (Ball et al., 2015).

! NURSING ALERT

Any child who is ill and develops a purpuric or petechial rash may have (overwhelming) meningococcemia and must receive medical attention immediately.

Diagnostic Evaluation. A lumbar puncture is the definitive diagnostic test for meningitis. The CSF pressure is measured, and samples are obtained for culture, Gram stain, blood cell count, and determination of glucose and protein content. The findings are usually diagnostic. Culture and sensitivity testing are needed to identify the causative organism. Spinal fluid pressure is usually elevated, but interpretation is often difficult when the child is crying. Sedation with fentanyl and midazolam can alleviate the child's pain and fear associated with this procedure. If there is evidence or suspicion of increased ICP (papilledema, focal neurological deficits, bulging fontanel), a CT scan of the head may be warranted before the procedure. Lumbar puncture is contraindicated in any patient with imaging to suggest that the procedure is not safe (e.g., midline shift, mass effect, transependymal migration of CSF).

BOX 50.5 Clinical Manifestations of Bacterial Meningitis

Children and Adolescents

Usually abrupt onset
Fever
Chills
Headache
Vomiting
Alterations in sensorium
Seizures (often the initial sign)
Irritability
Agitation
May develop:
- Photophobia
- Delirium
- Hallucinations
- Aggressive behaviour
- Drowsiness
- Stupor
- Coma

Nuchal rigidity: May progress to opisthotonos
Positive Kernig and Brudzinski signs
Hyperactive but variable reflex responses
Signs and symptoms peculiar to individual organisms:
- Petechial or purpuric rashes (meningococcal infection), especially when associated with a shocklike state
- Joint involvement (meningococcal and *Haemophilus influenzae* infection)
- Chronically draining ear (pneumococcal meningitis)

Infants and Young Children

Classic picture (above) is rarely seen in children between 3 months and 2 years of age
Fever
Poor feeding
Vomiting
Marked irritability
Frequent seizures (often accompanied by a high-pitched cry)
Bulging fontanel
Nuchal rigidity (may or may not be present)
Brudzinski and Kernig signs not helpful in diagnosis (difficult to elicit and evaluate in this age group)
Subdural empyema (*H. influenzae* infection)

Newborns: Specific Signs

Extremely difficult to diagnose
Manifestations vague and nonspecific
Well at birth but within a few days begins to look and behave poorly
Refusal of feedings
Poor sucking ability
Vomiting or diarrhea
Poor tone
Lack of movement
Weak cry
Full, tense, and bulging fontanel sometimes appearing late in course of illness
Neck usually supple

Newborns: Nonspecific Signs That May Be Present

Hypothermia or fever (depending on the infant's maturity)
Jaundice
Irritability
Drowsiness
Seizures
Respiratory irregularities or apnea
Cyanosis
Weight loss

The patient with meningitis generally has an elevated white blood cell count in the CSF, often predominantly polymorphonuclear leukocytes. Typically in bacterial meningitis the CSF glucose level is reduced, generally in proportion to the duration and severity of the infection. Protein concentration is usually increased.

A blood culture is advisable for all children suspected of having meningitis and occasionally will be positive when CSF culture is negative. Nose and throat cultures may provide helpful information in some cases.

Therapeutic Management. Acute bacterial meningitis is a medical emergency that requires early recognition and immediate institution of therapy to prevent death or residual disabilities. The initial therapeutic management includes the following:

- Isolation precautions
- Initiation of antimicrobial therapy
- Maintenance of hydration
- Maintenance of ventilation
- Reduction of increased ICP
- Management of systemic shock
- Control of seizures
- Control of temperature
- Treatment of complications

The child should be placed in respiratory isolation and is usually in a critical care unit for close observation. An IV infusion is started to facilitate the administration of antimicrobial agents, fluids, antiepileptic medications, steroids, and blood, if needed.

Medications. Until the causative organism is identified, the choice of antibiotic is based on the known sensitivity of the organism most likely to be the infective agent. After identification of the organism, antimicrobial agents are adjusted accordingly.

Dexamethasone can be used as an adjunctive treatment for children older than 6 weeks of age with suspected bacterial meningitis (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2020). It should not be used if aseptic or nonbacterial meningitis is suspected. The role of steroids in the management of acute bacterial meningitis in children continues to be debated, except in the case of Hib meningitis, for which there is evidence that steroids decrease hearing impairment in children if they are administered just before or with the initial antimicrobial therapy (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2020). Signs of gastrointestinal hemorrhage or secondary infection may complicate steroid administration. Antibiotic treatment with cephalosporins demonstrates superiority for promptly sterilizing the CSF and reducing the incidence of severe hearing impairment.

Nonspecific measures. Maintaining hydration is a primary concern; IV fluids and the type and amount of fluid are determined by the patient's condition. Children with bacterial meningitis must be monitored for electrolyte and fluid abnormalities. The optimum hydration involves correction of any fluid deficits followed by fluid restriction until normal serum sodium levels and no signs of increased ICP are present. If needed, measures to decrease ICP are implemented (see discussion earlier in this chapter). Long-term fluid restriction is not the standard of care because a lack of adequate fluid volume can reduce blood pressure and cerebral perfusion pressure, causing CNS ischemia (Janowski & Hunstad, 2020).

Complications need to be treated appropriately, such as aspiration of subdural effusion in infants and disseminated intravascular coagulation syndrome. Shock is managed by restoration of circulating blood volume and maintenance of electrolyte balance. Seizures can occur during the first few days of treatment. These are controlled with the appropriate antiepileptic medication. Hearing impairment is common. Audiology assessment should be performed as soon as possible after diagnosis of meningitis for all children affected (and always before discharge from hospital) to optimize management in the event of hearing impairment, and follow-up evaluation needs to be done (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2020).

Lumbar puncture is carried out as needed to determine the effectiveness of therapy. The patient should be evaluated neurologically during the convalescent period.

Prognosis. Approximately 10% of cases of bacterial meningitis are fatal (Government of Canada, 2014). The child's age, the duration of illness before antibiotic therapy, rapidity of diagnosis after onset, type of organism, and adequacy of therapy are important in the prognosis for bacterial meningitis. Survivors can experience significant physical and neurological sequelae, including hearing impairment, cognitive impairment, recurrent seizures, delay in acquisition of language, visual impairment, and behavioural issues (Janowski & Hunstad, 2020).

The prognosis is worse among infants younger than 6 months of age and in those with a high bacterial burden in their CSF. Those with seizures occurring more than 4 days into therapy or with coma or focal neurological signs on presentation also have an increased risk of long-term sequelae (Janowski & Hunstad, 2020). The residual deficits in infants are primarily a result of communicating hydrocephalus and the greater effects of cerebritis on the immature brain. In older children, the residual effects are related to the inflammatory process itself or result from vasculitis associated with the disease.

Prevention. In Canada, meningococcal C conjugate vaccines are recommended for routine immunization of infants, children aged 1 to 4 years, and adolescent and young adults, to prevent the increased risk of serogroup C meningococcal disease in these age groups. The recommended schedule differs depending on the vaccine used. For children at least 5 years of age who have not reached adolescence, immunization with a single dose of MenC-conjugate vaccine may also be considered. A single dose is required for any person at least 1 year of age. Routine vaccinations for Hib and pneumococcal conjugate vaccine are recommended for all children beginning at 2 months of age (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2020; Government of Canada, 2021) (see Immunizations, Chapter 35).

Nursing Care. The room should be kept as quiet as possible and environmental stimuli kept to a minimum, because most children with meningitis are sensitive to noise, bright lights, and other external stimuli. Most children are more comfortable without a pillow and with the head of the bed slightly elevated. A side-lying position is more often assumed because of nuchal rigidity. The nurse should avoid actions that cause pain or increase discomfort, such as lifting the child's head. Evaluating the child for pain and implementing appropriate relief measures are important during the initial 24 to 72 hours. Acetaminophen or ibuprofen are often used. The nurse should determine if a patient is febrile before giving acetaminophen or ibuprofen because either of these medications may mask a fever, which is an important clinical indication of infection. Measures to ensure the child's safety should be observed, because the child is often restless and subject to seizures.

The nursing care of the child with meningitis is determined by the child's symptoms and treatment. Observation of vital signs, neurological signs, LOC, urine output, and other pertinent data needs to be carried out at frequent intervals. The child who is unconscious is managed as described previously (see discussion earlier in chapter), and all children are observed for signs of the complications described in Box 50.5, especially increased ICP, shock, or respiratory distress. Frequent assessment of the open fontanels is needed in the infant because

subdural effusions and obstructive hydrocephalus can develop as a complication of meningitis.

! NURSING ALERT

A major priority of nursing care of a child suspected of having meningitis is to administer antibiotics as soon as they are ordered. The child is placed on respiratory isolation for at least 24 hours after initiation of antimicrobial therapy.

Fluids and nourishment are determined by the child's status. The child with dulled sensorium is usually given nothing by mouth. Other children are allowed clear liquids initially and, if these are tolerated, progress to a diet suitable for their age. Careful monitoring and recording of intake and output are needed to determine deviations that might indicate impending shock or increasing fluid accumulation, such as cerebral edema or subdural effusion.

One of the most difficult challenges in the nursing care of children with meningitis is maintaining IV infusion for the length of time needed to provide adequate antimicrobial therapy (usually 10 days). Because continuous IV fluids are usually not necessary, an **intermittent infusion device** is used. In some cases, children who are recovering uneventfully are sent home with the device, and the parents are taught IV medication administration.

Supporting the family. The sudden nature of the illness makes emotional support of the child and parents extremely important. Parents are upset and concerned about their child's condition and often feel guilty for not having suspected the seriousness of the illness sooner. They need reassurance that the natural onset of meningitis is sudden and that they acted responsibly in seeking medical assistance when they did. The nurse should encourage the parents to openly discuss their feelings to minimize blame and guilt. They also need to be kept informed of the child's progress and of all procedures, results, and treatments. In the event that the child's condition worsens, they need the same psychological care as parents who face the possible death of their child (see Chapter 41).

Nonbacterial (Aseptic) Meningitis

The term *aseptic meningitis* refers to the onset of meningeal symptoms, fever, and pleocytosis without bacterial growth from CSF cultures. Aseptic meningitis is caused by many different viruses, including arbovirus, herpes simplex virus (HSV), cytomegalovirus, adenovirus, and HIV. Enteroviruses are the most common cause of viral meningitis (Janowski & Hunstad, 2020). Viral meningitis can occur at any age but is most common in the very young child. It has many of the same presenting signs and symptoms as bacterial meningitis, including headache, fever, photophobia, and nuchal rigidity. It can also be accompanied by cutaneous and mucosal manifestations of enterovirus, including hand, foot, and mouth syndrome, herpangina, and maculopapular rash. The onset may be abrupt or gradual. Signs of meningeal irritation develop 1 or 2 days after the onset of illness. Onset is more insidious in infants and toddlers. Signs and symptoms are vague and are often thought to be associated with a minor illness. The clinical course of viral meningitis is much shorter and typically without any significant complications.

Diagnosis is based on clinical features and CSF findings. Variations in CSF values in bacterial and viral meningitis are listed in Table 50.3. It is important to differentiate this self-limited disorder from the more serious forms of meningitis.

Treatment is primarily symptomatic, such as acetaminophen for headache and muscle pain, maintenance of hydration, and positioning for comfort. Until a definitive diagnosis is made, antimicrobial agents may be administered and isolation enforced as a precaution against the possibility that the disease might be of bacterial origin. Nursing care is similar to the care of the child with bacterial meningitis.

TABLE 50.3 Variation of Cerebrospinal Fluid Analysis in Bacterial and Viral Meningitis

Manifestations	Bacterial*	Viral
White blood cell count	Elevated; increased polymorphonuclears	Slightly elevated; increased lymphocytes
Protein content	Elevated	Normal or slightly increased
Glucose content	Decreased	Normal
Gram stain; bacteria culture	Positive	Negative
Colour	Cloudy	Clear

*Results may vary in the newborn.

Encephalitis

Encephalitis is an inflammatory process of the CNS that is caused by a variety of organisms, including bacteria, spirochetes, fungi, protozoa, helminths, and viruses. Autoimmune encephalitis can also occur as a primary or secondary diagnosis in conjunction with another autoimmune disease (e.g., lupus). Most infectious encephalopathies are associated with viruses; this discussion is limited to those agents.

Encephalitis can occur as a result of (1) direct invasion of the CNS by a virus or (2) postinfectious involvement of the CNS after a viral disease. Often the specific type of encephalitis may not be identified. The cause of more than half the cases reported in Canada is unknown. The majority of cases of known etiology are associated with the childhood diseases of measles, mumps, varicella, and rubella and, less often, with the enteroviruses, herpesviruses, and West Nile virus.

While herpes simplex encephalitis is an uncommon disease, 30% of cases involve children. The initial clinical findings are nonspecific (fever, altered mental status), but most cases evolve to demonstrate focal neurological signs and symptoms. Children may experience focal seizures. The CSF is abnormal in most cases. Because of a rise in the number of children with herpes simplex encephalitis, suspected cases require prompt attention, especially because the diagnosis can be difficult. CSF polymerase chain reaction testing can confirm the clinical diagnosis. The early use of IV acyclovir reduces mortality and morbidity. Empiric therapy with acyclovir is given before precise virological diagnosis has been established.

The variety of causes of viral encephalitis makes diagnosis difficult. Most are those involved with arthropod vectors (togaviruses and bunyaviruses) and those associated with hemorrhagic fevers (arenaviruses, filoviruses, and Hantaviruses). The vector reservoir for most agents pathogenic for humans is the mosquito (St. Louis or West Nile encephalitis); therefore, most cases of encephalitis appear during the hot summer months and subside during the autumn. In Canada, the risk of acquiring West Nile virus is very low, particularly in children.

Clinical Manifestations. The clinical features of encephalitis are similar regardless of the agent involved. Manifestations can range from a mild, benign form that resembles aseptic meningitis, lasts a few days, and is followed by rapid and complete recovery to a fulminating encephalitis with severe CNS involvement. The onset may be sudden or may be gradual with malaise, fever, headache, dizziness, apathy, nuchal rigidity, nausea and vomiting, ataxia, tremors, hyperactivity, and speech difficulties (Box 50.6). In severe cases the patient has high fever, stupor, seizures, disorientation, spasticity, and coma that may proceed to death. Ocular palsies and paralysis also may occur.

BOX 50.6 Clinical Manifestations of Encephalitis

Onset: Sudden or Gradual
Malaise
Fever
Headache
Dizziness
Apathy
Lethargy
Nucal rigidity

Severe Cases
High fever
Stupor
Seizures
Disorientation
Nausea and vomiting
Ataxia
Tremors
Hyperactivity
Speech difficulties—mutism
Altered mental status
Spasticity
Coma (may proceed to death)
Ocular palsies
Paralysis

Diagnostic Evaluation. The diagnosis is made on the basis of clinical findings and, where possible, identification of the specific virus. Early in the course of encephalitis, CT scan results may be normal. Later, hemorrhagic areas in the frontotemporal region may be seen. Togaviruses (some of which were formerly labelled arboviruses) are rarely detected in the blood or spinal fluid, but viruses of herpes, mumps, measles, and enteroviruses may be found in the CSF. Serological testing may be required. The first blood sample should be drawn as soon as possible after onset, with the second sample drawn 2 or 3 weeks later.

Therapeutic Management. Patients suspected of having encephalitis are hospitalized promptly for observation. Only HSV encephalitis has specific treatment available. In other cases treatment is primarily supportive and includes conscientious nursing care, control of cerebral manifestations, and adequate nutrition and hydration, with observation and management as for other cerebral disorders. Viral encephalitis can cause devastating neurological injury. Cerebral edema, seizures, abnormal fluid and electrolyte balances, aspiration, and cardiac or respiratory arrest occur in severe viral encephalitis, and close monitoring is needed (Janowski & Hunstad, 2020).

The prognosis for the child with encephalitis depends on the child's age, the type of organism causing the disease, and residual neurological damage. Long-term outcomes of HSV encephalitis in children can be serious; impairments include visual, auditory, motor, and psychiatric (Janowski & Hunstad, 2020). Very young children (younger than 2 years of age) may exhibit increased neurological disabilities, including learning difficulties and seizure disorders. Follow-up care with periodic re-evaluation is important because symptoms are often subtle. Rehabilitation is essential for patients who develop residual effects of the disease.

Nursing Care. Nursing care of the child with encephalitis is the same as for any unconscious child and for the child with meningitis. Additional nursing interventions include observation for deterioration in consciousness. Isolation of the child is not necessary; however, thorough hand hygiene must be followed. A main focus of nursing management is the control of rapidly rising ICP. Neurological monitoring, administration of medications, and support of the child and parents are the major aspects of care.

Reye Syndrome

Reye syndrome (RS) is a disorder defined as acute metabolic encephalopathy associated with other characteristic organ involvement. It is characterized by fever, profoundly impaired consciousness, and disordered hepatic function.

The etiology of RS is not well understood, but most cases follow a common viral illness, most commonly influenza or varicella. RS is a condition characterized pathologically by cerebral edema and fatty changes of the liver. The onset of RS is notable for profuse vomiting and varying degrees of neurological impairment, including personality changes, seizures, and coma, that lead to increased ICP, herniation, and death (Ibrahim & Balistreri, 2020). The cause of RS is a mitochondrial insult induced by different viruses, medications, exogenous toxins, and genetic factors. Elevated serum ammonia levels tend to correlate with the clinical manifestations and prognosis.

Definitive diagnosis is established by liver biopsy. The staging criteria for RS are based on liver dysfunction and on neurological signs that range from lethargy to coma. As a result of improved diagnostic techniques, children who would have been diagnosed with RS in the past are now diagnosed with other illnesses, such as viral or inborn metabolic errors affecting organic acid, ammonia, and carbohydrate metabolism. Cases of unrecognized, medication-induced encephalopathy by antiemetics given to children during viral illnesses have symptoms similar to those of RS.

The potential association between acetylsalicylic acid (ASA) therapy for the treatment of fever in children with varicella or influenza and the development of RS precludes its use in these patients. Manufacturers must label all over-the-counter products that have ASA with a warning about the dangers of giving ASA to a child under 12 years of age or to a teenager under 18 years if the teenager has varicella, a cold, or influenza symptoms (Government of Canada, 2013). Since the labelling of Aspirin with this warning, the number of RS diagnoses has decreased, with increased public awareness of Aspirin risk.

Nursing Care. The most important aspect of successful management of the child with RS is early diagnosis and aggressive supportive therapy. Rapid progression to coma and high peak ammonia concentrations are associated with a more serious prognosis. Cerebral edema with increased ICP represents the most immediate threat to life. Recovery from RS is rapid and usually without sequelae given early diagnosis and implementation of therapy.

Care and observations are implemented as for any child with an altered state of consciousness (see discussion earlier in this chapter) and increasing ICP. Accurate and frequent monitoring of intake and output is essential for adjusting fluid volumes to prevent both dehydration and cerebral edema. Because of related liver dysfunction, laboratory studies to determine impaired coagulation, such as prolonged bleeding time, should be monitored.

Parents of children with RS need to be kept informed of the child's progress, have diagnostic procedures and therapeutic management explained, and be given empathetic support. Families need to be aware that salicylate, the alleged offending ingredient in Aspirin, is contained in other products (e.g., Pepto-Bismol) as well. They should refrain from administering any product for influenza-like symptoms without first checking the label for "hidden" salicylates.

SEIZURE DISORDERS

Seizures are the most common pediatric neurological disorder. About 4 to 10% of children will have at least one seizure by 16 years of age (Mikati & Tchapyjnikov, 2020). Seizures are caused by excessive and disorderly neuronal discharges in the brain. The manifestation of seizures depends on the region of the brain in which they originate and may include unconsciousness or altered consciousness; involuntary movements; and changes in perception, behaviours, sensations, and posture. Seizures can occur with a wide variety of conditions involving the CNS. The most common cause of seizures in children is a febrile seizure (Mikati & Tchapyjnikov, 2020).

Seizures are a symptom of an underlying disease process. Potential causes include infectious, intracranial lesions or hemorrhage, metabolic disorders, trauma, brain malformations, genetic disorders, or toxic ingestion. *Epilepsy* is a condition characterized by two or more unprovoked seizures more than 24 hours apart and can be caused by a variety of pathological processes in the brain. A single seizure event should not be classified as epilepsy and is generally not treated with long-term antiepileptic medications. Some seizures may result from an acute medical or neurological illness and cease once the illness is treated. In other cases, children may have a single seizure without the cause ever being known.

Approximately 1% of the Canadian population has epilepsy. This includes those who take anticonvulsant medications or who had a seizure within the past 5 years. In approximately 50% of cases of childhood epilepsy, seizures disappear completely. In 50 to 60% of cases, the cause of epilepsy is unknown (Epilepsy Canada, 2021).

After it is determined that the child has had a seizure, it is important to classify the seizure, according to the Classification of Epileptic Seizures, and assign it to the appropriate epilepsy syndrome. Optimum treatment and prognosis require an accurate diagnosis and a determination of the cause whenever possible (Figure 50.7).

Etiology

Seizures in children have many different causes. Seizures are classified according to not only type but also etiology. Acute symptomatic seizures are associated with an acute insult, such as head trauma or meningitis. Remote symptomatic seizures are those without an immediate cause but with an identifiable prior brain injury such as major head trauma, meningitis or encephalitis, hypoxia, stroke, or a static encephalopathy such as cognitive impairment or cerebral palsy. Cryptogenic seizures are those occurring with no clear cause. **Idiopathic** seizures are genetic in origin. A partial list of causative factors in epilepsy is presented in Box 50.7.

Pathophysiology

Regardless of the etiological factor or type of seizure, the basic mechanism is the same. Abnormal electrical discharges (1) may arise from central areas in the brain that affect consciousness, (2) may be restricted to one area of the cerebral cortex, producing manifestations characteristic of that particular anatomical focus, or (3) may begin in a localized area of the cortex and spread to other portions of the brain and, if sufficiently extensive, produce generalized seizure activity.

Seizure activity begins with a group of neurons in the CNS that, because of excessive excitation and loss of inhibition, amplify their discharge simultaneously. These discharges occur in response to the activity of sodium, potassium, calcium, and chloride ion channels. Normally these discharges are restrained by inhibitory mechanisms. In response to physiological stimuli, such as brain injury or infection, genetic abnormalities, cellular dehydration, severe hypoglycemia, electrolyte imbalance, sleep deprivation, emotional stress, and toxic exposures, these abnormal neuronal discharges can spread to nearby cortex and subcortical structures. Generalized seizures begin with abnormal discharges in both hemispheres, which can involve connections between the thalamus and neocortex. On the basis of these characteristic neuronal discharges (manifested as stereotypic symptoms observed and reported during seizures and/or as recorded by the EEG), seizures are designated as focal onset, generalized onset, and unknown onset (Figure 50.7).

Seizure Classification and Clinical Manifestations

There are many different types of seizures, and each has unique clinical manifestations. Seizures are classified into three major categories (Scheffer et al., 2017):

1. *Focal seizures* (previously called *partial seizures*), which have a local onset and start in an area of cells on one side of the brain. The person maintains awareness although may not be able to talk during the seizure.
2. *Generalized seizures*, which involve both hemispheres of the brain and are without local onset. These seizures are accompanied by a loss of awareness.
3. *Unknown onset seizures*

Descriptions of the different types of seizures are found in Box 50.8.

Diagnostic Evaluation

Establishing a diagnosis is critical for establishing a prognosis and planning the proper treatment. The process of diagnosis in a child suspected of having epilepsy includes (1) determining whether the events thought to be seizures are epileptic seizures or nonepileptic events (NEE), and (2) defining the underlying cause, if possible. The assessment and diagnosis rely heavily on a thorough history, skilled observation, and several diagnostic tests.

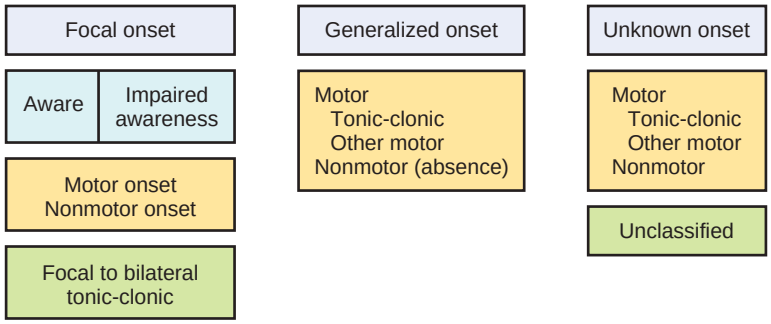

Fig. 50.7 Classification of seizure types. *ILAE,* International League Against Epilepsy. (Source: Scheffer, I. E., Berkovic, S., Capovilla, G., et al. [2017]. ILAE classification of the epilepsies: Position paper of the ILAE Commission for Classification and Terminology. *Epilepsia, 58*[4], 512–521.)

BOX 50.7 Etiology of Seizures in Children

Nonrecurrent (Acute)

Febrile episodes
Intracranial infection
Intracranial hemorrhage
Space-occupying lesions (cyst, tumour)
Acute cerebral edema
Anoxia
Toxins
Medications
Tetanus
Lead encephalopathy
Shigella, Salmonella organisms
Metabolic alterations:

- Hypocalcemia
- Hypoglycemia
- Hyponatremia or hypernatremia
- Hypomagnesemia
- Alkalosis
- Disorders of amino acid metabolism
- Deficiency states
- Hyperbilirubinemia

Recurrent (Chronic)

Idiopathic epilepsy
Epilepsy secondary to:

- Trauma
- Hemorrhage
- Anoxia
- Infections
- Toxins
- Degenerative phenomena
- Congenital defects
- Parasitic brain disease
- Hypoglycemia injury

Epilepsy—sensory stimulus
Epilepsy-stimulating states:

- Narcolepsy and catalepsy
- Psychogenic
- Tetany from hypocalcemia, alkalosis

Hypoglycemic states:

- Hyperinsulinism
- Hypopituitarism
- Adrenocortical insufficiency
- Hepatic disorders

Uremia
Allergy
Cardiovascular dysfunction or syncopal episodes
Migraine

BOX 50.8 Classification and Clinical Manifestations of Seizures

Focal Seizures

Focal Aware Seizures (Formerly Known as Simple Partial Seizures)

Characterized by:

- Localized motor symptoms
- Somatosensory, psychic, autonomic symptoms
- Combination of these
- Abnormal discharges remaining unilateral

Manifestations:

- Aversive seizure (most common motor seizure in children)—Eye or eyes and head turn away from the side of the focus; awareness of movement or loss of consciousness
- Rolandic (Sylvan) seizure—Tonic-clonic movements involving the face, salivation, arrested speech; most common during sleep
- Jacksonian march (rare in children)—Orderly, sequential progression of clonic movements beginning in a foot, hand, or face and moving, or "marching," to adjacent body parts

Uncommon in children younger than 8 years of age
Characterized by various sensations, including the following:

- Numbness, tingling, prickling, paresthesia, or pain originating in one area (e.g., face or extremities) and spreading to other parts of the body
- Visual sensations or formed images
- Motor phenomena such as posturing or hypertonia
- Jerking may begin in one area of body such as arm, leg, or face; cannot be stopped, but child stays awake and aware; jerking may proceed from one area of the body to another and sometimes spreads to become a generalized seizure
- May be mistaken for acting-out, bizarre behaviour, hysteria, mental illness, psychosomatic illness, parapsychological or mystical experience, tics

Focal Impaired Awareness Seizures (Formerly Known as Complex Partial Seizures)

Observed more often in children from 3 years through adolescence
Characterized by:

- Period of altered behaviour
- Amnesia for event (no recollection of behaviour)
- Inability to respond to environment
- Impaired consciousness during event
- Drowsiness or sleep usually following seizure
- Confusion and amnesia possibly prolonged
- Complex sensory phenomena (aura)—Most frequent sensation is a strange feeling in the pit of the stomach that rises toward the throat; often accompanied by odd or unpleasant odours or tastes; complex auditory or visual hallucinations; ill-defined feelings of elation or strangeness (e.g., déjà vu, a feeling of familiarity in a strange environment); strong feelings of fear and anxiety; distorted sense of time and self; and in small children, emission of a cry or attempt to run for help

Patterns of motor behaviour:

- Stereotypical
- Similar with each subsequent seizure
- May suddenly cease activity, appear dazed, stare into space, become confused and apathetic, and become limp or stiff or display some form of posturing. May be confused and unaware of surroundings.
- May perform purposeless, complicated activities in a repetitive manner (automatisms), such as walking, running, kicking, laughing, or speaking incoherently, most often followed by postictal confusion or sleep; may exhibit oropharyngeal activities, such as smacking, chewing, drooling, swallowing, and nausea or abdominal pain followed by stiffness, a fall,

Continued

BOX 50.8 Classification and Clinical Manifestations of Seizures—cont'd

and postictal sleep; rarely manifests actions such as rage or temper tantrums; aggressive acts uncommon during seizure
- May be mistaken for disorderly conduct
- May last 1 to 2 minutes

Generalized Seizures

Generalized Tonic-Clonic Seizures of Unknown Onset (Formerly Known as Grand Mal and Tonic-Clonic Seizures)

Most common and most dramatic of all seizure manifestations
Occur without warning
Tonic phase: lasts approximately 10 to 20 seconds or 2 to 3 minutes
Manifestations:
- Eyes roll upward
- Immediate loss of consciousness
- If standing, falls to floor or ground
- Stiffens in generalized, symmetrical tonic contraction of entire body musculature
- Arms usually flexed
- Legs, head, and neck extended
- May utter a peculiar piercing cry
- Apneic; may become cyanotic
- Increased salivation and loss of swallowing reflex
- Followed by some confusion, a period of sleep (postictal lethargy), and then return to full consciousness

Clonic phase: lasts about 30 seconds but can vary from only a few seconds to a half-hour or longer
Manifestations:
- Violent jerking movements as the trunk and extremities undergo rhythmic contraction and relaxation
- May foam at the mouth
- May be incontinent of urine and feces

As event ends, movements are less intense, occurring at longer intervals, then ceasing entirely
Status epilepticus: series of seizures at intervals too brief to allow the child to regain consciousness between the time one event ends and the next begins
- Requires emergency intervention
- Can lead to exhaustion, respiratory failure, and death

Postictal state:
- Appears to relax
- May remain semiconscious and difficult to arouse
- May awaken in a few minutes
- Remains confused for several hours
- Poor coordination
- Mild impairment of fine motor movements
- May have visual and speech difficulties
- May vomit or state they have a severe headache
- When left alone, usually sleeps for several hours
- On awakening is fully conscious
- Usually feels tired and has symptoms of sore muscles and headache
- No recollection of entire event

Generalized Absence Seizures (Typical, Atypical, Myoclonic, or With Eyelid Myoclonia) (Formerly Called Absence Seizures or Petit Mal Seizures)

Characterized by:
- Onset usually between 4 and 12 years of age
- More common in girls than in boys
- Usually cease at puberty
- Brief loss of consciousness
- Minimum or no alteration in muscle tone
- May go unrecognized because of little change in child's behaviour
- Abrupt onset; suddenly develops 20 or more attacks daily
- Event often mistaken for inattentiveness or daydreaming
- Events possibly precipitated by hyperventilation, hypoglycemia, stresses (emotional and physiological), fatigue, or sleeplessness

Manifestations:
- Brief loss of consciousness
- Appear without warning or aura
- Usually last about 5 to 10 seconds
- Slight loss of muscle tone may cause child to drop objects
- Ability to maintain postural control; seldom falls
- Minor movements such as lip smacking, twitching of eyelids or face, or slight hand movements
- Not accompanied by incontinence
- Amnesia for episode
- Child is unaware of what is going on during seizure but quickly returns to full awareness after it has stopped; may result in learning difficulties if not recognized and treated
- May need to reorient self to previous activity

Focal or Generalized Atonic Seizures (Formerly Known as Drop Attacks)

Characterized by:
- Onset usually between 2 and 5 years of age
- Sudden, momentary loss of muscle tone and postural control
- Events recurring frequently during the day, particularly in the morning hours and shortly after awakening

Manifestations:
- Loss of tone causing child to fall to the floor violently after 10 seconds to 1 minute; unable to break fall by putting out hand; may incur a serious injury to the face, head, or shoulder. Child recovers and can stand and walk again.
- Loss of consciousness only momentary
- May be mistaken for clumsiness, normal childhood stage, lack of good walking skills, or drunkenness.

Focal, Generalized, Unknown-Onset Epileptic Spasms (Formerly Known as Infantile Spasms)

Also called infantile myoclonus, massive spasms, hypsarrhythmia, salaam episodes, or infantile myoclonic spasms
Most commonly occur during the first 6 to 8 months of life
Twice as common in boys as in girls
Numerous seizures during the day without postictal drowsiness or sleep
Possible cognitive impairment
Manifestations:
- Possible series of sudden, brief, symmetrical, muscular contractions
- Head flexed, arms extended, and legs drawn up
- Eyes sometimes rolling upward or inward
- May be preceded or followed by a cry or giggling
- May or may not include loss of consciousness
- Sometimes flushing, pallor, or cyanosis

Infants who are able to sit but not stand:
- Sudden dropping forward of the head and neck with trunk flexed forward and knees drawn up—the salaam or jackknife seizure

Less often: alternative clinical forms:
- Extensor spasms rather than flexion of arms, legs, and trunk, and head nodding
- Lightning events involving a single, momentary, shocklike contraction of the entire body

It is especially important to differentiate epilepsy from other brief alterations in consciousness or behaviour. Clinical entities that mimic seizures include migraine headaches, toxic effects of medications, syncope (fainting), breath-holding spells in infants and young children, movement disorders (tics, tremor, chorea), prolonged QT syndrome, sleep disturbances (sleepwalking, night terrors), psychogenic seizures, rage attacks, and transient ischemic attacks (rare in children) (Mikati & Tchapyjnikov, 2020). The toxic effects of drug use by the pregnant parent and withdrawal from these drugs should be considered in the differential diagnosis of new-onset seizure activity in a newborn.

The history of the seizure should be equally detailed, including the type of seizure or description of the child's behaviour during the event, especially at the onset, and the time at which the seizure occurs (e.g., early morning, before meals, while awake, or during sleep). Any factors that may have precipitated the seizure are important, including fever, infection, head trauma, anxiety, fatigue, sleep deprivation, menstrual cycle, alcohol, and activity (e.g., hyperventilation or exposure to strong stimuli such as bright flashing light or loud noises). If the child can describe any sensory phenomena, these should be recorded. The duration and progression of the seizure (if any) and the postictal feelings and behaviour (e.g., confusion, inability to speak, amnesia, headache, and sleep) should also be recorded. It is important to determine whether more than one seizure type exists. It is often more informative to ask parents to mime the seizure rather than relying on their oral description. Miming often reveals features, such as head turning, that would otherwise go unrecognized. Some seizures are overlooked by parents. For example, some parents may not identify brief head nods or brief single jerks as seizures unless specifically asked whether their child has these symptoms.

The family history should include whether other family members have had a seizure, cognitive impairment, cerebral palsy, autism, or other neurological disorders. A family history can offer clues to paroxysmal disorders, such as migraine headaches, breath-holding spells, febrile seizures, or neurological diseases.

A complete physical and neurological examination, including developmental assessment of language, learning, behaviour, and motor abilities, may provide clues to the cause of the seizures. A number of laboratory and neuroimaging tests may be ordered depending on the child's age, whether this is a new-onset seizure, characteristics of the seizure, and the history. Laboratory studies that may prove to be of value include a venous lead level if the history warrants or white blood cell count (for signs of infection). Blood glucose may give evidence of hypoglycemic episodes, and serum electrolytes, blood urea nitrogen, calcium, serum amino acids, lactate, ammonia, and urine organic acids may indicate metabolic disturbances. Blood for chromosomal analysis may also be tested if a genetic etiology is suspected. A toxic screen may be done if alcohol or drug use or withdrawal is suspected. Lumbar puncture can confirm a suspected diagnosis of meningitis. CT may be done to detect a cerebral hemorrhage, infarctions, and gross malformations. MRI provides greater anatomical detail and is used to detect developmental malformations, tumours, and cortical dysplasias.

An EEG is obtained for most children with seizures. The EEG is the most useful tool for evaluating the child's risk for recurrent seizures, helping to determine the type of seizure the child had, and diagnosing the type of epilepsy. The EEG confirms the presence of abnormal electrical discharges and provides information on the seizure type and the focus. The EEG is carried out under varying conditions—with the child asleep, awake, awake with provocative stimulation (flashing lights, noise), and hyperventilating. Stimulation may elicit abnormal electrical activity, which is recorded on the EEG. Various seizure types produce characteristic EEG patterns: high-voltage spike discharges are seen in tonic-clonic seizures, with abnormal patterns in the intervals between seizures; a three-per-second spike and wave pattern is observed in an absence seizure; and absence of electrical activity in an area suggests a large lesion, such as an abscess or subdural collection of fluid.

A normal EEG does not rule out seizures because the EEG is only a surface recording that represents approximately 1 hour of time; therefore, it may show normal interictal activity. If there is concern about whether a child has seizures or the seizure type cannot be determined, then a longer video EEG may be done to record the child during wakefulness and sleep. The full body image is recorded on video, with selected EEG channels displayed on the same screen for simultaneous recording and viewing. EEG monitoring is also available in digital EEG and digital video imaging, which allows for greater selection of EEG channels and is available in both routine and long-term EEGs. Although the EEG is very valuable, it should not be used alone to determine the type of seizure. Rather, the EEG interpretation, along with a thorough clinical description of the patient's behaviour during the seizure episode, can be a guide to the correct classification of the seizure and the appropriate treatment choice.

Therapeutic Management

The goal of treatment of seizures and epilepsy is to control the seizures or to reduce their frequency and severity, discover and correct the cause when possible, and help the child live as healthy a life as possible. Discovering and, when possible, correcting the underlying cause of the seizures can lead to complete control of all seizures. If the seizure activity is a manifestation of an infectious, traumatic, or metabolic process, the seizure therapy is instituted as part of the general therapeutic regimen. Management of epilepsy has four treatment options: medication therapy, the ketogenic diet, vagus nerve stimulation, and epilepsy surgery.

Medication Therapy. People predisposed to epilepsy tend to have seizures when their basal level of neuronal excitability exceeds a critical point; no event occurs if the excitability is maintained below this threshold. The administration of antiepileptic medications serves to raise this threshold and prevent seizures. Consequently, the primary therapy for seizure disorders is administration of the appropriate antiepileptic medication or combination of medications in a dosage that provides the desired effect without causing undesirable adverse effects or toxic reactions. Antiepileptic medications are believed to exert their effect primarily by reducing the responsiveness of normal neurons to the sudden, high-frequency nerve impulses that arise in the epileptogenic focus. Thus the seizure is effectively suppressed; however, the abnormal brain waves may or may not be altered. The chance of total control of seizures depends on the underlying cause of the seizures.

The initiation of anticonvulsant therapy is based on several factors, including the child's age, type of seizure, risk of recurrence, and other comorbid or predisposing medical issues. For children who develop recurrent seizures or epilepsy, treatment is begun with a single medication known to be effective and have the lowest toxicity (i.e., the safest adverse-effect profile for the child's particular type of seizure). The dosage is gradually increased until the seizures are controlled or the maximum recommended dose has been reached and seizures are still not controlled. If a child develops intolerable adverse effects, the medication is stopped and another one is tried. If the medication reduces but does stop all the seizures, a second medication is added in gradually increasing doses. When seizures are controlled, the first medication may be tapered to reduce the potential adverse effects and medication interactions of polytherapy. However, this decision is individualized for each child. While monotherapy remains the treatment method of choice for epilepsy, a combination of medications may be a viable alternative for children who cannot attain seizure control with only one medication (Mikati & Tchapyjnikov, 2020).

Sleepiness, changes in mood or behaviour, vision changes, and ataxia are some of the potential adverse effects of antiepileptic medications. These are very distressing to both children and families. They often disappear over time or when medication dosages are reduced. Blood cell counts, urinalysis, and liver function tests are obtained at regular intervals in children receiving particular antiepileptic medications that can affect organ function. If complete seizure control is maintained on an anticonvulsant medication for 2 years, it may be safe to slowly discontinue the medication for patients with no risk factors. When seizure medications are discontinued, the dosage is decreased gradually over weeks or months. Sudden withdrawal of a medication is not recommended because it can cause seizures, which may be longer and more intense than previously, to recur. Risk factors for recurrence of seizures include older age at onset, numerous seizures before control is achieved, presence of a neurological dysfunction (e.g., motor or cognitive impairment), and the characteristics of epilepsy syndrome (Verrotti et al., 2012). Recurrence occurs most frequently within the first year of discontinuation (Braun & Schmidt, 2014).

MEDICATION ALERT

Fosphenytoin is often used to treat seizures instead of IV phenytoin because of possible complications and medication interactions associated with IV phenytoin. If IV phenytoin is used, it should be administered via slow IV push at a rate that does not exceed 50 mg/min. Because phenytoin precipitates when mixed with glucose, only normal saline is used to flush the tubing or catheter. Fosphenytoin may be given in saline or glucose solutions at a rate of up to 150 mg PE (phenytoin equivalent)/min, and it may be given intramuscularly if necessary.

Ketogenic Diet. The ketogenic diet is a high-fat, low-carbohydrate, and adequate-protein diet (Mikati & Tchapyjnikov, 2020). Consumption of such a diet forces the body to shift from using glucose as the primary energy source to using fat, and the individual develops a state of ketosis. The diet is rigorous. All foods and liquids the child consumes must be carefully weighed and measured. The diet is deficient in vitamins and minerals; thus, vitamin supplements are necessary. Early adverse effects of the diet are diarrhea, hypoglycemia, dehydration, acidosis, and lethargy. Long-term effects of the diet are dyslipidemia, kidney stones, and poor growth (Kossoff, 2013).

The ketogenic diet has been shown to be an efficacious and tolerable treatment for medically refractory seizures. The modified Atkins diet may be more tolerable to patients and also shows some promise but requires further study (Martin-McGill et al., 2018).

Vagus Nerve Stimulation. Vagus nerve stimulation (VNS) was developed as a palliative treatment for patients with seizures not controlled by medications and who are not candidates for diet or surgical therapy (Moshé et al., 2015). It is currently indicated as adjunct therapy in patients 12 years of age and older with focal-onset seizures (with or without secondary generalization) who are refractory to antiepileptic medications (Elliott et al., 2011). A programmable signal generator is implanted subcutaneously in the chest. Electrodes underneath the skin deliver electrical impulses to the left vagus nerve (cranial nerve X). The device is programmed noninvasively to deliver a precise pattern of stimulation. The patient or caregiver can activate the device using a magnet at the onset of a seizure. No long-term adverse effects have been reported with VNS, but dysphonia, throat or neck pain, and cough can occur during stimulation. Studies show that approximately one-third to one-half of patients have a reduction in seizures after 1 year of therapy (Orosz et al., 2014).

Surgical Therapy. When seizures are determined to be caused by a hematoma, tumour, or other cerebral lesion, surgical removal is the treatment. In children with epilepsy, surgery is reserved for those who suffer from incapacitating, refractory seizures. *Refractory seizures* are usually defined as the persistence of seizures despite adequate trials of three antiepileptic medications, alone or in combination (Mikati & Tchapyjnikov, 2020). An extensive medical (e.g., invasive EEG monitoring), psychosocial, and psychoneurological evaluation is required before surgery. There are several types of surgical interventions. Focal resection entails removal of the epileptogenic zone, and hemispherectomy involves removing all or most of one hemisphere in patients with catastrophic hemispheric epilepsy (Mikati & Tchapyjnikov, 2020). Corpus callosotomy consists of the separation of the connections between the two hemispheres in the brain to prevent seizure activity by blocking epileptic discharges. Patients undergoing surgical resection can experience a decrease in the frequency and severity of seizures, a decrease in antiepileptic medication requirements, and an improvement in their quality of life.

Treatment for Status Epilepticus. *Status epilepticus* (SE) is a medical emergency that should be anticipated in any patient who presents with an acute seizure. For generalized tonic-clonic seizures, SE is defined as continuous convulsive activity or recurrent generalized convulsive seizure activity without regaining of consciousness. The time at which treatment should be initiated is 5 minutes, and at 30 minutes continuous seizure activity leads to long-term sequelae such as neuronal injury. The definition differs for SE consisting of focal seizures with impaired awareness in that treatment should be initiated at 10 minutes (Mikati & Tchapyjnikov, 2020). Mortality for SE has been reported to be between 2.7 and 8%, with an overall morbidity (including newly diagnosed neurological disorders, hemodynamic instability, long-term focal neurological deficits, persisting cognitive impairment, and behaviour problems) of between 10 and 20% (McKenzie et al., 2021). The initial treatment is directed toward support and maintenance of vital functions such as airway, breathing, and circulation, administering oxygen, and gaining IV access, immediately followed by IV administration of antiepileptic agents to stop the seizure and prevent recurrence (McKenzie et al., 2021).

MEDICATION ALERT

Lorazepam (buccal), or midazolam (intramuscular, buccal or intranasally), and diazepam (rectally) are quick, effective, and safe treatments for the prehospital treatment of status epilepticus (McKenzie et al., 2021). Respiratory depression is a potential adverse effect of these medications, and patients should be monitored closely after administration (Mikati & Tchapyjnikov, 2020).

For in-hospital management of SE, IV lorazepam (Ativan) or midazolam (IV or IM) is equally recommended as the first-line medications of choice (McKenzie et al., 2021). IV loading with fosphenytoin, phenytoin, or phenobarbital is usually necessary if benzodiazepines (lorazepam, or midazolam) are not effective for sustained control of seizures. Adverse effects of both phenytoin and fosphenytoin include cardiac arrhythmias, bradycardia, and hypotension such that continuous blood pressure and electrocardiogram (ECG) monitoring is recommended during infusion (McKenzie et al., 2021). Children may also receive an antiepileptic medication, IV valproate or levetiracetam. Children who continue to have seizures despite this medication treatment may require general anaesthesia with a continuous infusion of midazolam, propofol, or pentobarbital (Abend & Loddenkemper, 2014). In this situation, the child will need to be intubated, and continuous EEG monitoring is begun to monitor for and treat electrographic seizures (Abend & Loddenkemper, 2014).

Nursing care of a child with SE includes, in addition to circulation, airway, and breathing of life support, monitoring blood pressure and body temperature. During the first 30 to 45 minutes of the seizure the blood pressure may be elevated. Thereafter the blood pressure typically returns to normal but may be decreased, depending on the medications being administered for seizure control. Hyperthermia requiring treatment may occur as a result of increased motor activity. SE is a medical emergency that requires immediate intervention to prevent possible brain injury and death. Diagnosis and correction of the underlying cause of the SE is essential.

Prognosis

Only about one-half of children who experience a first seizure will experience additional seizures (El-Radhi, 2015). Therefore, children who have had a single seizure are rarely started on antiepileptic medications. Prognosis for eventual remission of childhood epilepsy depends on the etiology and epilepsy syndrome diagnosis. Some seizures almost always remit, whereas others almost never do (Camfield & Camfield, 2014). Intractable seizures are those that fail to be controlled after two appropriately selected antiepileptic medications have been trialled (Wassenaar et al., 2013). Most mortality in children with epilepsy is due to factors associated with a child's coexisting neurological conditions and poorly controlled seizures (Berg & Rychlik, 2015).

Sudden Unexpected Death in Epilepsy. Sudden unexpected death in epilepsy (SUDEP) is the most common epilepsy-related cause of mortality and is responsible for up to 17% of deaths in patients with epilepsy. Risk factors include polytherapy with more than three antiepileptic medications, male gender, young age at epilepsy onset, developmental delay, poor antiepileptic medication adherence, nocturnal seizures, poorly controlled convulsive seizures (especially if more than three per year), high frequency of seizures (especially if more than 50 per year), and having epilepsy for more than 30 years in adults. Patients are usually found dead in their bed in a prone position with evidence suggesting a recent seizure (Mikati & Tchapyjnikov, 2020).

Nursing Care

An important nursing responsibility is to observe the seizure episode and accurately document the events. Any alterations in behaviour preceding the seizure and the characteristics of the episode, such as sensory-hallucinatory phenomena (e.g., an aura), motor effects (e.g., eye movements, muscular contractions), alterations in consciousness, and postictal state (e.g., behaviour after the seizure), should be noted and recorded (Box 50.9). The nurse should describe only what is observed, rather than trying to label a seizure type. The time that the seizure began and the duration of the seizure should also be noted.

The child must be protected from injury during the seizure. Nursing observations made during the event provide valuable information for diagnosis and management of the disorder (see Emergency box: Management of Seizures). For nursing care of the child with a seizure disorder see the Nursing Care Plan available on Evolve.

BOX 50.9 General Observations: The Child During a Seizure

Observations During a Seizure

Describe

Order of events (before, during, and after)

Duration of seizure (depending on type of seizure)

- From first signs of event until jerking stops
- From loss of consciousness until consciousness is regained
- From first sign of unresponsiveness, motor activity, automatisms until there are signs of responsiveness to environment

Onset

Time of onset

Significant precipitating events—missed medication dosage, illness, stress, sleep deprivation, menses

Behaviour

Change in facial expression

Cry or other sound

Stereotypical and automatic movements

Random activity (wandering)

Position of eyes, head, body, extremities

Unilateral or bilateral posturing of one or more extremities

Movement

Change of position, if any

Site of commencement—hand, thumb, mouth, generalized

Tonic phase—length, parts of body involved

Clonic phase—twitching or jerking movements, parts of body involved, sequence of parts involved, generalized, change in character of movements

Lack of movement or muscle tone of body part or entire body

Face

Colour change—pallor, cyanosis, flushing

Perspiration

Mouth—position, deviation to one side, teeth clenched, tongue bitten, frothing at mouth, flecks of blood or bleeding

Lack of expression

Asymmetrical expression

Eyes

Position—straight ahead, deviation upward or outward, conjugate or divergent gaze

Pupils—change in size, equality, reaction to light

Respiratory Effort

Presence and length of apnea

Other

Incontinence

Postictal Observations

Duration of postictal period

State of consciousness

Orientation

Arousability

Motor ability:

- Any change in motor function
- Ability to move all extremities
- Paresis or weakness

Speech

Sensations:

- Symptoms of discomfort or pain
- Any sensory impairment

Recollection of preseizure sensations (aura)

It is impossible to physically stop a seizure once it has begun, and no attempt should be made to do so. The nurse must remain calm, stay with the child, and prevent the child from sustaining any harm during the seizure. If possible, the child should be isolated from the view of others by closing a door or pulling screens. If other persons are present, they should be assured that everything is being done for the child. After the seizure, they can be given a simple explanation about the event as needed.

EMERGENCY

Management of Seizures

During the Seizure

Do not restrain child.
Remain calm.
Time seizure episode.
Redirect child to safe area.
Remove harmful objects from area.
Do not agitate; instead, talk in calm, reassuring manner.
Do not expect child to follow instructions.
If child is standing or seated, ease child down to the floor.
Place pillow or folded blanket under child's head.
Loosen restrictive clothing.
Remove eyeglasses.
Look for medical identification.
Observe and record stages and manifestations.
Allow seizure to end without interference.
If vomiting occurs, turn child to one side.
Do not:

- Attempt to restrain child or use force
- Put anything in child's mouth
- Give any food or liquids

After the Seizure

Time postictal period.
Check for breathing. Check position of head and tongue.
Reposition if head is hyperextended. If child is not breathing, give rescue breathing and call emergency medical services (EMS).
Keep child on their side.
Remain with the child.
Do not give food or liquids until the child is fully alert and swallowing reflex has returned.
Look for medical identification, and determine what factors occurred before onset of seizure that may have been triggering factors.
Check the head and body for possible injuries.
Check inside of mouth to see if tongue or lips have been bitten.
Stay with the child and reassure them until fully conscious.

Call Emergency Medical Services If

The child stops breathing.
There is evidence of injury or the child is diabetic or pregnant.
The seizure lasts for more than 5 minutes (unless duration of seizure is typically longer than 5 minutes) or if there are multiple seizures.
Seizures continue for more than 10 minutes after administration of rescue medications.
Status epilepticus occurs.
Pupils are not equal after seizure.
The child vomits continuously 30 minutes after seizure has ended (sign of possible acute condition).
The child cannot be awakened and is unresponsive to pain after seizure has ended.
The seizure occurs in water.
This is the child's first seizure.

Modified from Epilepsy Foundation. (2020). *Seizure first aid and safety.* https://www.epilepsy.com/learn/seizure-first-aid-and-safety/first-aid-seizures-stay-safe-side.

If the nurse is able to reach the child in time, a child who is standing or seated in a chair is eased to the floor immediately. A child in a wheelchair should not be removed from the chair as the wheelchair provides support and padding. During (and sometimes after) the tonic-clonic seizure, the swallowing reflex is lost, salivation increases, and the tongue is hypotonic. Thus, the child is at risk for aspiration and airway occlusion. Placing the child on their side facilitates drainage and helps maintain a patent airway. Suctioning the oral cavity and posterior oropharynx may be necessary. Vital signs should be taken. The child should be allowed to rest if at school or away from home. When feasible, the child should be integrated into the environment as soon as possible. Sending a child with a chronic seizure disorder home from school is not necessary unless requested by the parents.

Seizure precautions are required for children who are known to have seizures or who are under observation for seizures. The extent of these measures depends on the type and frequency of the seizure (Box 50.10).

! NURSING ALERT

Do not move or forcefully restrain the child during a tonic-clonic seizure, and do not place a solid object between the teeth.

Long-Term Care. Care of the child with a recurrent seizure disorder involves physical care and instruction regarding the importance of the medication therapy and, probably more significant, the issues related to the emotional aspects of the disorder. Few diseases generate as much anxiety among family, friends, and school personnel as epilepsy. Fears and misconceptions about the disease and its treatment are common. For many, it represents the archetype of severe hereditary affliction. Nursing care is directed toward educating the child and family about epilepsy and helping them develop strategies to cope with the psychological issues related to epilepsy, and directing them to resources for living with epilepsy.

Children with epilepsy are prescribed antiepileptic medications. These medications need to be administered at regular intervals to maintain adequate levels in the blood. The nurse can help the parents plan the administration of the medication at convenient times to avoid disruptions of family routines as much as possible. It is important to impress on the family the necessity of giving the antiepileptic medication regularly and for as long as required. In general, antiepileptic

BOX 50.10 Seizure Precautions

The extent of precautions depends on type, severity, and frequency of seizures. They may include the following:

- Side rails raised when child is sleeping or resting
- Side rails and other hard objects padded
- Waterproof mattress or pad on bed or crib

Appropriate precautions during potentially hazardous activities may include the following:

- Swimming with a companion
- Taking showers; bathing only with close supervision
- Using protective helmet and padding during bicycle riding, skateboarding, in-line skating
- Supervising child during use of hazardous machinery or equipment

Have child carry or wear medical identification.
Alert other caregivers to need for any special precautions.
The child may not drive or operate hazardous machinery or equipment unless seizure free for designated period (varies by province).

medications are continued until the child has been seizure free for 2 years (Mikati & Tchapyjnikov, 2020). The medication is then slowly tapered over a period of weeks to avoid the possibility of precipitating a seizure. It is sometimes easy to skip doses or omit them for a variety of reasons, especially when the child is free of seizures most of the time. This is particularly so when the child is older and assumes responsibility for their medication. The seizure threshold may be lowered during any illness, but particularly with fever. Therefore, parents should be aware that if their child has an illness they are at increased risk for seizures. Parents should contact their health care provider if their child misses medications during an illness because of vomiting.

Rectal preparations of some antiepileptic medications are highly effective when a child is unable to take oral medications because of repeated vomiting, gastrointestinal surgery, or SE. Parents can learn to administer rectal antiepileptic medication for home treatment. Buccal midazolam or rectal diazepam is a useful adjunctive home treatment for children at risk for prolonged seizures or clusters of seizures and can minimize the need for hospitalization while enhancing parental confidence.

MEDICATION ALERT

Children taking phenobarbital or phenytoin should receive adequate vitamin D and folic acid, since deficiencies of both have been associated with these medications. Phenytoin should not be taken with milk.

Nurses need to educate the child and parents about the possible adverse reactions to the medications used to treat seizures. Parents should understand the rare but potentially serious adverse effect of allergic reaction to the medication. They must immediately report rashes to the child's health care provider. More common but less serious potential adverse effects include excessive sleepiness, changes in appetite, and worsening behaviour and mood. Parents should be encouraged to share their observations with their child's health care provider. Parents should understand that the child needs periodic physical assessment. Depending on the medication prescribed, some children will need regular testing of their complete blood count and liver functions. Possible adverse effects on the hematopoietic system, liver, and kidneys may be reflected in symptoms such as fever, sore throat, enlarged lymph nodes, jaundice, and bleeding (e.g., easy bruising, petechiae, ecchymoses, epistaxis).

The degree to which activities are restricted is individualized for each child and depends on the type, frequency, and severity of the seizures; the child's response to therapy; and the length of time the seizures have been controlled. To prevent head injuries, children should always wear helmets and other safety devices when participating in sports such as biking, skiing, skateboarding, horseback riding, and in-line skating. Only children with frequent seizures must avoid these activities. Children with epilepsy should avoid activities involving heights, such as climbing on play structures taller than they are. A medical alert bracelet indicating the child's diagnosis of epilepsy is important for the child to wear at all times.

Children with epilepsy are at higher risk for submersion injury than children without epilepsy. Young children should never be left alone in the bathtub, even for a few seconds. Older children and adolescents should also not bathe alone and are encouraged to use a shower and reminded not to lock the bathroom door when showering. No person with epilepsy should ever swim unsupervised.

Because the child is encouraged to attend school, camp, and other normal activities, teachers should be made aware of the child's condition and therapy. They can help ensure regularity of medication administration and provision of any special care the child might need. Teachers, child care providers, camp counsellors, youth organization leaders, coaches, and other adults who assume responsibility for children should be instructed in care of the child during a seizure so they can act calmly for the child's welfare and influence the attitude of their peers. A seizure management plan identifying the type and character of the child's typical seizures should be created by the health team for the child's school and camps. This plan should clearly identify how the school or camp should monitor and respond in the event of a seizure, and what the emergency management of the seizure should involve (i.e., administer antiepileptic agent, call EMS). This plan should be reviewed and modified by the health care team regularly.

Triggering Factors. Careful and detailed documentation of seizures over time may indicate a pattern. About one half of the people 12 years of age and older with epilepsy can recognize at least one trigger for their seizures (Wassenaar et al., 2014). When this occurs, the nurse or responsible adult may intervene to identify the triggering factors and make changes in the environment that may prevent seizures or decrease their frequency. Often the necessary changes are simple but can make an enormous difference in the lives of the child and family.

The most common factors that may trigger seizures in children include emotional stress, sleep deprivation, fatigue, fever, and illness (Epilepsy Foundation, 2014). Other precipitating factors include flickering lights, menstrual cycle, alcohol, heat, hyperventilation, and fasting. Some individuals have pattern- or photo-sensitive epilepsy, that is, seizures precipitated by changes in dark–light patterns, such as those that occur with a flash on a camera, automobile headlights, reflections of light on snow or water, or rotating blades on a fan. Most of these individuals have absence, myoclonic, or generalized tonic-clonic seizures. Some children have seizures while playing video games.

Febrile Seizures

Febrile seizures are one of the most common neurological conditions of childhood, affecting approximately 2 to 5% of children between the ages of 6 and 60 months, with the peak incidence between 12 and 18 months of age (Mikati & Tchapyjnikov, 2020). A *febrile seizure* is a seizure associated with a febrile illness in a child who does not have a CNS infection. Simple febrile seizures occur in children with no pre-existing neurological abnormality and consist of a tonic-clonic seizure that occurs with a fever (>38.0°C) and resolves within 15 minutes with a return to alert mental status after the seizure and with no further seizure occurring within a 24-hour period (Mikati & Tchapyjnikov, 2020).

There is evidence for both genetic and environmental causes for febrile seizures. Children with a family history of febrile seizures are at increased risk for both a single febrile seizure and recurrent febrile seizures (Mikati & Tchapyjnikov, 2020). Environmental factors that have been implicated include a viral illness and an age younger than 18 months (Mewasingh, 2014).

Most febrile seizures have stopped by the time the child is taken to a medical facility and require no treatment. If the seizure continues for more than 5 minutes, acute treatment is needed and consists of administering a benzodiazepine: IV lorazepam; IV or rectal diazepam; or IV, buccal, or intranasal midazolam (Mikati & Tchapyjnikov, 2020). Antipyretics can decrease the discomfort of the child but do not reduce the risk of having a recurrent febrile seizure (Mikati & Tchapyjnikov, 2020). Tepid sponge baths are not recommended, for several reasons: they are ineffective in significantly lowering the temperature, the shivering effect further increases metabolic output, and cooling causes discomfort to the child (see Chapter 44, Therapeutic Management of Fever). Parental education and emotional support are important

interventions, and information may need to be repeated, depending on the parents' anxiety and education level. Parents need reassurance regarding the benign nature of simple febrile seizures.

There is no indication for the use of daily prophylactic antiepileptic medication for febrile seizures because the risk for adverse effects outweighs any potential benefit. Although approximately 15% of children with epilepsy have had febrile seizures, only 5% of children who experience febrile seizures proceed to develop epilepsy later in life (Makita & Tchapyjnikov, 2020).

! NURSING ALERT

If a febrile seizure lasts more than 5 minutes, parents should seek medical attention right away. Instruct them to call for emergency assistance (911) and not to place the child who is actively having a seizure in the car.

CEREBRAL MALFORMATIONS

Cranial Deformities

In the healthy newborn the cranial sutures are separated by membranous seams several millimetres wide. Up to 2 days after birth, the cranial bones are highly mobile, which allows them to mould and slide over one another. The principal sutures in the infant's skull are the sagittal, coronal, and lambdoidal sutures, and the major soft areas at the juncture of these sutures are the anterior and posterior fontanels (see Figure 16.1).

After birth, growth of the skull bones occurs in a direction perpendicular to the line of the suture, and normal closure occurs in a regular and predictable order. Although there are wide variations in the age at which closure takes place in individual children, normally all sutures and fontanels are ossified by the following ages:

8 weeks—Posterior fontanel closed
6 months—Fibrous union of suture lines and interlocking of serrated edges
18 months—Anterior fontanel closed
After 12 years—Sutures unable to be separated by increased ICP

A solid union of all sutures is not completed until late childhood. **Craniosynostosis** (closure of a suture before the expected time) inhibits the perpendicular growth. Since the normal increase in brain volume requires expansion, the skull is forced to grow in a direction parallel to the fused suture. This alteration in skull growth always produces a distortion of the head shape when the underlying brain growth is normal. A small head with closed and normal shape is a result of deficient brain growth; the suture closure is secondary to this brain growth failure.

Various types of cranial deformities are encountered in early infancy. These include an enlarged head with frontal protrusion (bossing; characteristic of hydrocephalus), parietal bossing that is seen in chronic subdural hematoma, a small head (microcephaly), and a variety of skull deformities. Some occur during prenatal development; in others, head circumference is usually within normal limits at birth, and the deviation from normal development becomes apparent with advancing age. The majority of infants with craniosynostosis have normal brain development. The exceptions are those with genetic disorders that involve brain pathological conditions.

Microcephaly. *Microcephaly* is a congenital condition that refers to a head circumference that measures more than 3 standard deviations below the mean for age and sex. Brain growth is usually restricted and thus cognitive impairment is common. Microcephaly can be the result of a genetic disorder; fetal exposure to teratogens such as radiation; maternal substance use; and congenital infections such as rubella, toxoplasmosis, cytomegalovirus, or Zika virus. Infants with microcephaly require supportive nursing care and medical observation to determine the extent of the psychomotor delay that almost always accompanies this abnormality. There is no treatment. Parents need support to learn to care for a child with an intellectual disability.

Positional Plagiocephaly. Positional plagiocephaly (PP) is a cranial asymmetry. An increase in the frequency of PP has been noted since the recommendation that infants be placed in the supine position for sleeping to reduce the incidence of sudden infant death syndrome (SIDS). There is unilateral flattening of the occiput, with ipsilateral anterior shifting of the ear. The incidence of PP is striking at 6 weeks of age but the vast majority of plagiocephaly cases resolve by 2 years of age (Cummings & CPS, Community Paediatrics Committee, 2011/2018).

The CPS (Cummings & CPS, Community Paediatrics Committee, 2011/2018) recommends the following:

- Prevention of plagiocephaly begins with positioning of the head to encourage lying on each side in the supine position.
- The child should be in a prone position during awake time (tummy time) for 10 to 15 minutes at least three times per day.
- Evaluation for craniosynostosis, congenital torticollis, and cervical spine abnormalities should be part of the examination of a child with plagiocephaly.
- Repositioning therapy plus physiotherapy as needed are the interventions for children with mild or moderate PP.
- Moulding therapy (helmet therapy) may be considered for children with severe asymmetry (see Figure 36.13).

Hydrocephalus

Hydrocephalus is a condition caused by an imbalance in the production and absorption of CSF in the ventricular system. When production is greater than absorption, CSF accumulates within the ventricular system, usually under increased pressure, producing passive dilation of the ventricles.

Pathophysiology. The causes of hydrocephalus are varied, but the result is either (1) impaired absorption of CSF fluid within the subarachnoid space, obliteration of the subarachnoid cisterns, or malfunction of the arachnoid villi (communicating hydrocephalus), or (2) obstruction to the flow of CSF through the ventricular system (noncommunicating hydrocephalus) (Kinsman & Johnston, 2020). Any imbalance of secretion and absorption causes an increased accumulation of CSF in the ventricles, which become dilated (ventriculomegaly) and compress the brain substance against the surrounding rigid bony cranium. When this occurs before fusion of the cranial sutures, it causes enlargement of the skull and dilation of the ventricles (Figure 50.8). In children younger than 12 years of age, partially closed suture lines, especially the sagittal suture, may become diastatic or opened. After 12 years of age the sutures are fused and will not open.

Most cases of hydrocephalus are a result of developmental malformations. Although the anomaly is usually apparent in early infancy, it may become evident at any time from the prenatal period to late childhood or early adulthood. Other causes include neoplasms, infections, and trauma. An obstruction to the normal flow can occur at any point in the CSF pathway to produce increased pressure and dilation of the pathways proximal to the site of obstruction.

Developmental anomalies (e.g., Arnold-Chiari malformations, aqueduct gliosis, and atresia of the foramina of Luschka and Magendie

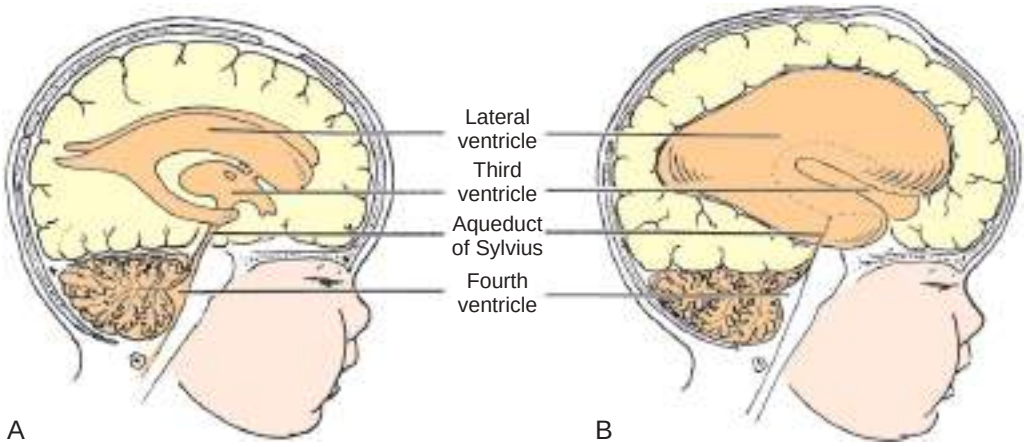

Fig. 50.8 Hydrocephalus: a block in flow of cerebrospinal fluid. **A:** Patent cerebrospinal fluid circulation. **B:** Enlarged lateral and third ventricles caused by obstruction of circulation—stenosis of aqueduct of Sylvius.

[Dandy-Walker syndrome]) account for most cases of hydrocephalus from birth to 2 years of age. Hydrocephalus is also often associated with myelomeningocele (see Chapter 54 for further discussion). All infants with this condition should be observed for its development. In the remainder of cases there is a history of intrauterine infection, perinatal hemorrhage, and newborn meningoencephalitis. In older children, hydrocephalus is most often a result of intracranial masses, intracranial infections, hemorrhage, pre-existing developmental anomalies, such as aqueduct stenosis or the Arnold-Chiari malformation (a congenital anomaly in which the cerebellum and medulla oblongata extend down through the foramen magnum), or trauma.

Clinical Manifestations. The factors that influence the clinical picture in hydrocephalus are the time and acuity of onset and associated structural malformations. In infancy, before closure of the cranial sutures, head enlargement is the predominant sign, whereas in older infants and children the lesions responsible for hydrocephalus produce other neurological signs through pressure on adjacent structures (Box 50.11).

In infants with hydrocephalus, the head grows at an abnormal rate, although the first signs may be bulging fontanels. The anterior fontanel is tense, often bulging and nonpulsatile. Scalp veins are dilated, especially when the infant cries. With the increase in intracranial volume, skull bones become thin and the sutures become palpably separated to produce a cracked-pot sound (Macewen sign) on percussion of the skull. In severe cases, infants display frontal bossing, eyes depressed and rotated downward (setting-sun sign), and sluggish pupils.

The signs and symptoms in early to late childhood are caused by increased ICP, and specific manifestations are related to the focal

BOX 50.11 Clinical Manifestations of Hydrocephalus

Infancy (Early)

Abnormally rapid head growth
Bulging fontanels (especially anterior) sometimes without head enlargement:
- Tense
- Nonpulsatile

Dilated scalp veins
Separated sutures
Macewen sign (cracked-pot sound on percussion)
Thinning of skull bones

Infancy (Later)

Frontal enlargement, or bossing
Depressed eyes
Setting-sun sign (sclera visible above the iris)
Pupils sluggish, with unequal response to light

Infancy (General)

Irritability
Lethargy
Infant crying when picked up or rocked and quieting when allowed to lie still
Early infantile reflex acts may persist
Normally expected responses failing to appear
May display:
- Change in level of consciousness
- Opisthotonos (often extreme)
- Lower extremity spasticity
- Vomiting

Advanced cases:
- Difficulty in sucking and feeding
- Shrill, brief, high-pitched cry
- Cardiopulmonary embarrassment

Childhood

Headache on awakening; improvement following emesis or upright posture
Papilledema
Strabismus
Extrapyramidal tract signs (e.g., ataxia)
- Irritability
- Lethargy
- Apathy
- Confusion
- Incoherence
- Vomiting

lesion. Most commonly resulting from posterior fossa neoplasms and aqueduct stenosis, the clinical manifestations are primarily those associated with space-occupying lesions (i.e., headaches on awakening with improvement after emesis or being in an upright position, strabismus, and ataxia).

Diagnostic Evaluation. Hydrocephalus in infants is based on head circumference that crosses at least one percentile line on the head measurement chart within 2 to 4 weeks. In evaluation of a preterm infant, specially adapted head circumference charts are consulted to distinguish abnormal head growth from normal rapid head growth. Fetal ultrasound is helpful in the detection of hydrocephalus. The primary diagnostic tools to detect hydrocephalus in older infants and children are CT and MRI. Diagnostic evaluation of children who have symptoms of hydrocephalus after infancy is similar to that used in those with suspected intracranial tumour. In newborns, echoencephalography is useful in comparing the ratio of lateral ventricle to cortex.

Therapeutic Management. The treatment of hydrocephalus is directed toward relief of the ventricular pressure, treatment of the cause, treatment of associated complications, and management of issues related to the effect of the disorder on psychomotor development. With few exceptions, the treatment is surgical. This is accomplished by direct removal of an obstruction (such as a tumour) or placement of a shunt that provides primary drainage of the CSF from the ventricles to an extracranial compartment, usually the peritoneum (ventriculoperitoneal [VP] shunt) (Figure 50.9).

Most shunt systems consist of a ventricular catheter, a flush pump, a unidirectional flow valve, and a distal catheter. In all models the valves are designed to open at a predetermined intraventricular pressure and close when the pressure falls below that level, thus preventing backflow of secretions.

The major complications of VP shunts are infection and malfunction. All shunts are subject to mechanical difficulties, such as kinking, plugging, or separation or migration of the tubing. Malfunction is most often caused by mechanical obstruction either within the ventricles from particulate matter (tissue or exudate) or at the distal end from thrombosis or displacement as a result of growth. Revisions are needed when signs of malfunction appear. The child with a shunt obstruction is often first seen in an emergency department with clinical manifestations of increased ICP, frequently accompanied by worsening neurological status.

Fig. 50.9 Ventriculoperitoneal shunt. Catheter is threaded beneath the skin.

The most serious complication, shunt infection, can occur at any time, but the period of greatest risk is 1 to 2 months after placement. The infection is generally a result of intercurrent infections at the time of shunt placement. Infections include septicemia, bacterial endocarditis, wound infection, shunt nephritis, meningitis, and ventriculitis. Meningitis and ventriculitis are of greatest concern, since any complicating CNS infection is a significant predictor of poor intellectual outcome. Infection is treated with antibiotics administered intravenously or intrathecally for a minimum of 7 to 10 days. A persistent infection requires removal of the shunt until the infection is controlled. External ventricular drainage (EVD) is used until CSF is sterile. The EVD allows for removal of CSF through a tube that is placed in the child's ventricle and flows by gravity into a collection device.

Prognosis. The prognosis for children with treated hydrocephalus depends largely on the cause of the dilated ventricles before shunt placement and the amount of irreversible brain damage before shunting (Kinsman & Johnston, 2020). For example, malignant tumours may have a high mortality rate regardless of other complicating factors.

Surgically treated hydrocephalus with continued neurosurgical and medical management has a survival rate of about 80%, with the highest incidence of mortality occurring within the first year of treatment (Paulsen et al., 2010). Those with poor outcomes include children shunted for posthemorrhagic hydrocephalus or meningitis. Most children who require shunting must depend on the shunt for the remainder of their life.

Nursing Care. Preoperatively the infant with diagnosed or suspected hydrocephalus is observed carefully for signs of increasing ICP. In infants the head is measured daily at the largest point, the occipitofrontal circumference (see Head Circumference, Chapter 33, for technique). If the infant's head is large, a special pressure-sensitive mattress and frequent position changes are necessary to prevent skin breakdown. Fontanels and suture lines are gently palpated for size, signs of bulging, tenseness, and separation. Irritability, lethargy, or seizure activity, as well as altered vital signs and feeding behaviour, may indicate an advancing pathological condition.

General nursing care of the infant with hydrocephalus may present special challenges. Maintaining adequate nutrition often requires flexible feeding schedules to accommodate diagnostic procedures, since feeding before or after handling can precipitate an episode of vomiting. Small feedings at more frequent intervals are often better tolerated than larger ones spaced further apart. These infants are often difficult to feed and require extra time and innovation.

In older children the most valuable indicator of increasing ICP is an alteration in the child's LOC and changes in the way the child interacts with the environment. Changes are identified by observation and by comparison of present behaviour with customary behaviour, sleep patterns, developmental capabilities, and habits, all obtained through a detailed history and a baseline assessment. This baseline information serves as a guide for postoperative assessment and evaluation of shunt function.

The nurse is responsible for preparing the child for diagnostic tests such as MRI or CT scan and assisting the health care provider with procedures such as a ventricular tap, which is often performed to relieve excessive pressure during the preoperative period and for CSF examination. Sedation is required, since the child must remain absolutely still during diagnostic testing (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 44).

Postoperative care. In addition to routine postoperative care and observation, the infant or child is positioned carefully on the unoperated side to prevent pressure on the shunt valve. The child is kept flat to

avoid complications resulting from too-rapid reduction of intracranial fluid. When the ventricular size is reduced too rapidly, the cerebral cortex may pull away from the dura and tear the small interlacing veins, producing a subdural hematoma. The surgeon will indicate the position to be maintained and the extent of activity allowed. Pain management can be achieved with acetaminophen for mild to moderate pain and opioids for severe pain (see Pain Management, Chapter 34).

Observation is continued for signs of increased ICP, which indicates obstruction of the shunt. Neurological assessment includes evaluation of pupillary dilation (pressure causes compression or stretching of the oculomotor nerve, producing dilation on the same side as the pressure) and blood pressure (hypoxia to the brainstem causes variability in these vital signs). If there is increased ICP, the surgeon will prescribe elevation of the head of the bed and allow the child to sit up to enhance gravity flow through the shunt.

! NURSING ALERT

Arbitrary pumping of the shunt may cause obstruction or other issues and should not be performed unless indicated by the neurosurgeon.

Because infection is the greatest hazard of the postoperative period, nurses need to be on the alert for the usual manifestations of CSF infection, such as elevated temperature, poor feeding, vomiting, decreased responsiveness, and seizure activity. There may be signs of local inflammation at the operative sites and along the shunt tract. The child is also observed for abdominal distension, since CSF may cause peritonitis or a postoperative ileus as a complication of distal catheter placement. Antibiotics are administered by the IV route as ordered, and the nurse may also need to assist with intraventricular instillation. The incision site is inspected for leakage, and any suspected drainage is tested for glucose, an indication of CSF.

In addition, intake and output need to be carefully monitored. Children may be placed on fluid restriction with nothing by mouth for 24 hours. The IV infusion should be closely monitored to prevent fluid overload. Routine feeding is resumed after the prescribed NPO period, but the presence of bowel sounds should be determined before feeding a child with a VP shunt.

Meticulous skin care is continued postoperatively, with extra care to prevent tissue damage from pressure. A pressure-reducing mattress or overlay pad underneath the child helps prevent pressure on prominent areas. Skin should be inspected regularly for any signs of pressure, irritation, or infection.

Family support. Specific needs and concerns of parents during periods of hospitalization are related to the reason for the child's hospitalization (shunt revision, infection, diagnosis) and the diagnostic and surgical procedures to which the child is subjected. Parents may have little understanding of anatomy; therefore, they need further exploration and reinforcement of information that was given to them by the neurosurgeon, as well as information about what they can expect. They may be especially frightened of any procedure that involves the brain, and the fear of intellectual disability or brain damage is real and pervasive. Nurses can do much to allay their anxiety by explaining the rationale underlying the various nursing and medical activities, such as positioning or testing, and by simply being available and willing to listen to their concerns.

To prepare for the child's discharge and home care, the parents need to be instructed in how to recognize signs that indicate shunt malfunction or infection. Active children may have injuries, such as a fall, that can damage the shunt, and the tubing may pull out of the distal insertion site or become disconnected during normal growth. Contact sports should be avoided, and a helmet should be worn when outside play is vigorous.

The management of hydrocephalus in a child is a demanding task for both family and health care providers, and helping a family cope with the child is an important nursing responsibility. Children with hydrocephalus have lifelong special health care needs and require evaluation on a regular basis. The overall aim is to establish realistic goals and an appropriate educational program that will help the child to achieve their optimal potential.

Families can be referred to community agencies for support and guidance. The Spina Bifida and Hydrocephalus Association of Canada provides information on the condition for families and assists interested groups in establishing local organizations. Helpful booklets are available from this source (see Additional Resources at the end of this chapter).

KEY POINTS

- LOC is the most important indicator of neurological health; altered levels include full consciousness, confusion, disorientation, lethargy, obtundation, stupor, coma, and persistent vegetative state.
- Complete neurological examination includes LOC; posture; motor, sensory, cranial nerve, and reflex testing; and vital signs.
- Nursing care of the unconscious child focuses on ensuring respiratory management; performing neurological assessment; monitoring ICP; supplying adequate nutrition and hydration; providing medication therapy; promoting elimination, hygienic care, proper positioning, exercise, and stimulation; and providing family support.
- Primary head injury involves features that occur at the time of trauma, including fractured skull, contusions, intracranial hematoma, and diffuse injury. Secondary complications include hypoxic brain damage, increased ICP, infection, cerebral edema, and posttraumatic syndromes.
- Fractures resulting from head injuries may be classified as linear, depressed, comminuted, basilar, open, and growing.
- The young child's response to head injury is different from that of adults because of the following features: larger head size, expandable skull, larger blood volume to the brain, and small subdural spaces.
- Conditions resulting from submersion injuries include hypoxia and asphyxiation, aspiration, and hypothermia.
- Nursing care of the child with a brain tumour includes observing for signs and symptoms related to the tumour, preparing the child and family for diagnostic tests and operative procedures, preventing postoperative complications, planning for discharge, and promoting a return to optimal health.
- Nursing care of the child with meningitis includes administering antibiotics, taking isolation precautions, removing environmental stimuli, ensuring correct positioning, monitoring vital signs, administering IV therapy, promoting adequate fluid and nutritional status, and providing supportive care to the family.
- Routine immunization of infants with *H. influenzae* type b and pneumococcal conjugate vaccines has reduced the incidence of bacterial meningitis.
- Encephalitis may result from direct invasion of the CNS by a virus or from involvement of the CNS after viral disease.
- A seizure is a symptom of an underlying pathological condition and may be manifested by sensory-hallucinatory phenomena, motor effects, sensorimotor effects, or loss of consciousness.
- Seizures are categorized as generalized, focal, or unknown.
- Generalized seizures are categorized as tonic, clonic, tonic-clonic, absence, atonic, and myoclonic.
- Long-term care of the child with recurrent seizure disorders includes physical care and education regarding the importance of medication therapy and concerns related to emotional aspects of the disorder.

- Febrile seizures are the most common type of childhood seizure.
- Some cranial deformities are amenable to surgical correction.
- Hydrocephalus is a symptom of an underlying brain pathological condition demonstrated by impaired absorption of CSF or obstruction to the flow of CSF within the ventricles.
- Therapy for hydrocephalus involves relief of the hydrocephalus, treatment of the underlying brain disorder if possible, prevention or treatment of complications, and management of issues related to psychomotor development.

Endocrine Conditions

Cheryl Sams and Nancy Caprara
Originating US chapter by *Cheryl C. Rodgers*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Differentiate between the disorders caused by hypopituitary and hyperpituitary dysfunction.
2. Describe the manifestations of thyroid hypofunction and hyperfunction and the care of children with the disorders.
3. Distinguish between the manifestations of adrenal hypofunction and hyperfunction.
4. Differentiate among the various categories of diabetes mellitus.
5. Discuss care of the child with diabetes mellitus in the acute care setting.
6. Distinguish between a hypoglycemic and a hyperglycemic reaction.
7. Design a teaching plan for a child with diabetes mellitus along with their family.

THE ENDOCRINE SYSTEM

The endocrine system controls or regulates metabolic processes governing energy production, growth, fluid and electrolyte balance, response to stress, and sexual reproduction. The endocrine system consists of three components: (1) the cells, which send chemical messages by means of hormones; (2) the target cells, or end organs, which receive the chemical messages; and (3) the environment through which the chemicals are transported (blood, lymph, extracellular fluids) from the sites of synthesis to the sites of cellular action. The pathophysiology review in Figure 51.1 provides a summary of the principal pituitary hormones and their target organs.

Hormones

A *hormone* is a complex chemical substance produced and secreted into body fluids by a cell or group of cells that exerts a physiological controlling effect on other cells. These effects may be local or distant and may affect either most cells of the body or specific "target" tissues. Hormones are released by the endocrine glands into the bloodstream, and production is regulated by a feedback mechanism. The master gland of the endocrine system is the anterior pituitary gland, which is responsible for stimulation and inhibition of tropic hormones. However, some hormones, such as insulin, are regulated by other mechanisms.

DISORDERS OF PITUITARY FUNCTION

The pituitary gland is divided into two lobes—the anterior (adenohypophysis) and the posterior (neurohypophysis) lobe. Each lobe is responsible for secreting different hormones. Disorders of the anterior pituitary hormones may be attributable to organic defects or have an idiopathic etiology and may occur as a single hormonal disorder or in combination with other hormonal disorders. The clinical manifestations of pituitary dysfunction depend on the hormones involved and the age of the patient. *Panhypopituitarism* is defined clinically as the loss of all anterior pituitary hormones, leaving only posterior function intact (Lang et al., 2015). Clinical manifestations of panhypopituitarism are listed in Box 51.1.

! NURSING ALERT

Children with panhypopituitarism should wear a medical alert bracelet or necklace.

Hypopituitarism

Hypopituitarism is diminished or deficient secretion of one or more pituitary hormones. The consequences of the condition depend on the degree of dysfunction. It often leads to gonadotropin deficiency

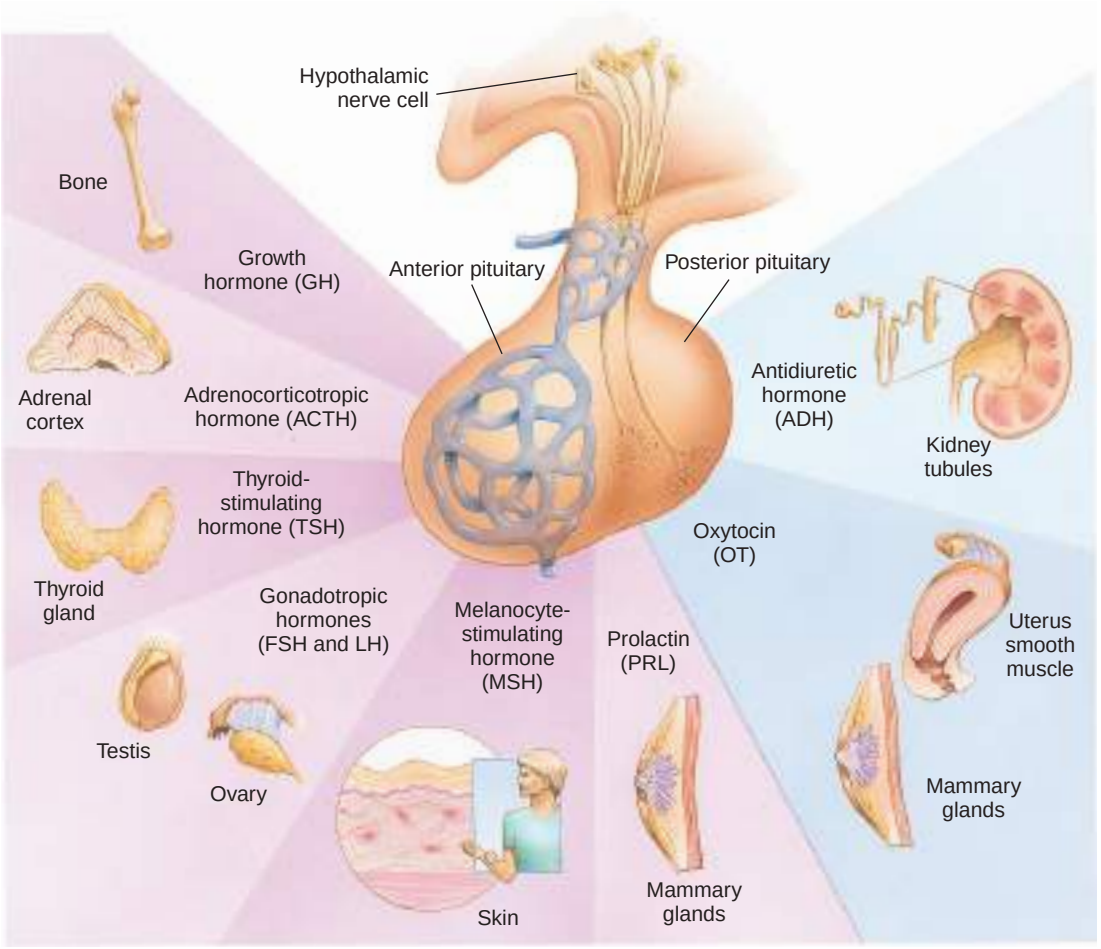

Fig. 51.1 Principal anterior and posterior pituitary hormones and their target organs. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone. (From Patton, K. T., & Thibodeau, G. A. [2016]. *Anatomy and physiology* [9th ed.]. Elsevier.)

BOX 51.1 Clinical Manifestations of Panhypopituitarism

Growth Hormone
- Short stature but proportional height and weight
- Delayed epiphyseal closure
- Delayed bone age proportional to height
- Premature aging common in later life
- Increased insulin sensitivity

Thyroid-Stimulating Hormone
- Short stature with infantile proportions
- Dry, coarse skin; yellow discoloration, pallor
- Cold intolerance
- Constipation
- Somnolence
- Bradycardia
- Dyspnea on exertion
- Delayed dentition, loss of teeth

Gonadotropins
- Absence of sexual maturation or loss of secondary sexual characteristics
- Atrophy of genitalia, prostate gland, breasts
- Amenorrhea without menopausal symptoms
- Decreased spermatogenesis

Adrenocorticotropic Hormone
- Severe anorexia, weight loss
- Hypoglycemia
- Hypotension
- Hyponatremia, hyperkalemia
- Adrenal apoplexy, especially in response to stress
- Circulatory collapse

Antidiuretic Hormone
- Polyuria
- Polydipsia
- Dehydration

Melanocyte-Stimulating Hormone
- Decreased pigmentation

with absence or regression of secondary sex characteristics; growth hormone (GH) deficiency, in which children display stunted somatic growth; thyroid-stimulating hormone (TSH) deficiency, which produces hypothyroidism; and adrenocorticotropic hormone (ACTH) deficiency, which results in adrenal hypofunction.

Hormones associated with this condition and the respective clinical manifestations are listed in Box 51.1. The most common organic cause of pituitary undersecretion is a tumour in the pituitary or hypothalamic region, especially the craniopharyngiomas. Congenital hypopituitarism can be seen in newborns and can run in families, suggesting a genetic cause (Alatzoglou & Dattani, 2010). Symptoms of apnea, cyanosis, severe hypoglycemia, prolonged newborn cholestatic jaundice, and seizure activity often manifest in infants with congenital hypopituitarism (Patterson & Felner, 2020).

Idiopathic hypopituitarism, or idiopathic pituitary growth failure, is usually related to *GH deficiency*, which inhibits somatic growth in all cells of the body (Patterson & Felner, 2020). *Growth failure* is defined as an absolute height of less than −2 standard deviations (SD) for age or a linear growth velocity consistently less than −1 SD for age. When this occurs without the presence of hypothyroidism, systemic disease, or malnutrition, an abnormality of the GH–insulin-like growth factor (IGF-I) axis should be considered (Patterson & Felner, 2020).

Not all children with short stature have GH deficiency. In most instances, the cause is either familial short stature or constitutional growth delay. *Familial short stature* refers to otherwise healthy children who have ancestors with adult height in the lower percentiles. *Constitutional growth delay* refers to individuals (usually boys) with delayed linear growth, generally beginning as a toddler, and skeletal and sexual maturation that is behind that of age-mates (Patterson & Felner, 2020). The untreated child will proceed through normal changes as expected on the basis of bone age. Although treatment with GH is not usually indicated, its use has become controversial, especially in relation to parental and child requests for treatment to accelerate growth.

Clinical Manifestations. Children with GH deficiency generally grow normally during the first year and then follow a slowed growth curve that is below the third percentile. These children may appear overweight or obese due to stunted height in combination with good nutrition. A nourished appearance is an important diagnostic clue that may differentiate patients with GH deficiency from patients with failure to thrive. Sexual development is usually delayed but is otherwise normal unless the gonadotropin hormones are deficient. Growth may extend into the third or fourth decade of life, but permanent height is usually diminished if the disorder is left untreated. Because of an underdeveloped jaw, teeth may be crowded or malpositioned.

Diagnostic Evaluation. Only a small number of children with delayed growth or short stature have hypopituitary-related growth failure. In most instances the cause is constitutional delay. Diagnostic evaluation is aimed at isolating organic causes, which, in addition to GH deficiency, may include hypothyroidism, oversecretion of cortisol, gonadal aplasia, chronic illness, nutritional inadequacy, Russell-Silver dwarfism, or hypochondroplasia.

A complete diagnostic evaluation should include a family history, a history of the child's growth patterns and previous health status, physical examination, and psychosocial evaluation. Specific radiographic imaging, including magnetic resonance imaging (MRI), endocrine studies, and genetic testing, may be warranted. Accurate measurement of height and weight and comparison with standard growth charts are essential. Multiple height measures reflect a more accurate assessment of abnormal growth patterns (Box 51.2). Parental height and familial patterns of growth are important clues to the diagnosis. A skeletal survey in children less than 3 years of age and radiographic examination of the hand-wrist for centres of ossification (bone age) in older children are important in evaluating growth (Box 51.3).

BOX 51.2 Evaluating the Growth Curve

Ensure reliability of measurements—Accurately obtain and plot height and weight measurements.

Determine absolute height—The child's absolute height bears some relationship to the likelihood of a pathological condition. However, most children who have a height below the lowest percentile (either third or fifth percentile on the height curve) do not have a pathological growth condition.

Assess height velocity—The most important aspect of a growth evaluation is observation of a child's height over time, or height velocity. Accurate determination of height velocity requires at least 4 and preferably 6 months of observation. A substantial deceleration in height velocity (crossing several percentiles) between 3 and 12 or 13 years of age indicates a pathological condition until proven otherwise.

Determine weight-to-height relationship—Determination of the weight-to-height ratio has some diagnostic value in ascertaining the cause of growth restriction in a short child.

Project target height—The height of a child can be judged inappropriately short only in the context of their genetic potential. The target height of the child can be determined with the formula:

[Father's height (cm) + Mother's height (cm) + 13] /2 for boys

or

[Father's height (cm) + Mother's height (cm) − 13] /2 for girls

Most children achieve an adult stature within approximately 10 cm of the target height.

Modified from Vogiatzi, M. G., & Copeland, K. C. (1998). The short child. *Pediatrics in Review, 19*(3), 92–99.

BOX 51.3 Bone Age for Evaluating Growth Disorders

Bone age refers to a method of assessing skeletal maturity by comparing the appearance of representative epiphyseal centres obtained on X-ray examination with age-appropriate published standards.

Most conditions that cause poor linear growth also cause a delay in skeletal maturation and a restricted bone age. Observation of even a profoundly delayed bone age is never diagnostic or even indicative of a specific diagnosis. A delayed bone age merely indicates that the associated short stature is to some extent "partially reversible," since linear growth will continue until epiphyseal fusion is complete. In comparison, a bone age that is not delayed in a short child is of much greater concern and may, in fact, be of some diagnostic value under certain circumstances.

Modified from Vogiatzi, M. G., & Copeland, K. C. (1998). The short child. *Pediatrics in Review, 19*(3), 92–99.

Definitive diagnosis of GH deficiency is based on absent or subnormal reserves of pituitary GH. Because GH levels are variable in children, GH stimulation testing is usually required for diagnosis. It is recommended that GH stimulation tests be reserved for children with low serum IGF-I and IGFBP3 levels and poor growth who do not have other causes for short stature (Patterson & Felner, 2020). GH stimulation testing involves the use of pharmacological agents such as levodopa, clonidine, arginine, insulin, propranolol, or glucagon followed by the measurement of GH blood levels (Patterson & Felner, 2020). Children with poor linear growth, delayed bone age, and abnormal GH stimulation tests are considered GH deficient.

Therapeutic Management. Treatment of GH deficiency caused by organic lesions is directed toward correction of the underlying disease process (e.g., surgical removal or irradiation of a tumour). The definitive treatment of GH deficiency is replacement of GH, which is successful in 80% of affected children. Biosynthetic GH is administered subcutaneously on a daily basis. Growth velocity increases in the first year and then declines in subsequent years. Final height is likely to remain less than normal and early diagnosis and intervention are essential (Patterson & Felner, 2020).

Some patients develop hypothyroidism while under treatment with GH. Similarly, there is a risk of developing adrenal insufficiency as an associated component of hypopituitarism. If unrecognized, hypothyroidism and adrenal insufficiency can be fatal. Periodic evaluation of thyroid and adrenal function is indicated for all patients diagnosed with GH deficiency (Patterson & Felner, 2020). The decision to stop GH therapy is made jointly by the child, family, and health care team. Growth rates of less than 2.5 cm/year, a decision by the patient that they are tall enough, and a bone age of more than 14 years in girls and more than 16 years in boys are often used as criteria to stop GH therapy (Patterson & Felner, 2020).

Children with other hormone deficiencies require replacement therapy to correct the specific disorders. This may involve administration of thyroid extract, cortisone, testosterone, or estrogens and progesterone. Treatment with the sex hormones is usually begun during adolescence to promote normal sexual maturation.

Nursing Care. The principal nursing consideration is identifying children with growth deficiencies. Even though the majority of growth issues are not a result of organic causes, any delay in normal growth and sexual development can pose emotional adjustments for these children.

The nurse may be a key person in helping to establish a diagnosis. For example, if serial height and weight records are not available, the nurse can question parents about the child's growth compared with that of siblings, peers, or relatives. Preparation of the child and family is especially important if a number of tests are being performed, and the child requires particular attention during provocative testing. Blood samples are usually taken every 30 minutes over a 3-hour period. Children also have difficulty overcoming hypoglycemia generated by tests, surgeries, and procedures, so they must be observed carefully for signs of hypoglycemia. Children receiving glucagon are at risk for nausea and vomiting. Clonidine may cause hypotension, requiring administration of intravenous (IV) fluids.

Child and family support. Children undergoing hormone replacement require additional support. The nurse should provide education for patient self-management during the school-age years. Nursing functions include family education concerning medication preparation and storage, injection sites, injection technique, and syringe disposal (see Chapter 44). Administration of GH is facilitated by family routines that include a specific time of day for the injection. Younger children may enjoy using a calendar and colourful stickers to designate received injections.

! NURSING ALERT

Optimum dosing is frequently achieved when growth hormone (GH) is administered at bedtime. Physiological release is more normally stimulated due to a result of pituitary release of GH during the first 45 to 90 minutes after the onset of sleep.

Even when hormone replacement is successful, these children attain their eventual adult height at a slower rate than that of their peers; therefore, they need assistance in setting realistic expectations regarding improvement. Because these children appear younger than their chronological age, others frequently relate to them in infantile or childish ways. Parents and teachers benefit from guidance directed toward setting realistic expectations for the child based on age and abilities. For example, in the home, these children should have the same age-appropriate responsibilities as their siblings. As they approach adolescence, they should be encouraged to participate in group activities with peers. If abilities and strengths are emphasized rather than physical size, these children are more likely to develop a positive self-image.

Pituitary Hyperfunction

Excess GH before closure of the epiphyseal shafts results in proportional overgrowth of the long bones until the individual reaches a height of 2.4 m or more. Vertical growth is accompanied by rapid and increased development of muscles and viscera. Weight is increased but is usually in proportion to height. Proportional enlargement of head circumference also occurs and may result in delayed closure of the fontanels in young children. Children with a pituitary-secreting tumour may also demonstrate signs of increasing intracranial pressure, especially headache.

If oversecretion of GH occurs after epiphyseal closure, growth is in the transverse direction, producing a condition known as *acromegaly*. Typical facial features include overgrowth of the head, lips, nose, tongue, jaw, and paranasal and mastoid sinuses; separation and **malocclusion** of the teeth in the enlarged jaw; disproportion of the face to the cerebral division of the skull; increased facial hair; thickened, deeply creased skin; and increased tendency toward **hyperglycemia** and diabetes mellitus (DM). Acromegaly can develop slowly, which may delay diagnosis and treatment.

Diagnostic Evaluation. Excessive secretion of GH by a pituitary adenoma causes most cases of acromegaly. Diagnosis is based on a history of excessive growth during childhood and evidence of increased levels of GH. MRI may reveal a tumour or an enlarged sella turcica, normal bone age, enlargement of bones (e.g., the paranasal sinuses), and evidence of joint changes. Endocrine studies to confirm an excess of other hormones, specifically thyroid, cortisol, and sex hormones, should also be included in the differential diagnosis.

Therapeutic Management. If a lesion is present, surgical treatment by cryosurgery or hypophysectomy is performed to remove the tumour, when feasible. Other therapies aimed at destroying pituitary tissue include external irradiation and radioactive implants. Several pharmacological agents have been developed that may be used in combination with other therapies (Ali, 2020). Depending on the extent of surgical excision and degree of pituitary insufficiency, hormone replacement with thyroid extract, cortisone, and sex hormones may be necessary.

Nursing Care. The primary nursing consideration is early identification of children with excessive growth rates. Although medical management is unable to reduce growth already attained, further growth can be restricted. The earlier the treatment, the more control there is in predetermining adult height. Nurses in ambulatory settings who are frequently involved in growth screening should refer children who demonstrate excessive linear growth for a medical evaluation. They should also observe for signs of a tumour, especially headache, and evidence of concurrent hormonal excesses, particularly the gonadotropins, which cause sexual precocity. Children with excessive growth rates require as much emotional support as those with short stature. Children and their parents need an opportunity to express their thoughts. A compassionate nurse can be supportive to these children, especially before adolescence, when they are larger than their peers.

Precocious Puberty

Manifestations of sexual development before age 9 years in boys or age 8 years in girls have traditionally been considered precocious development, and these children were recommended for further evaluation. The onset of puberty varies among children and may be influenced by ethnicity, making this a subjective definition. Recent examination of the age limit for defining when puberty is precocious reveals that the onset of puberty in girls is occurring earlier than previous studies had documented (Garibaldi & Chemaitilly, 2020). Mean onset of puberty is presently 10.2 and 9.6 years in White and Black girls, respectively (Latronico et al., 2016). Based on this pattern, it is recommended that precocious puberty evaluation for a pathological cause be performed for White girls younger than 7 years of age and for Black girls younger than 6 years of age. There is a concern that early menarche will increase the risk of future breast cancer (Canadian Cancer Society, 2021). No change in the guidelines for evaluation of precocious puberty in boys is recommended.

Normally, the hypothalamic-releasing factors stimulate secretion of the **gonadotropic hormones** from the anterior pituitary at the time of puberty. In boys, interstitial cell–stimulating hormone stimulates Leydig's cells of the testes to secrete testosterone; in girls, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) stimulate the ovarian follicles to secrete estrogens. This sequence of events is known as the *hypothalamic–pituitary–gonadal axis*. If for some reason the cycle undergoes premature activation, the child will display evidence of advanced or precocious puberty. Causes of precocious puberty are listed in Box 51.4.

Isosexual precocious puberty is more common among girls than boys. Approximately 80% of children with precocious puberty have *central precocious puberty (CPP)*, in which pubertal development is activated by the hypothalamic gonadotropin-releasing hormone (GnRH) (Garibaldi & Chemaitilly, 2020). This produces early maturation and development of the gonads with secretion of sex hormones, development of secondary sex characteristics, and sometimes production of mature sperm and ova. CPP may be the result of congenital anomalies; infectious, neoplastic, or traumatic insults to the central nervous system (CNS); or treatment of long-standing sex hormone exposure (Latronico et al., 2016). CPP occurs more frequently in girls and is usually idiopathic, with 90% of cases demonstrating no causative factor (Garibaldi & Chemaitilly, 2020). A CNS insult or structural abnormality is found in more than 75% of boys with CPP (Garibaldi & Chemaitilly, 2020).

Peripheral precocious puberty includes early puberty resulting from hormone stimulation other than the hypothalamic GnRH–stimulated pituitary gonadotropin release. Isolated manifestations that are usually associated with puberty may be seen as variations in normal sexual development (Garibaldi & Chemaitilly, 2020). They appear without other signs of **pubescence** and are probably caused by unusual end-organ sensitivity to prepubertal levels of estrogen or androgen. Included are premature thelarche (development of breasts in prepubertal girls), premature pubarche (premature adrenarche, early development of sexual hair), and premature **menarche** (isolated menses without other evidence of sexual development).

Therapeutic Management. Treatment of precocious puberty is directed toward the specific cause, when known. In 50% of cases, precocious pubertal development regresses or stops advancing without any treatment. If needed, precocious puberty of central (hypothalamic–pituitary) origin is managed with monthly injections of a synthetic analogue of luteinizing hormone–releasing hormone, which regulates pituitary secretions (Garibaldi & Chemaitilly, 2020). The available preparation, leuprolide acetate (Lupron Depot), is given intramuscularly once every 4 to 12 weeks depending on the preparation. The GnRH analogue (GnRHa) histrelin has been formulated to implant in the subdermal tissue and may be useful for patients who want to avoid injections (Garibaldi & Chemaitilly, 2020).

Once treatment is initiated, breast development regresses or does not advance, and growth returns to normal rates, enhancing predicted height. Studies suggest that not all patients attain adult targeted heights

BOX 51.4 Causes of Precocious Puberty

Central Precocious Puberty

Idiopathic, with or without hypothalamic hamartoma

Secondary

- Congenital anomalies
- Postinflammatory—Encephalitis, meningitis, abscess, granulomatous disease
- Radiotherapy
- Trauma
- Neoplasms

After effective treatment of long-standing pseudosexual precocity

Peripheral Precocious Puberty

Familial male-limited precocious puberty

Albright syndrome

Gonadal or extragonadal tumours

Adrenal

- Congenital adrenal hyperplasia
- Adenoma, carcinoma
- Glucocorticoid resistance

Exogenous sex hormones

Primary hypothyroidism

Incomplete Precocious Puberty

Premature thelarche

Premature menarche

Premature pubarche or adrenarche

Modified from Garibaldi, L. R., & Chemaitilly, W. (2020). Disorders of pubertal development. In R. M. Kliegman, J. St. Geme, N. J. Blum, et al. (Eds.), *Nelson textbook of pediatrics* (21st ed.). Elsevier.

and the addition of GH therapy may be warranted (Garibaldi & Chemaitilly, 2020). Treatment is discontinued at a chronologically appropriate time, allowing pubertal changes to resume.

Nursing Care. Psychological support and guidance of the child and family are the most important aspects of nursing care. Both parents and the affected child should be taught the injection procedure. Parents need anticipatory guidance, support and information resources, and reassurance of the **benign** nature of the condition. Dress and activities for the physically precocious child should be appropriate to the **chronological age**. Sexual interest is not usually advanced beyond the child's chronological age, and parents need to understand that the child's mental age is congruent with the chronological age.

Diabetes Insipidus

The principal disorder of posterior pituitary hypofunction is diabetes insipidus (DI), also known as neurogenic DI, resulting from undersecretion of antidiuretic hormone (ADH), also known as vasopressin, and producing a state of uncontrolled diuresis (Breault & Majzoub, 2020). This disorder is not to be confused with nephrogenic DI, a rare hereditary disorder affecting primarily males and caused by unresponsiveness of the renal tubules to the hormone.

Neurogenic DI may result from a number of different causes. Primary causes are **familial** or idiopathic; in about 10% of children the etiology is idiopathic. Other pituitary hormone deficiencies may be present. Over time, up to 35% of those with idiopathic DI will develop other hormone deficiencies or have an underlying etiology identified (Breault & Majzoub, 2020). Secondary causes include **trauma** (accidental or surgical), tumours, granulomatous disease, **infections** (meningitis or encephalitis), and vascular anomalies (aneurysm). Certain drugs, such as alcohol or phenytoin (diphenylhydantoin), can cause a transient polyuria. DI may be an early sign of an evolving cerebral process (Breault & Majzoub, 2020).

The cardinal signs of DI are polyuria and polydipsia. In the older child, signs such as excessive urination accompanied by a compensatory insatiable thirst may be so intense that the child does little more than go to the toilet and drink fluids. Frequently the first sign is enuresis. In infants, the initial symptom is irritability that is relieved with feedings of water but not milk. These infants are also prone to dehydration, electrolyte imbalance, hyperthermia, azotemia, and potential circulatory collapse.

Dehydration is usually not a serious issue in older children, who are able to drink larger quantities of water. However, any period of unconsciousness, such as after trauma or anaesthesia, may be life-threatening because the voluntary demand for fluid is absent. During such instances careful monitoring of urine volumes, blood concentration, and IV fluid replacement is essential to prevent dehydration.

! NURSING ALERT

The child with DI complicated by congenital absence of the thirst centre must be encouraged to drink sufficient quantities of liquid to prevent electrolyte imbalance.

Diagnostic Evaluation. The simplest test used to diagnose this condition is restriction of oral fluids and observation of consequent changes in urine volume and concentration. Normally, reducing fluids results in concentrated urine and diminished volume. In DI, fluid restriction has little or no effect on urine formation but causes weight loss from dehydration. Accurate results from this procedure require strict monitoring of fluid intake and urine output, measurement of urine concentration (specific gravity or osmolality), and frequent weight checks. A weight loss between 3 and 5% indicates significant dehydration and requires termination of the fluid restriction.

! NURSING ALERT

Small children require close observation during fluid deprivation to prevent them from drinking from toilet bowls, flower vases, or other unlikely sources of fluid.

If this test is positive, the child should be given a test dose of injected aqueous vasopressin, which should alleviate the polyuria and polydipsia. Unresponsiveness to exogenous vasopressin usually indicates nephrogenic DI. An important diagnostic consideration is to differentiate DI from other causes of polyuria and polydipsia, especially DM.

Therapeutic Management. The usual treatment is intranasal, oral, or parenteral desmopressin (DDAVP), a synthetic hormone replacement of aqueous lysine vasopressin. The injectable form of DDAVP has the advantage of lasting 48 to 72 hours; however, it has the disadvantage of requiring frequent injections and proper preparation of the medication (Breault & Majzoub, 2020).

Nursing Care. The initial objective is identification of the disorder. Because an early sign may be sudden enuresis in a child who has achieved toilet independence, excessive thirst with bed-wetting is an indication for further investigation. Another clue is persistent irritability and crying in an infant that is relieved only by bottle-feedings of water. After head trauma or certain neurosurgical procedures, the development of DI can be anticipated; these patients must be closely monitored.

Assessment includes measurement of body weight, serum electrolytes, blood urea nitrogen (BUN), hematocrit, and urine specific gravity taken before surgery and every other day after the procedure. Fluid intake and output should be carefully measured and recorded. Alert patients are able to adjust intake to urine losses, but unconscious or very young patients require closer fluid observation. In children who have not achieved toilet independence, collection of urine specimens may require application of a urine-collecting device.

After confirmation of the diagnosis, parents need a thorough explanation regarding the condition with specific clarification that DI is a different condition from DM. They must realize that treatment is lifelong. If children are to receive the injectable vasopressin, ideally two caregivers should be taught the correct procedure for preparation and administration of the medication. Once children are old enough, they should be encouraged to assume full responsibility for their care.

For emergency purposes, these children should wear a medical alert identifier. Older children should carry the nasal spray with them for temporary relief of symptoms. School personnel need to be aware of the child's condition so they can grant children unrestricted use of the lavatory. Failure to permit this may result in embarrassing accidents that often lead to a child's unwillingness to attend school.

Syndrome of Inappropriate Antidiuretic Hormone

The disorder that results from hypersecretion of ADH from the posterior pituitary hormone is known as *syndrome of inappropriate antidiuretic hormone (SIADH)*. It is observed with increased frequency in a variety of conditions, especially those involving infections, tumours, or other CNS disease or trauma, and is a common cause of hyponatremia in the pediatric population (Greenbaum, 2020).

The manifestations are directly related to fluid retention and hypotonicity. Excess ADH causes most of the filtered water to be reabsorbed from the kidneys back into central circulation. Serum osmolality is low, and urine osmolality is inappropriately elevated. When serum sodium levels are diminished to 120 mmol/L, affected children display anorexia, nausea (and sometimes vomiting), stomach cramps, irritability, and personality changes. With progressive reduction in sodium, other neurological signs, stupor, and convulsions may be evident (Greenbaum, 2020). The symptoms usually disappear when the underlying disorder is corrected.

The immediate management consists of restricting fluids. Subsequent management depends on the cause and severity. Fluids continue to be restricted to one-fourth to one-half maintenance. When there are no fluid abnormalities but SIADH can be anticipated, fluids are often restricted expectantly at two-thirds to three-fourths maintenance.

Nursing Care. The first goal of nursing care is recognizing the presence of SIADH from symptoms described in patients at risk, especially those in the pediatric critical care unit.

! NURSING ALERT

Nausea, vomiting, and malaise may precede the onset of more severe stages, such as disorientation, confusion, coma, and seizures (Greenbaum, 2020).

Accurately measuring intake and output, noting daily weight, and observing for signs of fluid overload are primary nursing functions, especially in children receiving IV fluids. Seizure precautions should be implemented, and the child and family need education regarding the rationale for fluid restrictions. Rarely, children with chronic SIADH will be placed on long-term ADH-antagonizing medication, and the child and family will require instructions for its administration.

DISORDERS OF THYROID FUNCTION

The thyroid gland secretes two types of hormones: *thyroid hormone* (TH), which consists of the hormones thyroxine (T_4) and triiodothyronine (T_3), and calcitonin. The secretion of thyroid hormones is controlled by TSH from the anterior pituitary, which in turn is regulated by thyrotropin-releasing factor (TRF) from the **hypothalamus** as a negative feedback response. Consequently, hypothyroidism or hyperthyroidism may result from a defect in the target gland or from a disturbance in the secretion of TSH or TRF. Because the functions of T_3 and T_4 are qualitatively the same, the term *TH* is used throughout this discussion.

The synthesis of TH depends on available sources of dietary iodine and tyrosine. The thyroid is the only endocrine gland capable of storing excess amounts of hormones for release as needed. During circulation in the bloodstream, T_4 and T_3 are bound to carrier proteins (thyroxine-binding globulin). They must be unbound before they are able to exert their metabolic effect.

The main physiological action of TH is to regulate the basal metabolic rate and thereby control the processes of growth and tissue differentiation. Unlike GH, TH is involved in many more diverse activities that influence the growth and development of body tissues. Therefore, a deficiency of TH exerts a more profound effect on growth than that seen in GH deficiency.

Calcitonin helps maintain blood calcium levels by decreasing the calcium concentration. Its effect is the opposite of parathyroid hormone (PTH) in that it inhibits skeletal demineralization and promotes calcium deposition in the bone.

Juvenile Hypothyroidism

Hypothyroidism is one of the most common endocrine conditions of childhood. In Canada, hypothyroidism affects 1in 4 000 children (Thyroid Foundation of Canada, 2018). It may be either congenital or acquired and represents a deficiency in secretion of TH.

Beyond infancy, primary hypothyroidism may be caused by a number of defects. For example, a congenital hypoplastic thyroid gland may provide sufficient amounts of TH during the first year or two but be inadequate when rapid body growth increases demands on the gland. A partial or complete thyroidectomy for cancer or thyrotoxicosis can leave insufficient thyroid tissue to furnish hormones for body requirements. Radiotherapy for Hodgkin disease or other malignancies may lead to hypothyroidism (Wassner & Smith, 2020). Infectious processes may cause hypothyroidism. It can also occur when dietary iodine is deficient, which is rare in Canada, due to iodized salt availability. Rare cases of hypothyroidism have been reported following use of iodinated contrast media (ICM), particularly in term and preterm newborns (Government of Canada, 2018).

Clinical manifestations depend on the extent of dysfunction and the child's age at onset. Primary congenital hypothyroidism is characterized by low levels of circulating thyroid hormones and raised levels of TSH at birth. If left untreated, congenital hypothyroidism causes intellectual disability. In Canada, all newborns are screened for hypothyroidism at birth, and this has led to earlier detection and prevention of complications. This screening may not detect rarer disorders such as central hypothyroidism or congenital primary hypothyroidism with delayed TSH elevation. The presenting symptoms are decelerated growth from chronic deprivation of TH or thyromegaly. Impaired growth and development are less severe when hypothyroidism is acquired at a later age, and, because brain growth is nearly complete by 2 to 3 years of age, intellectual disability and neurological sequelae are not associated with juvenile hypothyroidism. Other manifestations are myxedematous skin changes (dry skin, puffiness around the eyes, sparse hair), constipation, sleepiness, and cognitive decline.

Therapy is TH replacement, the same as for hypothyroidism in the infant, although the prompt treatment needed in the infant is not required in the child. In children with severe symptoms, the restoration of euthyroidism is achieved more gradually with administration of increasing amounts of L-thyroxine daily over a period of 4 to 8 weeks to avoid symptoms of hyperthyroidism, which can occur with treatment of chronic hypothyroidism. Children who are treated early continue to have mild delays in skills in reading, comprehension, and math but catch up by grade 6. However, adolescents may demonstrate difficulties with memory, attention, and visuospatial processing.

Nursing Care. Growth cessation or restriction in a child whose growth has previously been normal should alert the nurse to the possibility of hypothyroidism. After diagnosis and implementation of thyroxine therapy, the importance of adhering to the treatment and periodic monitoring of response to therapy should be stressed to parents. Children should learn to take responsibility for their own health as soon as they are old enough.

Goitre

A *goitre* is an enlargement or hypertrophy of the thyroid gland. It may occur with deficient (*hypothyroid*), excessive (*hyperthyroid*), or normal (**euthyroid**) TH secretion. It can be congenital or acquired. Congenital disease usually occurs as a result of maternal administration of antithyroid medications or iodides during pregnancy. Acquired disease can result from increased secretion of pituitary TSH in response to decreased circulating levels of TH or from infiltrative neoplastic or inflammatory processes. In most children, goitre is caused by chronic

autoimmune thyroiditis (Latronico et al., 2016). In areas where dietary iodine (essential for TH production) is deficient, goitre can be endemic.

Enlargement of the thyroid gland may be mild and noticeable only when there is an increased demand for TH (e.g., during periods of rapid growth). Enlargement of the thyroid at birth can be sufficient to cause severe respiratory distress. Colloid goitres are diffuse and benign and occur more frequently in adolescent girls. Thyroid function is normal, and the gland will gradually decrease over several years without treatment. TH replacement is necessary to treat the hypothyroidism and reverse the TSH effect on the gland.

Therapeutic Management. Large goitres are identified by their obvious appearance. In older children, each lobe of the thyroid should be approximately the same as the terminal phalanx of the child's thumb (Wassner & Smith, 2020). Smaller nodules may be evident only on palpation. Benign enlargement of the thyroid gland may occur during adolescence and should not be confused with pathological states. Nodules rarely are caused by a cancerous tumour but always require evaluation. Questions regarding exposure to radiation should be included in the assessment (see Chapter 33 for thyroid examination technique).

! NURSING ALERT

If an infant is born with a goitre, immediate precautions need to be instituted for emergency ventilation, such as giving supplemental oxygen and having a tracheostomy set nearby. Hyperextension of the neck often facilitates breathing. Immediate surgery to remove part of the gland may be lifesaving in newborns with a goitre.

Lymphocytic Thyroiditis

Lymphocytic thyroiditis (Hashimoto disease, juvenile autoimmune thyroiditis) is the most common cause of thyroid disease in children and adolescents and is associated with the largest percentage of juvenile hypothyroidism. It accounts for many of the enlarged thyroid glands formerly designated *thyroid hyperplasia of adolescence* or *adolescent goitre*. Although it can develop during the first 3 years of life, it occurs more frequently after age 6. It reaches a peak incidence during adolescence, and there is evidence that the disease is self-limiting. The presence of a goitre and elevated thyroglobulin antibody with progressive increase in both thyroid peroxidase antibody and TSH may be predictive factors for future development of hypothyroidism (Wassner & Smith, 2020).

The presence of an enlarged thyroid gland is usually detected by the health care provider during a routine examination, although it may be noted by parents when the youngster swallows. In most children the entire gland is enlarged symmetrically (though it may be asymmetrical) and is firm, freely movable, and nontender. There may be manifestations of moderate tracheal compression (sense of fullness, hoarseness, and dysphagia), but it is extremely rare for a nontoxic diffuse goitre to enlarge to the extent that it causes airway obstruction. Most children are euthyroid, but some display symptoms of hypothyroidism, including delayed growth and puberty and declining school performance. Other signs suggestive of lymphocytic thyroiditis are listed in Box 51.5.

Diagnostic Evaluation. Thyroid function tests are usually normal, though TSH levels may be slightly or moderately elevated. With progressive disease the T_4 decreases, followed by a decrease in T_3 levels and an increase in TSH. Most affected children have antithyroid antibody titres. However, levels in children are lower than in adults; repeated measurements may be needed in doubtful cases, since titres may increase later in the disease.

BOX 51.5 Clinical Manifestations of Lymphocytic Thyroiditis

Enlarged thyroid gland
- Usually symmetrical
- Firm
- Freely movable
- Nontender

Tracheal compression
- Sense of fullness
- Hoarseness
- Dysphagia

Hyperthyroidism (possible)
- Nervousness
- Irritability
- Increased sweating
- Hyperactivity

Therapeutic Management. In many cases the goitre is transient and asymptomatic and regresses spontaneously within a year or two. Therapy of a nontoxic diffuse goitre is usually simple, uncomplicated, and effective. Oral administration of TH decreases the size of the gland significantly and provides the feedback needed to suppress TSH stimulation, and the hyperplastic thyroid gland gradually regresses in size. TSH levels should be monitored with the goal of restoring normal growth and development. Surgery is contraindicated in this disorder. Untreated patients should be evaluated periodically.

Nursing Care. Nursing care consists of identifying the child with thyroid enlargement, reassuring the child and parents that the condition is probably only temporary, and reinforcing instructions for thyroid therapy.

Hyperthyroidism

The largest percentage of hyperthyroidism in childhood is caused by Graves' disease, which is usually associated with an enlarged thyroid gland and exophthalmos. Graves' disease occurs in approximately 1 in 5 000 children. Graves' disease has a peak incidence in the 11- to 15-year-old age group, and there is a 5 to 1 female-to-male ratio. Many children with Graves' disease have a family history of autoimmune thyroid disease. Although rare, Graves' disease has been reported in children between 6 weeks and 2 years of age born to mothers without a history of hyperthyroidism (Wassner & Smith, 2020).

The hyperthyroidism of Graves' disease is apparently caused by an autoimmune response to TSH receptors, but no specific etiology has been identified. There is definitive evidence for familial association, with a high concordance incidence in twins. There may be an association with other autoimmune diseases such as rheumatoid arthritis and lupus.

The development of manifestations is highly variable. Signs and symptoms develop gradually, with an interval between onset and diagnosis of approximately 6 to 12 months. The principal clinical features are excessive motion, irritability, hyperactivity, short attention span, tremors, insomnia, and emotional lability. Clinical manifestations are presented in Box 51.6.

BOX 51.6 Clinical Manifestations of Hyperthyroidism (Graves' Disease)

Cardinal Signs
Emotional lability
Physical restlessness, characteristically at rest
Decelerated school performance
Voracious appetite with weight loss in 50% of cases
Fatigue

Physical Signs
Tachycardia
Widened pulse pressure
Dyspnea on exertion
Exophthalmos (protruding eyeballs)
Wide-eyed, staring expression with lid lag
Tremor
Goitre (hypertrophy and hyperplasia)
Warm, moist skin
Accelerated linear growth
Heat intolerance (may be severe)
Hair fine and unable to hold a curl
Systolic murmurs

Thyroid Storm
Acute onset:
- Severe irritability and restlessness
- Vomiting
- Diarrhea
- Hyperthermia
- Hypertension
- Severe tachycardia
- Prostration

May progress rapidly to:
- Delirium
- Coma
- Death

Exophthalmos (protruding eyeballs), observed in many children, is accompanied by a wide-eyed staring expression, increased blinking, eyelid lag, lack of convergence, and absence of wrinkling of the forehead when looking upward. As protrusion of the eyeball increases, the child may not be able to completely cover the cornea with the lid. Visual disturbances may include blurred vision and loss of visual acuity. Eye disease associated with hyperthyroidism can develop long before or after the onset of hyperthyroidism.

Diagnostic Evaluation. The diagnosis is established on the basis of increased levels of T_4 and T_3. TSH is suppressed to unmeasurable levels. Graves' disease is confirmed by measurement of the thyroid-stimulating immunoglobulins. Other tests are rarely indicated.

Therapeutic Management. Therapy for hyperthyroidism has not been firmly established, but all methods are directed toward slowing the rate of hormone secretion. The three acceptable modes available are the antithyroid medications, including propylthiouracil (PTU) and methimazole (MTZ, Tapazole), which interfere with the biosynthesis of TH; subtotal thyroidectomy when other treatments are not effective; and ablation with radioiodine (^{131}I iodide) (Wassner & Smith, 2020). Each treatment is effective, but each has its own advantages and disadvantages. Pharmacological therapy may induce a remission, and treatment may be discontinued. However, relapse may occur. Radioactive iodine ablation is usually effective but response may be slower, and there have been concerns about a possible link to thyroid cancer in younger children. Surgery is often used when other treatments are not effective. These children require lifelong monitoring.

When affected children exhibit signs and symptoms of hyperthyroidism (e.g., weight loss, tachycardia, increased pulse pressure, and hypertension), their activity should be limited to quiet and low-impact play and to classwork. Vigorous exercise is restricted until thyroid levels are decreased to normal or near-normal values.

Thyrotoxicosis (thyroid *crisis* or thyroid *storm*) may occur from the sudden release of the hormone. Although thyrotoxicosis is unusual in children, a crisis can be life-threatening. These "storms" are evidenced by the acute onset of severe irritability and restlessness, vomiting, diarrhea, hyperthermia, hypertension, severe tachycardia, and prostration (see Box 51.6). There may be rapid progression to delirium, coma, and even death. A crisis may be precipitated by acute infection, surgical emergencies, or discontinuation of antithyroid therapy. Treatment, in addition to antithyroid medications, is administration of beta-adrenergic blocking agents (propranolol), which provide relief from the adrenergic hyperresponsiveness that produces the disturbing adverse effects of the reaction. Therapy is usually required for 2 to 3 weeks.

The Thyroid Foundation of Canada has extensive information related to the prevention, treatment, and cure of thyroid disease (see Additional Resources at the end of this chapter).

Nursing Care. The initial nursing objective is identification of children with hyperthyroidism. Because the clinical manifestations often appear gradually, the goitre and ophthalmic changes may not be noticed, and the excessive activity may be attributed to behavioural issues. Nurses in ambulatory settings need to be alert to signs that suggest this disorder, especially weight loss despite an excellent appetite, academic difficulties resulting from a short attention span and inability to sit still, unexplained fatigue and sleeplessness, and difficulty with fine motor skills such as writing. Exophthalmos may develop long before the onset of signs and symptoms of hyperthyroidism and may be the only presenting sign.

Much of the care of these children is related to treating physical symptoms before a response to medication therapy is achieved. Children with hyperthyroidism need a quiet, unstimulating environment that is conducive to rest. Increased metabolic rate may cause heat intolerance and increased food intake in these patients. Mood swings and irritability can disrupt relationships, creating difficulties within and outside the home. A school consultation is important to provide education and suggest ways to assist a child after diagnosis. The child and parents should be encouraged to express their feelings about the behaviour and its effect on others. Heat intolerance may be minimized by the use of light cotton clothing, good ventilation, air conditioning or fans, frequent baths, and adequate hydration. Dietary requirements should be adjusted to meet the child's increased metabolic rate. Rather than three large meals, the child's appetite may be better satisfied by five or six moderate meals throughout the day.

! NURSING ALERT

Children being treated with propylthiouracil or methimazole must be carefully monitored for adverse effects of the medication. Because sore throat and fever accompany the grave complication of leukopenia, these children should be seen by a health care provider if such symptoms occur. Parents and children should be taught to recognize and report symptoms immediately.

DISORDERS OF PARATHYROID FUNCTION

The parathyroid glands secrete parathyroid hormone (PTH), the main function of which, along with vitamin D and calcitonin, is homeostasis of serum calcium concentration. The effect of PTH on calcium is opposite that of calcitonin. The net result of the integrated action of PTH and vitamin D is maintenance of serum calcium levels within a narrow normal range and the mineralization of bone. Secretion of PTH is controlled by a negative feedback system involving the serum calcium ion concentration. Low ionized calcium levels stimulate PTH secretion, causing absorption of calcium by the target tissues; high ionized calcium concentrations suppress PTH.

Hypoparathyroidism

Hypoparathyroidism entails a spectrum of disorders that result in deficient PTH. Congenital hypoparathyroidism may be caused by a specific defect in the synthesis or cellular processing of PTH or by aplasia or hypoplasia of the gland (Doyle, 2020b).

Hypoparathyroidism can also occur secondary to other causes, including infection and autoimmune syndromes. Postoperative hypoparathyroidism may follow thyroidectomy with acute or gradual onset and be transient or permanent. Two forms of transient hypoparathyroidism may be present in the newborn, both of which are the result of a relative PTH deficiency. One type is caused by maternal hyperparathyroidism or maternal DM. A more common, later form appears almost exclusively in infants fed a milk formula with a high phosphate-to-calcium ratio.

Pseudohypoparathyroidism occurs when there is a genetic defect in the cellular receptors to PTH. The result is normal parathyroid gland and elevated PTH levels. Abnormal calcium and phosphorus levels are not affected by administration of PTH. Affected children typically have a short, stocky build; a round face; and abnormally shaped hands and fingers. Other endocrine dysfunction may be found concurrently. These children have an increased risk for neuropsychiatric disorders, cataracts, and seizures (Doyle, 2020b).

Clinical signs of hypoparathyroidism are presented in Box 51.7. Muscle cramps are an early symptom, progressing to numbness, stiffness, and tingling in the hands and feet. A positive Chvostek or Trousseau sign or laryngeal spasms may be present. Convulsions with loss of consciousness may occur. These episodes may be preceded by abdominal discomfort, tonic rigidity, head retraction, and cyanosis. Headaches and vomiting with increased intracranial pressure and papilledema may occur and may suggest a brain tumour (Doyle, 2020b).

Diagnostic Evaluation. The diagnosis of hypoparathyroidism is made on the basis of clinical manifestations associated with decreased serum calcium and increased serum phosphorus. Magnesium levels also need to be checked. Levels of plasma PTH are low in idiopathic hypoparathyroidism but high in pseudohypoparathyroidism. End-organ responsiveness is tested by the administration of PTH with measurement of urinary cyclic adenosine monophosphate (cAMP). Kidney function tests are included in the differential diagnosis to rule out renal insufficiency. Although bone radiographs are usually normal, they may demonstrate increased bone density and suppressed growth.

! NURSING ALERT

The earliest indication of hypoparathyroidism may be anxiety and mental depression, followed by paresthesia and evidence of heightened neuromuscular excitability:

Chvostek sign—Facial muscle spasm elicited by tapping the facial nerve in the region of the parotid gland

Trousseau sign—Carpal spasm elicited by pressure applied to nerves of the upper arm

Tetany—Carpopedal spasm (sharp flexion of wrist and ankle joints), muscle twitching, cramps, seizures, and stridor

Therapeutic Management. The objective of treatment is to maintain normal serum calcium and phosphate levels with minimum complications. Acute or severe tetany is corrected immediately by IV and oral administration of calcium gluconate and follow-up daily doses to achieve normal levels. Twice-daily serum calcium measurements are taken to monitor the efficacy of therapy and prevent hypercalcemia. When diagnosis is confirmed, vitamin D therapy is begun. Vitamin D therapy is somewhat difficult to regulate because the medication has a prolonged onset and a long half-life (Doyle, 2020b).

BOX 51.7 Clinical Manifestations of Hypoparathyroidism

Pseudohypoparathyroidism

Short stature
Round face
Short, thick neck
Short, stubby fingers and toes
Dimpling of skin over knuckles
Subcutaneous soft tissue calcifications
Intellectual disability a prominent feature

Idiopathic Hypoparathyroidism

None of the above physical characteristics observed
May include papilledema
May have intellectual disability

Both Types

Dry, scaly, coarse skin with eruptions
Hair often brittle
Nails thin and brittle with characteristic transverse grooves
Dental and enamel hypoplasia
Muscle contractions:
- Tetany
- Carpopedal spasm
- Laryngospasm (laryngeal stridor)
- Muscle cramps and twitching
- Positive Chvostek sign or Trousseau's sign

Neurological:
- Headache
- Seizures (generalized, absence, or focal)
- Swings of emotion
- Loss of memory
- Depression
- Confusion possible
- Paresthesias, tingling

Gastrointestinal:
- Muscle cramps
- Diarrhea
- Vomiting

Delayed skeletal growth

Long-term management usually consists of vitamin D and oral calcium supplementation. Serum calcium and phosphorus are monitored frequently until the levels have stabilized, then routinely thereafter. Renal function, blood pressure, and serum vitamin D levels are measured every 6 months. Serum magnesium levels are measured to detect hypomagnesemia, which may raise the requirement for vitamin D.

Nursing Care. The initial objective is recognition of hypocalcemia. Unexplained convulsions, irritability (especially to external stimuli), gastrointestinal symptoms (diarrhea, vomiting, cramping), and positive signs of tetany are signs of hypocalcemia related to hypoparathyroidism. Much of the initial nursing care is related to the physical manifestations and includes institution of seizure and safety precautions; reduction of aggravating environmental stimuli, such as avoiding sudden or loud noise, bright lights, and stimulating activities; and observation for signs of laryngospasm, such as stridor, hoarseness, and a feeling of tightness in the throat. A tracheostomy set and injectable calcium gluconate should be located near the bedside for emergency use. The administration of calcium gluconate requires precautions against extravasation of the medication and tissue destruction.

After initiating treatment, the nurse should discuss with the parents the need for continuous daily administration of calcium salts and vitamin D. Because vitamin D toxicity can be a serious consequence of therapy, parents are advised to watch for its signs, which include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Early renal impairment is manifested by polyuria, polydipsia, and nocturia.

Hyperparathyroidism

Hyperparathyroidism is rare in childhood but can be primary or secondary. The most common cause of primary hyperparathyroidism is adenoma of the gland (Doyle, 2020a). The most common causes of secondary hyperparathyroidism are chronic renal disease, renal osteodystrophy, and congenital anomalies of the urinary tract. The common factor is hypercalcemia. The clinical signs of hyperparathyroidism are listed in Box 51.8.

Diagnostic Evaluation. Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed. Measurement of PTH, as well as several tests to isolate the cause of the hypercalcemia, such as renal function studies, should be included. If parathyroid adenoma is suspected, imaging using ultrasound and a sestamibi nuclear subtraction study are recommended (Doyle, 2020a). Other procedures used to substantiate the physiological consequences of the disorder include electrocardiography and radiographic bone surveys.

Therapeutic Management. Treatment depends on the cause of hyperparathyroidism. The treatment of primary hyperparathyroidism is surgical removal of the tumour or hyperplastic tissue. Treatment of secondary hyperparathyroidism is directed at the underlying contributing cause, which subsequently restores the serum calcium balance. However, in some instances, such as in chronic kidney disease, the underlying disorder is irreversible. In this case, treatment is aimed at raising serum calcium levels to inhibit the stimulatory effect of low levels on the parathyroids. This includes oral administration of calcium salts, high doses of vitamin D to enhance calcium absorption, a low-phosphorus diet, and administration of a phosphorus-mobilizing aluminum hydroxide to reduce phosphate absorption.

Nursing Care. The initial nursing objective is recognition of the disorder. Because secondary hyperparathyroidism is a consequence of chronic kidney disease, the nurse needs to be alert to signs that suggest this complication, especially bone pain and fractures. Because urinary symptoms are the earliest indication, assessment of other body systems for evidence of high calcium levels is indicated when polyuria and polydipsia coexist. Clues to the possibility of hyperparathyroidism include a change in behaviour, especially inactivity; unexplained gastrointestinal symptoms; and cardiac irregularities.

BOX 51.8 Clinical Manifestations of Hyperparathyroidism

Gastrointestinal
Nausea
Vomiting
Abdominal discomfort
Constipation

Central Nervous System
Delusions
Confusion
Hallucinations
Impaired memory
Lack of interest and initiative
Depression
Varying levels of consciousness

Neuromuscular
Weakness
Easy fatigability
Muscle atrophy (especially proximal muscles of lower limbs)
Tongue twitching
Paresthesias in extremities

Skeletal
Vague bone pain
Subperiosteal resorption of phalanges
Spontaneous fractures
Absence of lamina dura around teeth

Renal
Polyuria
Polydipsia
Renal colic
Hypertension

DISORDERS OF ADRENAL FUNCTION

The adrenal cortex secretes three main groups of hormones collectively called *steroids* and classified according to their biological activity: (1) glucocorticoids (cortisol, corticosterone), (2) mineralocorticoids (aldosterone), and (3) sex steroids (androgens, estrogens, and progestins). The glucocorticoids and mineralocorticoids affect metabolism and stress. The sex steroids influence sexual development but are not essential because the gonads secrete the major supply of these hormones. Alterations in the levels of these hormones produce significant dysfunction in a variety of body tissues and organs. Because the adrenocortical cells are capable of producing any of the steroids, pathological conditions may result in a deficiency or an excess of more than one type of hormone. However, most of these conditions are rare in children.

The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Both hormones have essentially the same effects on various organs as those caused by direct sympathetic stimulation, except that the hormonal effects last several times longer. Catecholamine-secreting tumours are the primary cause of adrenal medullary hyperfunction.

Acute Adrenocortical Insufficiency

The acute form of adrenocortical insufficiency (*adrenal crisis*) may have a number of causes during childhood. Although a rare disorder, some of the more common etiological factors include hemorrhage into the gland from trauma, which may be caused by a prolonged, difficult labour; fulminating infections, such as meningococcemia, which result in hemorrhage and necrosis (Waterhouse-Friderichsen syndrome); abrupt withdrawal of exogenous sources of cortisone or failure to increase exogenous supplies during stress; or congenital adrenogenital hyperplasia of the salt-losing type.

Early symptoms of adrenocortical insufficiency include increased irritability, headache, diffuse abdominal pain, weakness, nausea and vomiting, and diarrhea. Other clinical signs are presented in Box 51.9. In the newborn, adrenal crisis is accompanied by extreme hyperpyrexia (high temperature), tachypnea, cyanosis, and seizures. Usually there is no evidence of infection or purpura. However, hemorrhage into the adrenal gland may be evident as a palpable retroperitoneal mass.

Diagnostic Evaluation. There is no rapid, definitive test for confirmation of acute adrenocortical insufficiency. Routine procedures such as measurement of plasma cortisol levels are too time consuming to be practical. Thus diagnosis is usually made on the basis of clinical presentation, especially when a fulminating sepsis is accompanied by hemorrhagic manifestations and signs of circulatory collapse despite adequate antibiotic therapy. Because there is no real danger in administering a cortisol preparation for a short period, treatment should be instituted immediately. Improvement with cortisol therapy confirms the diagnosis.

Therapeutic Management. Treatment involves replacement of cortisol, replacement of body fluids to combat dehydration and hypovolemia, administration of glucose solutions to correct hypoglycemia, and specific antibiotic therapy in the presence of infection. Initially, IV hydrocortisone (Solu-Cortef) is administered. Normal saline containing 5% glucose is given parenterally to replace lost fluid, electrolytes, and glucose. If hemorrhage has been severe, whole blood may be replaced. In the event that these measures do not reverse the circulatory collapse, vasopressors are used for immediate vasoconstriction and elevation of blood pressure.

Once the child's condition is stabilized, oral doses of cortisone, fluids, and salt are given, similar to the regimen used for chronic adrenal insufficiency. To maintain sodium retention, aldosterone is replaced by synthetic salt-retaining steroids.

Nursing Care. Because of the abrupt onset and potentially fatal outcome of this condition, prompt recognition is essential. Vital signs and blood pressure are taken every 15 minutes to monitor the hyperpyrexia and shock-like state. Seizure precautions need to be instituted, since convulsions from the elevated temperature are not uncommon. As soon as therapy is instituted, the nurse should monitor the child's response to fluid and cortisol replacement. Rapid administration of fluids can precipitate cardiac failure, and overdosage with cortisol may cause hypotension and a sudden fall in temperature.

Once the acute phase is over and the hypovolemia is corrected, the child is given oral fluids, such as small quantities of ginger ale, fruit juice, or salted broth. Too-rapid ingestion of oral fluids may induce vomiting, which increases dehydration. Therefore, the nurse should plan a gradual schedule for reintroducing liquids.

! NURSING ALERT

When treating acute adrenocortical insufficiency, monitor serum electrolyte levels and observe for signs of hypokalemia or hyperkalemia, such as weakness, poor muscle control, paralysis, cardiac dysrhythmias, and apnea. The condition is rapidly corrected with IV or oral potassium replacement.

! NURSING ALERT

When an oral potassium preparation is given, it should be mixed with a small amount of strongly flavoured fruit juice to disguise its bitter taste.

The sudden, severe nature of this disorder necessitates a great deal of emotional support for the child and family. The child may be placed in a critical care unit where the surroundings are strange and frightening. Given the need for emergency intervention, the nurse must be sensitive to the family's psychological needs and prepare them for each procedure, even if with a brief statement such as "The intravenous infusion is necessary to replace fluid that the child is losing." Because recovery

BOX 51.9 Clinical Manifestations of Acute Adrenocortical Insufficiency

Early Symptoms
Increased irritability
Headache
Diffuse abdominal pain
Weakness
Nausea and vomiting
Diarrhea

Generalized Hemorrhagic Manifestations (Waterhouse-Friderichsen Syndrome)
Fever (increases as condition worsens)
Central nervous system signs:
- Nuchal rigidity
- Seizures
- Stupor
- Coma

Shocklike State
Weak, rapid pulse
Decreased blood pressure
Shallow respirations
Cold, clammy skin
Cyanosis
Circulatory collapse (terminal event)

Newborn
Hyperpyrexia
Tachypnea
Cyanosis
Seizures
Gland evident as palpable retroperitoneal mass (hemorrhagic)

within 24 hours is often dramatic, the nurse should keep the parents apprised of the child's condition, emphasizing signs of improvement, such as a lowered temperature and improved blood pressure.

Chronic Adrenocortical Insufficiency (Addison Disease)

Chronic adrenocortical insufficiency is rare in children. Causes include infections, destructive lesions of the adrenal gland or neoplasms, autoimmune processes, or idiopathic. Autoimmune destruction of the glands is the most common cause (White, 2020c). Evidence of this disorder is usually gradual in onset, since 90% of adrenal tissue must be nonfunctional before signs of insufficiency are manifested. However, during periods of stress, when demands for additional cortisol are increased, symptoms of acute insufficiency may appear in a previously well child (Box 51.10).

Definitive diagnosis is based on measurements of functional cortisol reserve. The fasting serum cortisol and urinary 17-hydroxycorticosteroid levels are low and fail to rise, and plasma ACTH (or corticotropin) levels are elevated with ACTH stimulation, the definitive test for the disease.

Therapeutic Management. Treatment involves replacement of glucocorticoids (cortisol) and mineralocorticoids (aldosterone). Some children are able to be maintained solely on oral supplements of cortisol (cortisone or hydrocortisone preparations) with a liberal intake of salt. During stressful situations, such as fever, infection, emotional upset, or surgery, the dosage must be tripled to accommodate the body's increased need for glucocorticoids. Failure to meet this requirement will precipitate an acute crisis. Overdosage produces the appearance of cushingoid signs.

Children with more severe states of chronic adrenal insufficiency require mineralocorticoid replacement to maintain fluid and electrolyte balance. Other forms of therapy include monthly injections of desoxycorticosterone acetate or implantation of desoxycorticosterone acetate pellets subcutaneously every 9 to 12 months.

Nursing Care. Once the disorder is diagnosed, parents need guidance with medication therapy. They must be aware of the continuous need for cortisol replacement. Sudden termination of the medication because of inadequate supplies or inability to ingest the oral form because of vomiting places the child in danger of an acute adrenal crisis.

! NURSING ALERT

The parents should always have a spare supply of cortisol in the home. Injectable cortisol should be available in a prefilled syringe in the home or when travelling. They need to be instructed in proper technique for intramuscular administration of the medication in case of a crisis. Unnecessary administration of cortisone will not harm the child, but if it is needed, it may be lifesaving. Any evidence of acute insufficiency should be reported to the primary health care provider immediately.

Undesirable effects of cortisone include gastric irritation, which is minimized by ingestion of certain foods or the use of an antacid; increased excitability and sleeplessness; weight gain, which may require dietary management to prevent obesity; and, rarely, behavioural changes, including depression or euphoria. Parents should be aware of signs of overdose and report these to the health care provider. In addition, the medication has a bitter taste, which creates a challenge for nurses and parents in its administration.

Because the body cannot supply endogenous sources of cortical hormones during times of stress, the home environment should be stable and relatively stress free. Parents need to be aware that during periods of emotional or physical crisis the child requires additional hormone replacement. The child should wear a medical alert bracelet, to permit medical personnel to adjust requirements during emergency care.

Cushing Syndrome

Cushing syndrome is a characteristic group of manifestations caused by excessive circulating free cortisol. It can result from a variety of causes, which generally fall under one of five categories (Box 51.11). Cushing syndrome in young children may be due to an adrenal tumour.

Cushing syndrome is uncommon in children. When seen, it is often caused by excessive or prolonged steroid therapy that produces a cushingoid appearance (Figure 51.2). This condition is reversible once the steroids are gradually discontinued. Abrupt withdrawal will precipitate

BOX 51.10 Clinical Manifestations of Chronic Adrenocortical Insufficiency

Neurological Symptoms
Muscular weakness
Mental fatigue
Irritability, apathy, and negativism
Increased sleeping, listlessness

Pigmentary Changes
Previous scars
Palmar creases
Mucous membranes
Hair
Hyperpigmentation over pressure points (elbows, knees, or waist)
Less frequently, vitiligo (loss of pigmentation)

Gastrointestinal Symptoms
Dehydration
Anorexia
Weight loss

Circulatory Symptoms
Hypotension
Small heart size
Dizziness
Syncopal (fainting) attacks

Hypoglycemia
Headache
Hunger
Weakness
Trembling
Sweating

Other Signs (Seen in Some Children)
Recurrent, unexplained seizures
Intense craving for salt
Acute abdominal pain
Electrolyte imbalances

BOX 51.11 Etiology of Cushing Syndrome

Pituitary—Cushing syndrome with adrenal hyperplasia, usually attributed to an excess of adrenocorticotropic hormone (ACTH)

Adrenal—Cushing syndrome with hypersecretion of glucocorticoids, generally a result of adrenocortical neoplasms

Ectopic—Cushing syndrome with autonomous secretion of ACTH, most often caused by extra pituitary neoplasms

Iatrogenic—Cushing syndrome, frequently a result of administration of large amounts of exogenous corticosteroids

Food dependent—Inappropriate sensitivity of adrenal glands to normal postprandial increases in secretion of gastric inhibitory polypeptide

Adapted from Magiakou, M. A., et al. (1994). Cushing's syndrome in children and adolescents: Presentation, diagnosis, and therapy. *New England Journal of Medicine, 331*(10), 629–636.

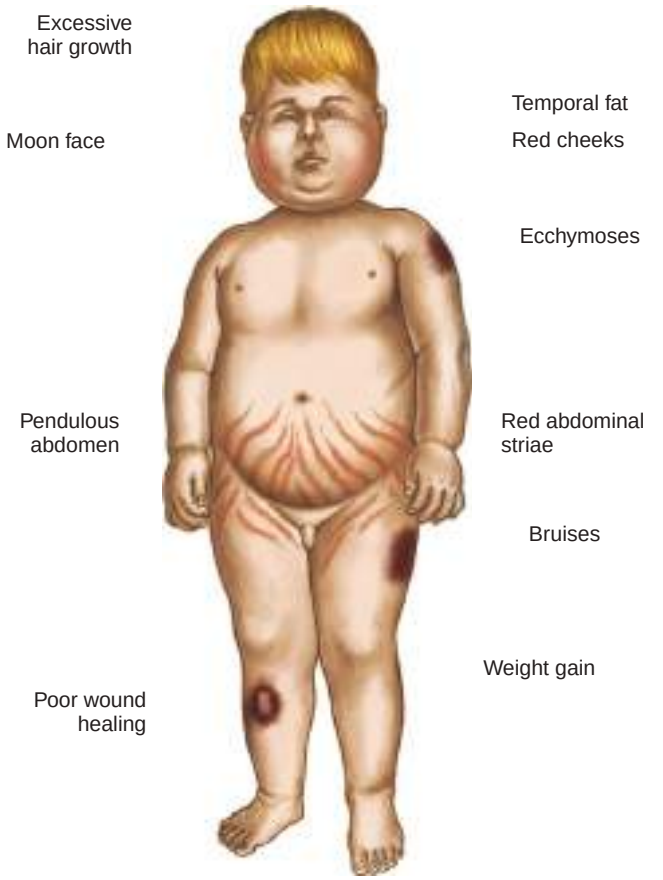

Fig. 51.2 Characteristics of Cushing syndrome.

acute adrenal insufficiency. Gradual withdrawal of exogenous supplies is necessary to allow the anterior pituitary an opportunity to secrete increasing amounts of ACTH to stimulate the adrenals to produce cortisol.

Clinical Manifestations. Because the actions of cortisol are widespread, clinical manifestations are equally profound and diverse. Those symptoms that produce changes in physical appearance occur early in the disorder and are of considerable concern to school-age and older children. The physiological disturbances, such as hyperglycemia, susceptibility to infection, hypertension, and hypokalemia, may have life-threatening consequences unless recognized early and treated successfully. Children with short stature may be responding to increased cortisol levels, resulting in Cushing syndrome. Cortisol inhibits the action of GH.

Diagnostic Evaluation. Several tests are helpful in confirming Cushing syndrome. Serum cortisol levels should be measured at midnight and in the morning along with corticotropin hormone, urinary free cortisol, fasting blood glucose levels for hyperglycemia, serum electrolyte levels for hypokalemia and alkalosis, and 24-hour urinary levels of elevated 17-hydroxycorticoids and 17-ketosteroids. Imaging of the pituitary and adrenal glands to assess for tumours, bone density studies for evidence of osteoporosis, and skull radiographs to determine enlargement of the sella turcica may also aid in the diagnosis. Another procedure used to establish a more definitive diagnosis is the dexamethasone (cortisone) suppression test (White, 2020b). Administration of an exogenous supply of cortisone normally suppresses ACTH production. However, in individuals with Cushing syndrome, cortisol levels remain elevated. This test is helpful in differentiating between obesity in children and those who appear to have cushingoid features.

Therapeutic Management. Treatment depends on the cause. In most cases surgical intervention involves bilateral adrenalectomy and postoperative replacement of the cortical hormones (the therapy for this is the same as that outlined for chronic adrenal insufficiency). If a pituitary tumour is found, surgical excision or irradiation may be chosen. In either of these instances, treatment of panhypopituitarism with replacement of GH, thyroid extract, ADH, gonadotropins, and steroids may be necessary for an indefinite period.

Nursing Care. Nursing care also depends on the cause of the disorder. When cushingoid features are caused by steroid therapy, the effects may be lessened with administration of the medication early in the morning and on an alternate-day basis. Giving the medication early in the day maintains the normal diurnal pattern of cortisol secretion. If given during the evening, it is more likely to produce symptoms because endogenous cortisol levels are already low and the additional supply exerts more pronounced effects. An alternate-day schedule allows the anterior pituitary an opportunity to maintain more normal hypothalamic–pituitary–adrenal control mechanisms.

If an organic cause is found, nursing care is related to the treatment regimen. Although a bilateral adrenalectomy permanently solves one condition, it reciprocally produces another syndrome. Before surgery, parents need to be adequately informed of the operative benefits and disadvantages. Postoperative teaching regarding medication replacement is the same as that discussed in the previous section.

! NURSING ALERT

Postoperative complications of adrenalectomy are related to the sudden withdrawal of cortisol. Observe for shocklike symptoms (e.g., hypotension, hyperpyrexia).

Anorexia, nausea, and vomiting are common and may be improved with the use of nasogastric decompression. Muscle and joint pain may be severe, requiring use of analgesics. The psychological depression can be profound and may not improve for months. Parents should be aware of the physiological reasons behind these symptoms in order to be supportive of the child.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a family of disorders caused by decreased enzyme activity required for cortisol production in the adrenal cortex. The adrenal glands produce excessive amounts of cortisol precursors and androgens to compensate. The most common defect is 21-hydroxylase deficiency, which leads to more than 90% of all cases of CAH (White, 2020a). This deficiency occurs in approximately 1 in 15 000 to 20 000 births. In its most severe form it can be life-threatening (White, 2020a).

Excessive androgens cause masculinization of the urogenital system at approximately the tenth week of fetal development. The most pronounced abnormalities occur in the girl, who is born with varying degrees of **ambiguous** genitalia. Masculinization of external genitalia causes the clitoris to enlarge so that it appears as a small phallus. Fusion of the labia produces a saclike structure resembling the scrotum without testes. This is called a disorder of sex development (DSD) (previously called *ambiguous genitalia*). However, no abnormal changes occur in the internal sexual organs, although the vaginal orifice is usually closed by the fused labia. In newborns with hypospadias or micropenis and no palpable gonads a diagnostic evaluation for CAH should be contemplated.

Increased pigmentation of skin creases and genitalia caused by increased ACTH may be a subtle sign of adrenal insufficiency. A salt-wasting crisis frequently occurs, usually within the first few weeks of life (White, 2020a). Infants fail to gain weight, and hyponatremia and hyperkalemia may be significant. Cardiac arrest can occur.

Untreated CAH results in early sexual maturation with enlargement of the external sexual organs; development of axillary, pubic, and facial hair; deepening of the voice; acne; and a marked increase in musculature with changes toward an adult male physique. However, in contrast to precocious puberty, breasts do not develop in girls and they remain amenorrheic and infertile. In boys, the testes remain small and spermatogenesis does not occur. In both sexes, linear growth is accelerated and epiphyseal closure is premature, resulting in short stature at the end of puberty.

Diagnostic Evaluation. Clinical diagnosis is initially based on congenital abnormalities that lead to difficulty in assigning sex to the newborn and on signs and symptoms of adrenal insufficiency. Most provinces and territories in Canada have universal newborn screening for CAH; the test is for the level of the cortisol precursor *17-hydroxyprogesterone*. Clinical symptoms need timely assessment and diagnostic testing even if their screen result is normal. Definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH (White, 2020a). In complete 21-hydroxylase deficiency, blood electrolytes demonstrate loss of sodium and chloride and elevation of potassium. In older children bone age is advanced, and linear growth is increased. DNA analysis typing for positive sex determination and to rule out any other genetic abnormality, such as Turner syndrome, is always done in any case of DSD.

Another test that can be used to visualize the presence of pelvic structures is **ultrasonography**, a noninvasive, painless imaging technique that does not require anaesthesia or sedation. It is especially useful in CAH because it readily identifies the absence or presence of female reproductive organs or male testes in a newborn or child with ambiguous genitalia. Because ultrasonography yields immediate results, it has the advantage of determining the child's gender long before the more complex laboratory results for chromosome analysis or steroid levels are available.

Therapeutic Management. After diagnosis is confirmed, medical management includes administration of glucocorticoids to suppress the abnormally high secretions of ACTH and adrenal androgens (White, 2020a). If cortisone is begun early enough, it is very effective. Cortisone depresses the secretion of ACTH by the adenohypophysis, which in turn inhibits the secretion of adrenocorticosteroids, which stems the progressive virilization. The signs and symptoms of masculinization in the female gradually disappear, and excessive early linear growth is slowed. Puberty occurs normally at the appropriate age.

The recommended oral dosage is divided to simulate the normal diurnal pattern of ACTH secretion. Because these children are unable to produce cortisol in response to stress, it is necessary to increase the dosage during episodes of infection, fever, surgery, or other stresses. Acute emergencies require immediate IV or intramuscular administration. Children with the salt-losing type of CAH require aldosterone replacement, as outlined earlier under Chronic Adrenal Insufficiency, and supplementary dietary salt. Frequent laboratory tests are conducted to assess the effects on electrolytes, hormonal profiles, and renin levels. The frequency of testing needs to be individualized to the child.

Gender assignment and surgical intervention in the newborn with DSD are complex and controversial. This issue is a significant stress for families, who need support from an interprofessional team of experienced specialists. Factors that influence gender assignment include genetic diagnosis, genitalia appearance, surgical options, fertility, and family and cultural preferences. Early reconstructive surgery should be considered only in the case of severe virilization. Emphasis is on functional rather than cosmetic outcomes, and surgery can often be delayed. Reports concerning sexual satisfaction after partial clitoridectomy indicate that the capacity for orgasm and sexual gratification is not necessarily impaired. Male infants may require phallic reconstruction by an experienced surgeon.

Unfortunately, not all children with CAH are diagnosed at birth and are raised in accordance with their **genetic sex**. Particularly in the case of affected girls, masculinization of the external genitalia may have led to sex assignment as a male. In boys, diagnosis is usually delayed until early childhood, when signs of virilism appear. Hormone replacement may be required to permit linear growth and to initiate male pubertal changes. Surgery is usually indicated to remove the female organs and reconstruct the phallus for satisfactory sexual relations. These individuals are not fertile. For further discussion see Disorders of Sex Development in Chapter 49.

Nursing Care. Of major importance is recognition of DSD and diagnostic confirmation in newborns. Parents need assistance in understanding and accepting the condition and time to adjust to the gender ambiguity in their newborn and time to grieve for the loss of what they may have anticipated in their child.

In general, rearing the genetically female child as a girl is preferred because of the success of surgical intervention and the satisfactory results with hormones in reversing virilism and providing a prospect of normal puberty and the ability to conceive. This is in contrast to the choice of rearing the child as a boy, in which case the child is sterile, and which can lead to the child struggling with gender identity and potentially with sexual relationships. The child with DSD should not receive gender assignment until a proper assessment has been done. Gender assignment is a very complex topic and should be based on age at presentation, potential for mature sexual function, potential fertility, and the long-term psychological and emotional impact on the child and family. Families should be referred to an interdisciplinary team to support them in addressing this challenging situation.

Nursing care regarding cortisol and aldosterone replacement is the same as that discussed for chronic adrenocortical insufficiency. Because infants are especially prone to dehydration and salt-losing crises, parents need to be aware of signs of dehydration and the urgency of

immediate medical intervention to stabilize the child's condition. Parents should have injectable hydrocortisone available and know how to prepare and administer the intramuscular injection (see Chapter 44).

In the unfortunate situation in which the sex is erroneously assigned and the correct sex is determined later, parents need a great deal of help in understanding the reason for the incorrect sex identification and the options for sex reassignment or medical-surgical intervention.

Parents should be referred for genetic counselling before they conceive again, as CAH is an autosomal recessive disorder. Prenatal diagnosis and treatments are available.

! NURSING ALERT

The parents should be advised that there is no physical harm in treating for suspected adrenal insufficiency that is not present; the consequence of not treating acute adrenal insufficiency can be fatal.

Pheochromocytoma

Pheochromocytoma is a rare tumour characterized by the secretion of catecholamines. The tumour most commonly arises from the chromaffin cells of the adrenal medulla but may occur wherever these cells are found, such as along the paraganglia of the aorta or thoracolumbar sympathetic chain (White, 2020c). Approximately 10% of these tumours are located in extra-adrenal sites. In children they are frequently bilateral or multiple and are generally benign. Often there is a familial transmission of the condition as an autosomal dominant trait (White, 2020c).

The clinical manifestations of pheochromocytoma are caused by an increased production of catecholamines, producing hypertension, tachycardia, headache, decreased gastrointestinal activity with resultant constipation, increased metabolism with anorexia, weight loss, hyperglycemia, polyuria, polydipsia, hyperventilation, nervousness, heat intolerance, and diaphoresis. In severe cases, signs of heart failure are evident.

Diagnostic Evaluation. The clinical manifestations mimic those of other disorders, such as hyperthyroidism or DM. Usually the tumour is identified by computed tomography (CT) scan or MRI. Definitive tests include 24-hour measurement of urinary levels of the catecholamines metabolites, histamine stimulation, and alpha-adrenergic blocking agents.

Therapeutic Management. Definitive treatment consists of surgical removal of the tumour. In children the tumours may be bilateral, requiring a bilateral adrenalectomy and lifelong glucocorticoid and mineralocorticoid therapy. The major complications during surgery include severe hypertension, tachydysrhythmias, and hypotension. The first two are caused by excessive release of catecholamines during manipulation of the tumour, and the latter results from catecholamine withdrawal and hypovolemic shock.

Preoperative treatment to inhibit the effects of the catecholamines is done 1 to 3 weeks before surgery to prevent these complications. The major group of medications used are alpha-adrenergic blocking agents. To control catecholamine release when alpha-adrenergic blocking agents are inadequate, the child is given beta-adrenergic blocking agents. Success of therapy is judged by lowering of blood pressure to normal, absence of hypertensive attacks (flushing or blanching, fainting, headache, palpitations, tachycardia, nausea and vomiting, profuse sweating), heat tolerance, a decrease in perspiration, and disappearance of hyperglycemia. A disadvantage of these medications is their inability to block the effects of catecholamines on beta receptors.

Nursing Care. An initial nursing objective is identification of children with this disorder. Outstanding clues are hypertension and hypertensive attacks. Because of behavioural changes (nervousness, excitability, overactivity, and even psychosis), increased cardiac and respiratory activity may appear to be related to an acute anxiety attack. Thus a careful history of the onset of symptoms and association with stressful events is helpful in distinguishing between an organic and a psychological cause for the symptoms.

Preoperative nursing care involves frequent monitoring of vital signs and observation for evidence of hypertensive attacks and heart failure. Therapeutic effects are evidenced by normal vital signs and absence of **glycosuria**. Daily blood glucose levels, urine acetone, and any signs of hyperglycemia need to be noted and reported immediately.

! NURSING ALERT

Do not palpate the mass. Preoperative palpation of the mass releases catecholamines, which can stimulate severe hypertension and tachydysrhythmias.

The environment should be made conducive to rest and free of emotional stress. This requires adequate preparation during hospital admission and before surgery. Play activities need to be tailored to the child's energy level without being overly strenuous or challenging because these can increase the metabolic rate and promote frustration and anxiety.

After surgery, the child needs to be observed for signs of shock from the removal of excess catecholamines. If a bilateral adrenalectomy was performed, the nursing interventions are those discussed for chronic adrenocortical insufficiency.

DISORDERS OF PANCREATIC HORMONE SECRETION

Diabetes mellitus (DM) is a chronic disorder of metabolism characterized by a partial or complete deficiency of the hormone insulin. It is the most common metabolic disease, resulting in metabolic adjustment or physiological change in almost all areas of the body. It is also one of the most common endocrine diseases and chronic conditions in the pediatric population.

Overall there are more than 3.2 million Canadians with either type 1 or type 2 DM (Government of Canada, 2021). Approximately 33 000 school-age children between the ages of 5 and 18 years old live with type 1 diabetes (Diabetic Children's Foundation, 2021).

The different types of DM include type 1 and type 2 diabetes. The characteristics of type 1 DM and type 2 DM are outlined in Table 51.1. In type 1 diabetes the body does not produce insulin and in type 2 the body can produce insulin but either not enough or is not able to use it properly. Type 1 diabetes is most often diagnosed in children, whereas type 2 diabetes is most often diagnosed in adults although an increasing number of children do have type 2 diabetes (Government of Canada, 2021).

Diabetes Mellitus Type 1

Over 300 000 Canadians have type 1 diabetes which is approximately 10% of Canadians living with diabetes (Diabetes Canada, 2021). The onset of type 1 diabetes usually occurs during childhood, making it one of the most common chronic diseases in children, with a prevalence of 1 in 300 children (Lawrence et al., 2015/2016). In Canada and in other areas of the world, the incidence is increasing steadily each year. Children younger than 5 years and early school-aged children are the fastest growing sector of the population with type 1 diabetes (Lawrence et al., 2015/2016).

TABLE 51.1 Characteristics of Types 1 and 2 Diabetes Mellitus

Characteristic	Type 1	Type 2
Age at onset	<20 years	Usually adult but increasingly occurring in younger children
Type of onset	Abrupt	Gradual
Sex ratio	Affects males slightly more than females	Females outnumber males
Percentage of diabetic population	5–8%	85–90%
Heredity:		
Family history	Sometimes	Frequently
Human leukocyte antigen	Association	No association
Twin concordance	25–50%	90–100%
Ethnic distribution	Primarily Whites	Increased incidence in Indigenous peoples and in people of Arab, Asian, Latin American, or African origins
Presenting symptoms	Three P's are common: polyuria, polydipsia, polyphagia	Fatigue, blurred vision, weight gain or loss, polydipsia, and polyuria
Nutritional status	Underweight	Overweight, high levels of fat or cholesterol in the blood
Insulin (natural):		
Pancreatic content	Usually none	>50% normal
Serum insulin	Low to absent	High or low
Primary resistance	Minimum	Marked
Islet cell antibodies	80–85%	<5%
Therapy:		
Insulin	Always	20–30% of patients
Oral agents	Ineffective	Often effective
Diet only	Ineffective	Often effective
Chronic complications	>80%	Variable
Ketoacidosis	Common	Infrequent

Adapted from Punthakee, Z., Goldenberg, R., Katz, P., & Diabetes Canada Clinical Practice Guidelines Expert Committee. (2018). Definition, classification and diagnosis of diabetes, prediabetes and metabolic syndrome. *Canadian Journal of Diabetes, 42*(Suppl 1), S1–S325. http://guidelines.diabetes.ca/cpg/chapter3.

Type 1 diabetes is characterized by destruction of the pancreatic **beta cells**, which produce insulin; this usually leads to absolute insulin deficiency. Type 1 diabetes has two forms. *Immune-mediated DM* results from an autoimmune destruction of the beta cells; it typically starts in children or young adults who are slim, but it can arise in adults of any age. *Idiopathic type 1* refers to rare forms of the disease that have no known cause.

The symptomatology of diabetes is more readily recognizable in children than in adults, so it is surprising that the diagnosis may sometimes be missed or delayed. Diabetes is a great imitator; influenza, gastroenteritis, and appendicitis are the conditions most often diagnosed when it turns out that the disease is really diabetes (Box 51.12).

BOX 51.12 Clinical Manifestations of Type 1 Diabetes Mellitus

Polyphagia
Polyuria
Polydipsia
Weight loss
Enuresis or nocturia
Irritability; the person is "not themself"
Shortened attention span
Lowered frustration tolerance
Dry skin
Blurred vision
Poor wound healing
Fatigue
Flushed skin
Headache
Frequent infections
Hyperglycemia
- Elevated blood glucose levels
- Glucosuria

Diabetic ketosis
- Ketones and glucose in urine
- Dehydration in some cases

Diabetic ketoacidosis
- Dehydration
- Electrolyte imbalance
- Acidosis
- Deep, rapid breathing (Kussmaul)

Pathophysiology. Insulin is needed to support the metabolism of carbohydrates, fats, and proteins, primarily by facilitating the entry of these substances into the cells. Insulin is needed for the entry of glucose into the muscle and fat cells, prevention of mobilization of fats from fat cells, and storage of glucose as glycogen in the cells of liver and muscle. Insulin is not needed for the entry of glucose into nerve cells or vascular tissue. The chemical composition and molecular structure of insulin are such that it fits into receptor sites on the cell membrane. Here it initiates a sequence of poorly defined chemical reactions that alter the cell membrane to facilitate the entry of glucose into the cell and stimulate enzymatic systems outside the cell that metabolize the glucose for energy production.

With a deficiency of insulin, glucose is unable to enter the cell, and its concentration in the bloodstream increases (*hyperglycemia*). The increased concentration of glucose produces an osmotic gradient that causes the movement of body fluid from the intracellular space to the interstitial space and then to the extracellular space and into the glomerular filtrate to "dilute" the hyperosmolar filtrate. Normally, the renal tubular capacity to transport glucose is adequate to reabsorb all the glucose in the glomerular filtrate. When the serum glucose level exceeds the renal threshold ±10 mmol/L, glucose "spills" into the urine (*glycosuria*), along with an osmotic diversion of water (*polyuria*), a cardinal sign of diabetes. The urinary fluid losses cause the excessive thirst (*polydipsia*) observed in diabetes. This water "washout" results in a depletion of other essential chemicals, especially potassium.

Protein is also wasted during insulin deficiency. Because glucose is unable to enter the cells, protein is broken down and converted to glucose by the liver (*glucogenesis*); this glucose then contributes to the

hyperglycemia. These mechanisms are similar to those seen in starvation when substrate (glucose) is absent. The body is actually in a state of starvation during insulin deficiency. Without the use of carbohydrates for energy, fat and protein stores are depleted as the body attempts to meet its energy needs. The hunger mechanism is triggered, but the increased food intake (*polyphagia*) enhances the issue by further elevating the blood glucose.

Ketoacidosis. When insulin is absent or insulin sensitivity is altered, glucose is unavailable for cellular metabolism, and the body chooses alternative sources of energy, principally fat. Consequently, fats break down into fatty acids, and glycerol in the fat cells is converted by the liver to ketone bodies (beta-hydroxybutyric acid, acetoacetic acid, acetone). Any excess is eliminated in the urine (*ketonuria*) or the lungs (*acetone breath*). The ketone bodies in the blood (*ketonemia*) are strong acids that lower serum pH, producing ketoacidosis.

Ketones are organic acids that readily produce excessive quantities of free hydrogen ions, causing a fall in plasma pH. Then chemical buffers in the plasma, principally bicarbonate, combine with the hydrogen ions to form carbonic acid, which readily dissociates into water and carbon dioxide. The respiratory system attempts to eliminate the excess carbon dioxide by increasing the depth and rate of respirations—**Kussmaul respirations**, or the hyperventilation characteristic of metabolic acidosis. The ketones are buffered by sodium and potassium in the plasma. The kidney attempts to compensate for the increased pH by increasing tubular secretion of hydrogen and ammonium ions in exchange for fixed base, thus depleting the base buffer concentration.

With cellular death, potassium is released from the cell (intracellular fluid) into the bloodstream (extracellular fluid) and excreted by the kidney, where the loss is accelerated by **osmotic diuresis**. The total body potassium is then decreased, even though the serum potassium level may be elevated as a result of the decreased fluid volume in which it circulates. Alteration in serum and tissue potassium can lead to cardiac arrest.

If these conditions are not reversed by insulin therapy in combination with correction of the fluid deficiency and electrolyte imbalance, progressive deterioration occurs, with dehydration, electrolyte imbalance, acidosis, coma, and death. **Diabetic ketoacidosis (DKA)** should be diagnosed promptly in a seriously ill patient and therapy instituted in a critical care unit.

Long-term complications. Long-term complications of diabetes involve both the microvasculature and the macrovasculature. The principal microvascular complications are nephropathy, retinopathy, and neuropathy. Microvascular disease develops during the first 30 years of diabetes, beginning in the first 10 to 15 years after puberty, with renal involvement evidenced by proteinuria and clinically apparent retinopathy.

With poor diabetic control, vascular changes can appear as early as 2 ½ to 3 years after diagnosis; however, with good to excellent control, changes can be postponed for 20 or more years. Glycemic control decreases the likelihood of long-term complications in patients with DM (Wherrett et al., 2018). Intensive insulin therapy appears to delay the onset and slow the progression of clinically important retinopathy, nephropathy, and neuropathy. Hypertension and atherosclerotic cardiovascular disease are also major causes of morbidity and mortality in patients with DM. The postpubertal duration, not the total duration, of type 1 DM is implicated as a risk factor for the development of microvascular disease (Wherrett et al., 2018). See Table 51.2 for screening for diabetes complications, dyslipidemia, and hypertension in children with type 1 diabetes.

Other complications have been observed in children with type 1 DM. Hyperglycemia appears to influence thyroid function, and altered function is frequently observed at the time of diagnosis and in poorly controlled diabetes. Children should be screened for thyroid function at diabetes diagnosis with repeat screening every 2 years using a serum TSH and thyroid peroxidase antibodies. More frequent screening is indicated in the presence of positive anti-thyroid antibodies, thyroid symptoms, or goitre (Wherrett et al., 2018). Primary adrenal insufficiency (Addison disease) is rare, even in those with type 1 DM. Targeted screening is required in those with unexplained recurrent hypoglycemia and decreasing insulin requirements (Wherrett et al., 2018). Children with type 1 DM are at increased risk for classic or atypical celiac disease during the first 10 years of diabetes (Wherrett et al., 2018). Limited mobility of small joints of the hand occurs in 30% of 7 to 18-year-old children with type 1 DM and appears to be related to changes in the skin and soft tissues surrounding the joint as a result of glycosylation.

Diagnostic Evaluation. Four groups of children who should be considered as possibly having diabetes are (1) children who have glycosuria, polyuria, and a history of weight loss or failure to gain weight despite a voracious appetite, (2) those with transient or persistent glycosuria, (3) those who display manifestations of metabolic acidosis, with or without stupor or coma, and (4) children with repeated urinary tract infections. In every case diabetes must be considered if there is glycosuria, with or without ketonuria, and unexplained hyperglycemia.

Glycosuria by itself is not diagnostic of diabetes. Other sugars, such as galactose, can produce a positive result with certain urine test strips, and a mild degree of glycosuria can be caused by other conditions, such as infection, trauma, emotional or physical stress, hyperalimentation, and some renal or endocrine diseases.

DM in children is diagnosed on the basis of any of the following three abnormal glucose metabolites: an 8-hour fasting blood glucose level of $\geq$7.0 mmol/L or more, a random blood glucose value of $>$11.1 mmol/L or more accompanied by classic signs of diabetes, or an oral glucose tolerance test (OGTT) finding of $\geq$11.1 mmol/L in the 2-hour sample (Punthakee et al., 2018). Postprandial blood glucose determinations and the traditional OGTTs have yielded low detection rates in children and are not usually necessary for establishing a diagnosis. Serum insulin levels may be normal or moderately elevated at the onset of diabetes; delayed insulin response to glucose indicates impaired glucose tolerance.

Ketoacidosis must be differentiated from other causes of acidosis or coma, including hypoglycemia, uremia, gastroenteritis with metabolic acidosis, salicylate intoxication encephalitis, and other intracranial lesions. DKA is a state of relative insulin insufficiency and may include the presence of hyperglycemia (blood glucose level $\geq$14mmol/dL), ketonemia (strongly positive), acidosis (pH $<$7.30 and bicarbonate $<$15 mmol/L), glycosuria, and ketonuria.

Therapeutic Management. The management of type 1 DM in children consists of an interprofessional approach involving the family, the child, and professionals, including a pediatric endocrinologist, diabetes nurse educator, nutritionist, exercise physiologist, and social worker. Often psychological support from a mental health care provider may be needed. Communication among the team members is essential and extends to other individuals in the child's life, such as teachers, the school guidance counsellor, and coaches.

The definitive treatment is replacement of insulin that the child is unable to produce. However, insulin needs are also affected by emotions, nutritional intake, activity, and other life events such as illnesses and puberty. The complexity of the disease and its management requires that the child and family incorporate diabetes needs into their

TABLE 51.2 Screening for Diabetes Complications, Dyslipidemia, and Hypertension in Children With Type 1 Diabetes

Complication/ Comorbidity	Indications and Intervals for Screening	Screening Methods
Nephropathy	• Yearly screening commencing at 12 years of age in those with duration of type 1 diabetes for >5 years	• First morning (preferred) or random urine ACR • Abnormal ACR requires confirmation at least 1 month later with a first morning ACR and, if abnormal, followed by timed, overnight, or 24-hour split urine collections for albumin excretion rate • Repeated sampling should be done every 3 to 4 months over a 6 to 12-month period to demonstrate persistence
Retinopathy	• Screening interval can increase to 2 years if good glycemic control, duration of diabetes <10 years, and no retinopathy at initial assessment	• 7-standard field, stereoscopic-colour fundus photography with interpretation by a trained reader (gold standard); or • Direct ophthalmoscopy or indirect slit-lamp fundoscopy through dilated pupil; or • Digital fundus photography
Neuropathy	• Children ≥15 years of age with poor metabolic control should be screened yearly after 5 years of type 1 diabetes	• Question and examine for symptoms of numbness, pain, cramps, and paresthesia, as well as skin sensation, vibration sense, light touch, and ankle reflexes
Dyslipidemia	• Delay screening postdiabetes diagnosis until metabolic control has stabilized • Screen at 12 and 17 years of age • <12 years of age: screen only those with BMI >97th percentile, family history of hyperlipidemia, or premature CVD	• Fasting or nonfasting TC, HDL-C, TG, calculated LDL-C. Measurement of nonfasting lipids may be considered if TG are not elevated.
Hypertension	• Screen all children with type 1 diabetes at least twice a year	• Use appropriate cuff size

ACR, Albumin to creatinine ratio; *BMI,* body mass index; *CVD,* cardiovascular disease; *HDL-C,* high-density lipoprotein cholesterol; *LDL-C,* low-density lipoprotein cholesterol; *TC,* total cholesterol; *TG,* triglycerides.

Diabetes Canada 2018 clinical practice guidelines for the prevention and management of diabetes in Canada: Type 1 diabetes in children and adolescents. *Canadian Journal of Diabetes, 42*(Suppl 1), S), S234–S246. http://guidelines.diabetes.ca/cpg/chapter34.

lifestyle. Medical and nutritional guidance are primary, but management also includes continuing diabetes education, family guidance, and emotional support.

Insulin therapy. Insulin replacement is the cornerstone of management of type 1 DM. Many children are now using continuous subcutaneous insulin infusion (CSII) therapy instead of the traditional boluses of insulin. Insulin dosage is tailored to each child through home blood glucose monitoring. The goal of insulin therapy is to maintain near-normal blood glucose values while avoiding too frequent episodes of hypoglycemia. The recommended glucose levels are listed in Table 51.3. Newly diagnosed children with diabetes should be started on boluses of rapid-acting insulin analogues combined with basal insulin (e.g., intermediate-acting insulin or long-acting basal insulin analogue) using an individualized routine that best suits the daily life of the child. There are many factors that go into the choice of insulin regimen, including the child's age, duration of diabetes, family lifestyle, school support, socioeconomic factors, and family, patient, and health care provider preferences. Regardless of the insulin regimen used, all children should be treated to meet glycemic targets (Wherrett et al., 2018).

TABLE 51.3 Recommended Glycemic Goals for Children and Adolescents With Type 1 Diabetes

Hemoglobin A_{1C} (%)	Fasting/ Preprandial Glucose (mmol/L)	2-Hour Postprandial PG* (mmol/L)	Considerations
<7.5%	4.0–8.0	5.0–10.0	Caution is required to minimize severe or excessive hypoglycemia. Consider preprandial targets of 6.0–10.0 mmol/L as well as higher A1C targets in children and adolescents who have had severe or excessive hypoglycemia or have hypoglycemia unawareness. Treatment targets should be tailored to each child, taking into consideration individual risk factors for hypoglycemia

A_{1C}, Glycated hemoglobin; PG, plasma glucose.
*Postprandial monitoring is rarely done in young children except for those on continuous subcutaneous insulin infusion (CSII) therapy for whom targets are not available.

Diabetes Canada 2018 clinical practice guidelines for the prevention and management of diabetes in Canada: Type 1 diabetes in children and adolescents. *Canadian Journal of Diabetes, 42*(Suppl 1), S234–S246. http://guidelines.diabetes.ca/cpg/chapter34.

BOX 51.13 Types of Insulin

There are four types of insulin, based on the following criteria:

- How soon the insulin starts working (onset)
- When the insulin works the hardest (peak time)
- How long the insulin lasts in the body (duration)

However, each person responds to insulin in their own way. That is why onset, peak time, and duration are given as ranges.

Rapid-acting insulin (e.g., NovoLog) reaches the blood within 15 minutes after injection. The insulin peaks 30 to 90 minutes later and may last as long as 5 hours.

Short-acting (regular) insulin (e.g., Novolin R) usually reaches the blood within 30 minutes after injection. The insulin peaks 2 to 4 hours later and stays in the blood for about 4 to 8 hours.

Intermediate-acting insulins (e.g., Novolin N) reach the blood 2 to 6 hours after injection. The insulins peak 4 to 14 hours later and stay in the blood for about 14 to 20 hours.

Long-acting insulin (e.g., Lantus) takes 6 to 14 hours to start working. It has no peak or a very small peak 10 to 16 hours after injection. The insulin stays in the blood between 20 and 24 hours.

Some insulins come mixed together (e.g., Novolin 70/30). For example, one can buy regular insulin and NPH insulins already mixed in one bottle, which makes it easier to inject two kinds of insulin at the same time. However, one cannot adjust the amount of one insulin without also changing how much one gets of the other insulin.

NPH, Neutral Protamine Hagedorn.

With commencement of insulin replacement there is a honeymoon period, which can last up to 2 years after diagnosis, for targeting glycemic control and with low insulin requirements (<0.5 units/kg/day). At the end of this time frame, more intensive management may be necessary to continue to meet glycemic targets.

Diabetes Canada recommends the following regimen:

- Insulin therapy should be assessed at each clinical appointment to ensure it still allows the child to meet glycated hemoglobin (A_{1C}) targets, minimizes the risk of hypoglycemia, and allows flexibility in carbohydrate intake, daily schedule, and activities.
- If these goals are not being met, an intensified diabetes management approach (including increased education, monitoring, and contact with the diabetes team) should be used. Treatment options may include the following:
  - Increased frequency of injections
  - Change in the type of basal and/or bolus insulin
  - Change to CSII therapy (Wherrett et al., 2018)

The closed-loop pancreas system (artificial beta cell pump), which is an artificial or bionic pancreas system, is one of the most rapidly developing areas of care for type 1 DM. This system comprises an insulin pump combined with an infusion of one or more hormones (insulin +/- glucagon), a glucose sensor, and an algorithm for glucose control. This system can decrease excursions in blood glucose levels while decreasing the overall burden of self-care. However, the system must ensure patient safety as well as prevent the incidence of severe hypo- and hyperglycemia, as well as DKA (Wherrett et al., 2018).

Healthy pancreatic cells secrete insulin at a low but steady basal rate with superimposed bursts of increased secretion that coincide with the intake of nutrients. Consequently, insulin levels in the blood increase and decrease coincidentally with rises and falls in blood glucose levels. In addition, insulin is secreted directly into the portal circulation; thus the liver, which is the major site of glucose disposal, receives the largest concentration of insulin. No matter which method of insulin replacement is used, this normal pattern cannot be duplicated. Subcutaneous injection results in absorption of the medication into the general circulation, thus reducing the concentrations of insulin to which the liver is exposed.

Insulin preparations. Insulin is available in highly purified pork preparations and in human insulin biosynthesized by and extracted from bacterial or yeast cultures. Most health care providers suggest human insulin as the treatment of choice. Insulin is available in rapid-, intermediate-, and long-acting preparations, and all are packaged in the strength of 100 units/mL. Some insulins are available as premixed insulins, such as 70/30 and 50/50 ratios, the first number indicating the percentage of intermediate-acting and the second number the percentage of rapid-acting insulin. The type of insulin therapy should be individualized to reach A_{1C} targets, minimize hypoglycemia, and optimize quality of life (Wherrett et al., 2018). The different types of insulin are listed in Box 51.13.

! NURSING ALERT

The human insulins from various manufacturers may be interchangeable, but human insulin and pork insulin or pure pork insulin should never be substituted for one another.

Dosage. Conventional management has consisted of a twice-daily insulin regimen of a combination of rapid-acting and intermediate-acting insulin drawn up into the same syringe and injected before breakfast and before the evening meal. The amount of morning regular insulin is determined by patterns in the late-morning and lunchtime blood glucose values. The morning intermediate-acting dose is determined by patterns in the late-afternoon and supper blood glucose values. Fasting blood glucose patterns at breakfast help determine the evening dose of intermediate-acting insulin, and the blood glucose patterns at bedtime help determine the evening dose of rapid-acting (regular) insulin. For some children, better morning glucose control is achieved by a later (bedtime) injection of intermediate-acting insulin.

Insulin requirements do not remain constant but change continuously during growth and development; the need varies according to the child's activity level and pubertal status. For example, less insulin is required during spring and summer months, when the child is more active. Illness also alters insulin requirements. And some children require more frequent insulin administration, such as children with difficult-to-control diabetes and those going through the adolescent growth spurt.

The *insulin pump* is an electromechanical device (CSII) designed to deliver fixed amounts of regular or lispro insulin continuously (basal rate), thereby more closely imitating the release of the hormone by the islet cells (see Figure 15.2). Although the pump delivers a programmed amount of basal insulin, the child or parent must program a dose for the pump to deliver before each meal. The CSII is effective and safe and can be started at any age and results in improved metabolic control in comparison to basal-bolus therapy (Wherrett et al., 2018). The system consists of a syringe to hold the insulin, a plunger, and a computerized mechanism to drive the plunger. The insulin flows from the syringe through a catheter to a needle inserted into subcutaneous tissue (the abdomen or thigh), and the lightweight device is worn on a belt or a shoulder holster. The needle and catheter are changed every

48 to 72 hours by the child or parent, using aseptic technique, and then taped in place.

Although the pump provides more consistent insulin delivery, it has certain disadvantages. Pump therapy is expensive and requires commitment from the parent and child. A certain level of math skills is required to calculate infusion rates. It should also not be removed for more than 1 hour at a time, which may limit some activities. Skin infections are common, and, as with any other mechanical device, it is subject to malfunction. However, the pumps are equipped with alarms that signal problems, such as a depleted battery, an occluded needle or tubing, or a microprocessor malfunction.

Monitoring. Daily monitoring of blood glucose levels is an essential aspect of appropriate DM management. Plasma blood glucose and hemoglobin A_{1c} goal ranges are listed in Table 51.3.

Blood glucose. Self-monitoring of blood glucose (SMBG) has improved diabetes management and is used successfully by children from the onset of their diabetes. It is an essential part of diabetes self-management. By testing their own blood, children are able to change their insulin regimen to maintain their glucose level in the euglycemic (normal) range of 4.4 mmol/L to 6.6 mmol/L. Diabetes management depends to a great extent on SMBG. In general, children tolerate the testing well.

There are two other methods that can be used to monitor blood glucose. Subcutaneous continuous glucose sensors allow for the detection of asymptomatic hypoglycemia and hyperglycemia. In some studies, use of continuous glucose monitoring resulted in improved glycemic control with less hypoglycemia (Rachmiel et al., 2015; Wherrett et al., 2018). In one larger randomized, controlled trial of 322 adults and children, use of continuous glucose monitoring was associated with improved glycemic control in adults but not in children and adolescents (Juvenile Diabetes Research Foundation Continuous Glucose Monitoring Study Group et al., 2008; Wherrett et al., 2018). A flash glucose monitor has a small sensor that is inserted under the skin of the upper arm and a separate touchscreen reader device reads the glucose level when needed. In one study on use of flash monitors, patients spent more time in the target blood glucose range and experienced fewer episodes of low blood glucose than people who used self-monitoring of blood glucose; flash monitors are recommended for children who experience hypoglycemia (Ontario Health, 2019). Some CSII devices have built-in algorithms that suspend insulin administration when a low glucose level is detected. This has been shown to significantly lower overnight hypoglycemia (Wherrett et al., 2018).

Glycated hemoglobin. The measurement of glycated hemoglobin (hemoglobin A_{1c}) levels is a satisfactory method for assessing control of the diabetes. As red blood cells circulate in the bloodstream, glucose molecules gradually attach to the hemoglobin A molecules and remain there for the lifetime of the red blood cell, approximately 120 days. The attachment is not reversible; this glycated hemoglobin reflects the average blood glucose levels over the previous 2 to 3 months. The test is a satisfactory method for assessing control, detecting incorrect testing, monitoring effectiveness of changes in treatment, defining patients' goals, and detecting nonadherence to the treatment regimen. Nondiabetic hemoglobin A_{1c} values are generally between 4 and 6% but can vary by laboratory. Diabetes control for children depends on age, with hemoglobin A_{1c} levels of less than 7.5% indicating an acceptable range (Wherrett et al., 2018). A_{1C} levels should be measured at least every 3 months when glycemic targets are not being met and when diabetes therapy is being adjusted or changed. Testing at 6-month intervals may be considered in situations where glycemic targets are consistently achieved (Wherrett et al., 2018).

Urine. Urine testing for glucose is no longer used for diabetes management; there is poor correlation between simultaneous glycosuria and blood glucose concentrations. However, urine testing can be carried out to detect evidence of ketonuria.

! NURSING ALERT

It is recommended that urine be tested for ketones every 3 hours during an illness or whenever the blood glucose level is over 13.3 mmol/L or when symptoms of diabetic ketoacidosis are present.

Nutrition. Essentially the nutritional needs of children with diabetes are no different from those of healthy children. Children with diabetes need no special foods or supplements. They need sufficient calories to balance daily expenditure for energy and to satisfy the requirement for growth and development. Unlike the child without diabetes, whose insulin is secreted in response to food intake, insulin injected subcutaneously has a relatively predictable time of onset, peak effect, duration of action, and absorption rate depending on the type of insulin used. Consequently, the timing of food consumption must be regulated to correspond to the timing and action of the insulin prescribed.

Meals and snacks should be eaten according to peak insulin action, and the total number of calories and proportions of basic nutrients should be consistent from day to day. The constant release of insulin into the circulation makes the child prone to hypoglycemia between the three daily meals unless a snack is provided between meals and at bedtime. The distribution of calories should be calculated to fit each child's activity pattern. For example, a child who is more active in the afternoon will need a larger snack at that time. This larger snack might also be split to allow some food at school and some food after school. Food intake should be altered to balance food, insulin, and exercise. Extra food is needed for increased activity.

Concentrated sweets are discouraged, and because of the increased risk for atherosclerosis in persons with DM, fat is reduced to 30% or less of the total caloric requirement. Dietary fibre has become increasingly important in dietary planning because of its influence on digestion, absorption, and metabolism of many nutrients. It has been found to diminish the rise in blood glucose after meals.

For the growing child, food restriction should never be used for diabetes control, although caloric restrictions may be imposed for weight control if the child is overweight. In general, the child's appetite should be the guide for the amount of calories needed, with the total caloric intake adjusted to appetite and activity. Carbohydrate counting is a commonly used method of matching insulin to carbohydrate intake that allows increased flexibility in diet, although fat and protein content also influence postprandial glucose levels. Nutrition therapy should be individualized and based on the child's nutritional needs, eating habits, lifestyle, ability and interest. Nutrition must ensure normal growth and development without compromising glycemic control. This plan should be evaluated regularly and at least annually (Wherrett et al., 2018). Following *Canada's Food Guide* should provide a balanced diet for the child with type 1 diabetes (see Appendix A).

Physical activity. Exercise should be encouraged and never restricted unless indicated by other health conditions. Exercise lowers blood glucose levels, depending on the intensity and duration of the activity. An exercise plan should be included as part of diabetes management, and the type and amount of exercise should be planned around the child's interests and capabilities. Increased physical activity is associated with better metabolic control (Wherrett et al., 2018). When children's activities are unplanned, the resulting decrease in blood glucose can be compensated for by providing extra snacks before (and, if the exercise is prolonged, during) the activity. In addition to a

feeling of well-being, regular exercise aids in the utilization of food and often results in a reduction of insulin requirements.

Hypoglycemia. Occasional episodes of hypoglycemia are an integral part of insulin therapy, thus an objective of diabetes management is to achieve the best possible glycemic control while minimizing the frequency and severity of hypoglycemia. Even with good control, a child may frequently experience mild symptoms of hypoglycemia. If the signs and symptoms are recognized early and promptly relieved by appropriate therapy, the child's activity should be interrupted for no more than a few minutes.

! NURSING ALERT

Hypoglycemic episodes most commonly occur before meals, or when the insulin effect is peaking.

The signs and symptoms of hypoglycemia are caused by both increased adrenergic activity and impaired brain function. The increased adrenergic nervous system activity plus increased secretion of catecholamines produces nervousness, pallor, tremulousness, palpitations, sweating, and hunger. Weakness, dizziness, headache, drowsiness, irritability, loss of coordination, seizures, and coma are more severe responses and reflect CNS glucose deprivation and the body's attempts to elevate the serum glucose levels.

It is often difficult to distinguish between hyperglycemia and a hypoglycemic reaction (Table 51.4). Because the symptoms are similar and usually begin with changes in behaviour, the simplest way to differentiate between the two is to test the blood glucose level. The blood glucose level is low in hypoglycemia, whereas in hyperglycemia the glucose level is significantly elevated. In doubtful situations it is safer to give the child some simple carbohydrate. This will help alleviate the symptoms in the case of hypoglycemia but will do little harm if the child is hyperglycemic.

Children are usually able to detect the onset of hypoglycemia, but some are too young to implement treatment. Parents should become adept at recognizing the onset of symptoms—for example, a change in a child's behaviour, such as tearfulness or euphoria. Decreased cognitive functioning is more apt to occur in children with early-onset type 1 diabetes and severe hypoglycemia.

! NURSING ALERT

Vomiting may occur after administration of glucagon; thus precautions against aspiration must be taken (e.g., placing the child on the side), since the child often becomes unconscious.

Morning hyperglycemia. The management of elevated morning blood glucose levels depends on whether the increase is a true dawn phenomenon, insulin waning, or a rebound hyperglycemia (the Somogyi effect). *Insulin waning* is a progressive rise in blood glucose levels from bedtime to morning. It is treated by increasing the nocturnal insulin dose. The *true dawn phenomenon* shows a relatively normal blood glucose level until about 0300, when the level begins to rise. The *Somogyi effect* may occur at any time but often entails an elevated blood glucose level at bedtime and a drop at 0200 with a rebound rise following. The treatment for this phenomenon is decreasing the nocturnal insulin dose to prevent the 0200 hypoglycemia. The rebound rise in the blood glucose level is a result of counterregulatory hormones (epinephrine, GH, and corticosteroids), which are stimulated by hypoglycemia. More frequent blood monitoring (especially at times of anticipated peak insulin action) will usually identify these conditions.

TABLE 51.4 Comparison of Manifestations of Hypoglycemia and Hyperglycemia

Variable	Hypoglycemia	Hyperglycemia
Onset	Rapid (minutes)	Gradual (days)
Mood	Labile, irritable, nervous, weepy	Lethargic
Mental status	Difficulty concentrating, speaking, focusing, coordinating Nightmares	Dulled sensorium Confusion
Inward feeling	Shaky feeling Hunger Headache Dizziness	Thirst Weakness Nausea and vomiting Abdominal pain
Skin	Pallor Sweating	Flushed Signs of dehydration
Mucous membranes	Normal	Dry, crusty
Respirations	Shallow, normal	Deep, rapid (Kussmaul)
Pulse	Tachycardia, palpitations	Less rapid, weak
Breath odour	Normal	Fruity, acetone
Neurological	Tremors	Diminished reflexes Paresthesia
Ominous signs	Late—Hyperreflexia, dilated pupils, seizure Shock, coma	Acidosis, coma
Blood:		
Glucose	Low: <3.3 mmol/L	High: ≥13.8 mmol/L
Ketones	Negative	High, large
Osmolarity	Normal	High
pH	Normal	Low (≤7.25)
Hematocrit	Normal	High
Bicarbonate	Normal	<20 mmol/L
Urine:		
Output	Normal	Polyuria (early) to oliguria (late)
Glucose	Negative	Enuresis, nocturia
Ketones	Negative or trace	High
Vision	Diplopia	Blurred vision

Illness management. Illness alters diabetes management, and maintaining control is usually related to the seriousness of the illness. In a child whose diabetes is well controlled, an illness will run its course as it does in the unaffected child. The goals during an illness are to restore euglycemia, treat urinary ketones, and maintain hydration. Blood glucose levels and urinary ketones should be monitored every 3 hours. Some hyperglycemia and ketonuria are expected in most illnesses, even with diminished food intake, and are an indication for increased insulin. Insulin should never be omitted during an illness, although dosage requirements may increase, decrease, or remain unchanged, depending on the severity of the illness and the child's appetite. Often the child will need supplemental insulin between usual dose times. If the child vomits more than once, if blood glucose levels remain above 13.3 mmol/L, or if urinary ketones remain high, the health care provider should be notified. Although insulin and diet are important tools in sick-day care, fluids are the most important intervention. Fluids must be encouraged to prevent dehydration and to flush out ketones.

Therapeutic management of diabetic ketoacidosis. DKA, the most complete state of insulin deficiency, is a life-threatening situation. Management consists of rapid assessment, adequate insulin to reduce the elevated blood glucose level, fluids to overcome dehydration, and electrolyte replacement (especially potassium). A small number of pediatric cases (0.5 to 1%) are complicated by cerebral edema, which is associated with significant morbidity (21 to 35%) and mortality (21 to 24%) (Wherrett et al., 2018). The risk factors for cerebral edema are listed in Box 51.14.

Because DKA constitutes an emergency situation, the child should be admitted to a critical care facility for management. The priority is to obtain venous access for administration of fluids, electrolytes, and insulin. The child should be weighed, measured, and placed on a cardiac monitor. Blood glucose and ketone levels are determined at the bedside, and samples are obtained for laboratory measurement of glucose, electrolytes, BUN, arterial pH, P_{O_2}, P_{CO_2}, hemoglobin, hematocrit, white blood cell count and differential, calcium, and phosphorus.

Oxygen may be administered to patients who are cyanotic and in whom arterial oxygen is less than 80%. Gastric suction is applied to unconscious children to avoid the possibility of pulmonary aspiration. Antibiotics may be administered to febrile children after appropriate specimens are obtained for culture. A Foley catheter may or may not be inserted for urine samples and measurement. Unless the child is unconscious, a collection bag is usually sufficient for accurate assessments.

Fluid and electrolyte therapy. All patients with DKA will have dehydration (10% of total body weight in severe ketoacidosis) because of the osmotic diuresis, accompanied by depletion of electrolytes, sodium, potassium, chloride, phosphate, and magnesium. Serum pH and bicarbonate reflect the degree of acidosis. Prompt and adequate fluid therapy restores tissue perfusion and suppresses the elevated levels of stress hormones. In children in DKA, rapid administration of hypotonic fluids should be avoided. Circulatory compromise should be treated with only enough isotonic fluids to correct circulatory inadequacy. Replacement of fluid deficit should be extended over a 48-hour period with regular reassessments of fluid status (Wherrett et al., 2018).

Serum potassium levels may be normal on admission, but after fluid and insulin administration the rapid return of potassium to the cells can seriously deplete serum levels, with the attendant risk of cardiac dysrhythmias. As soon as the child has established renal function (is voiding at least 25 mL/hr) and insulin has been given, vigorous potassium replacement is implemented. The cardiac monitor is used as a guide to therapy, and configuration of T waves should be observed every 30 to 60 minutes to determine changes that might indicate alterations in potassium concentration (widening of the QT interval and the appearance of a U wave following a flattened T wave indicate hypokalemia; an elevated and spreading T wave and shortening of the QT interval indicate **hyperkalemia**).

BOX 51.14 Risk Factors for Cerebral Edema During Treatment of Diabetic Ketoacidosis in Children

- Age under 5 years
- New-onset diabetes
- Greater severity of acidosis (lower pH and bicarbonate)
- High initial serum urea
- Low initial partial pressure of arterial carbon dioxide (pCO_2)
- Rapid administration of hypotonic fluids
- IV bolus of insulin
- Early IV insulin infusion (within first hour of administration of fluids)
- Failure of serum sodium to rise during treatment
- Use of bicarbonate

Source: Wherrett, D. K., Ho, J., Huot, C., et al. (2018). Diabetes Canada 2018 clinical practice guidelines for the prevention and management of diabetes in Canada: Type 1 diabetes in children and adolescents. *Canadian Journal of Diabetes, 42*(Suppl 1), S234–S246.

! NURSING ALERT

Potassium must never be given until the serum potassium level is known to be normal or low and urinary voiding is observed. When required, all maintenance IV fluids should include 20 to 40 mEq/L of potassium. Potassium should never be given as a rapid IV bolus, or cardiac arrest may result.

An IV insulin bolus should not be given. The insulin infusion should not be started for at least 1 hour after starting fluid replacement therapy. An IV infusion of short-acting insulin should be used at an initial dose of 0.05 to 0.1 units/kg/hr, depending on the clinical situation. The dextrose infusion should be increased, rather than reducing insulin, to prevent rapid decreases in glucose. Once blood glucose is less than 17.0 mmol/L, IV dextrose should be started, to prevent hypoglycemia. The insulin infusion should be maintained until pH normalizes and ketones have mostly cleared. Administration of sodium bicarbonate should be avoided except in extreme circulatory compromise, as this has been associated with cerebral edema. Either mannitol or hypertonic saline may be used in the treatment of cerebral edema (Wherrett et al., 2018).

When the critical period is over, the task of regulating insulin dosage in relation to diet and activity is started. Children should be actively involved in their own care and given responsibility according to their ability and the guidance of the nurse.

! NURSING ALERT

Because insulin can chemically bind to plastic tubing and in-line filters, thereby reducing the amount of medication reaching the systemic circulation, an insulin mixture is run through the tubing to saturate the insulin-binding sites before the infusion is started.

Nursing Care. Children with DM may be admitted to the hospital at the time of their initial diagnosis; during illness or surgery; or for episodes of ketoacidosis, which may be precipitated by any of a variety of factors. Many children are able to keep the disease under control with periodic assessment and adjustment of insulin, diet, and activity as needed under the supervision of a health care provider. Under most circumstances these children's diabetes can be managed well at home and they require hospitalization only for a serious illness or upset.

However, a small number of children with diabetes exhibit a degree of metabolic lability and have repeated episodes of DKA that require hospitalization, which interferes with their education and social development. These children appear to display a characteristic personality structure. They tend to be unusually passive and nonassertive and to come from families that are inclined to smooth over conflicts without resolution. Some studies have demonstrated that psychological interventions can increase diabetes treatment adherence, improve glycemic control, and improve psychosocial functioning (Wherrett et al., 2018).

Hospital management. The child with DKA requires intensive nursing care. Vital signs should be observed and recorded frequently. Hypotension caused by the contracted blood volume of the dehydrated state may cause decreased peripheral blood flow, which can be particularly hazardous to the heart, lungs, and kidneys. An elevated

temperature may indicate infection and should be reported immediately, and necessary testing and treatment may be implemented.

Careful and accurate records should be maintained, including vital signs (pulse, respiration, temperature, blood pressure), weight, IV fluids, electrolytes, insulin, blood glucose level, and intake and output. A urine collection device or retention catheter is used to obtain the urine measurements, which include volume, specific gravity, and glucose and ketone values. The volume relative to the glucose content is important because 5% glucose in a 300-mL sample is a significantly greater amount than a similar reading from a 75-mL sample. The level of consciousness needs to be assessed and recorded at frequent intervals. The comatose child generally regains consciousness fairly soon after initiation of therapy but is provided care like that for any unconscious child until then.

When the critical period is over, the task of regulating insulin dosage to diet and activity is begun. The same meticulous records of intake and output, urine glucose and acetone levels, and insulin administration should be maintained. Children who are able to should be actively involved in their own care and be given responsibility for keeping the intake and output record, testing the blood and urine, and, when appropriate, administering their own insulin—all under the nurse's supervision and guidance (see Family-Centred Care box: Teaching About Diabetes and Nursing Care Plan on Evolve).

FAMILY-CENTRED CARE

Teaching About Diabetes

The better the parents understand the pathophysiology of diabetes and the function and action of insulin and glucagon in relation to caloric intake and exercise, the better they will understand the disease and its effects on the child. Parents need answers to a number of questions (voiced or unvoiced) to increase their confidence in coping with the disease. For example, they may want to know about the various procedures performed on their child and treatment rationale, such as what is being put in the intravenous bag and the expected effect.

Medical identification. One of the first things the nurse should call to the parents' attention is the need for the child to wear some means of medical identification. Usually recommended is the medical alert identification, which is an identification bracelet that is visible and immediately recognizable. It contains a telephone number that medical personnel can call around the clock for medical records and personal information.

Meal planning. Good nutrition is a major aspect of the family education program. Diet instruction is usually conducted by the dietitian, with reinforcement and guidance from the nurse. The emphasis is on adequate intake for age, consistent menus, inclusion of complex carbohydrates in the child's diet, and consistent eating times. The family is taught how the meal plan relates to the requirements of growth and development, the disease process, and the insulin regimen. Meals and snacks should be modified on the basis of the child's preferences and current menu, preserving cultural patterns and preferences as much as possible.

Learning about foods within specific food groups can help in making choices regarding the child's diet. Weights and measures of foods can be used as eye-training devices for defining serving sizes and their use should be practised for about 3 months, with gradual progression to estimation of food portions. Even when the child and family become competent in estimating portion sizes, reassessment should take place weekly or monthly and when there is any change of brands.

Family members should also be guided in reading labels for the nutritional value of foods and food content. They need to become familiar with the carbohydrate content of food groups, as substituting foods of equal carbohydrate content is a useful skill for successful carbohydrate counting. Substitution might be necessary, for instance, if a food is not available in sufficient quantity or if the child wishes to eat fast food with peers.

Lists of items served at major fast-food chains can be obtained from the restaurants or online to help guide food selections. It is important that the child know the nutritional value of these items, but the child should be cautioned to avoid high-fat and high-sugar/high-carbohydrate items; for example, the child could choose a plain hamburger instead of a double cheeseburger.

Children should use sugar substitutes in moderation in items such as soft drinks. Artificial sweeteners have been shown to be safe, but if there is any question about amounts, the health care provider, dietitian, or nurse specialist can provide guidelines based on body weight. Sugar-free chewing gum and candies made with sorbitol may be used in moderation by children with DM. Although sorbitol is less cariogenic than other varieties of sugar substitutes, it is an alcohol sugar that is metabolized to fructose and then to glucose. Furthermore, large amounts can cause osmotic diarrhea. Most dietetic foods contain sorbitol. They are more expensive than regular foods. Also, while a product may be sugar free, it is not necessarily carbohydrate free.

Travelling. Travelling requires planning, especially when a trip involves crossing time zones. Before travelling it is important to consider what will be needed from the primary practitioner before leaving, what and how much to take along, needs in transit, what to consider at the destination, and planning for when the child returns home. Planning is needed no matter what type of travel is considered—automobile, plane, bus, or train.

Insulin. Families need to understand the treatment method and the insulin prescribed, including the effective duration, onset, and peak action. They also need to know the characteristics of the various types of insulins, the proper mixing and dilution of insulins, and how to substitute another type when their usual brand is not available (insulin is a nonprescription medication). Insulin need not be refrigerated but should be maintained at a temperature between 15° and 29.5°C. Freezing renders insulin inactive.

Insulin bottles that have been "opened" (i.e., the stopper has been punctured) should be stored at room temperature or refrigerated for up to 28 to 30 days. After 1 month these vials should be discarded. Diabetic supplies should not be left in a hot environment.

Injection procedure. Learning to give insulin injections can be a source of anxiety for both parents and children. It is helpful for the learner to know that this important aspect of care will become as routine as brushing their teeth. First, the basic injection technique is taught, using an orange or similar item and sterile normal saline for practice. To gain children's confidence, the nurse can demonstrate the technique by giving a skillful injection to the parent and then having the parent return the demonstration by giving the nurse an injection. With practice and confidence, the parents will soon be able to give the insulin injection to their children and their children will trust them. Another effective strategy is to instruct the child and then have them teach the technique to the parents while the nurse observes. Both parents should participate, and as little time as possible should elapse between instruction and the actual injection, especially with parents and teenage learners.

Insulin can be injected into any area in which there is adipose (fat) tissue over muscle; the medication is injected at a 90-degree angle. Newly diagnosed children may have lost adipose tissue, and care should be exerted not to inject intramuscularly. The pinch technique is the most effective method for tenting the skin to allow easy entrance of the needle to subcutaneous tissues in children. The site selected will sometimes depend on whether children or parents are administering the insulin. The arms, thighs, hips, and abdomen are usual injection sites for insulin. The child can reach the thighs, abdomen, and part

TABLE 51.5 Insulin's Onset and Duration of Action Related to Injection Site

	SITE OF INJECTION			
	Abdomen	**Arm**	**Leg**	**Buttock**
Rate	Very fast	Fast	Slow	Very slow
Duration	Very short	Short	Long	Very long

From Albisser, A. M., & Sperlich, M. (1992). Adjusting insulins. *Diabetes Education, 18*(3), 211–218.

of the hip and arm easily but may require help to inject other sites. For example, a parent can pinch a loose fold of skin of the arm while the child injects the insulin.

The parents and child should be helped to work out a rotation pattern to various areas of the body to enhance absorption, because insulin absorption is slowed by fat pads that develop in overused injection areas. The most efficient rotation plan involves giving about four to six injections in one area (each injection about 2.5 cm apart, or the diameter of the insulin vial from the previous injection) and then moving to another area.

It is important to remember that the absorption rate varies in different parts of the body (Table 51.5). The methodical use of one anatomical area and then movement to another minimizes variations in absorption rates. However, absorption is also altered by vigorous exercise, which enhances absorption from exercised muscles; it is recommended that a site be chosen other than the exercising extremity (e.g., avoiding legs and arms when playing in a tennis tournament).

Injection sites for an entire month can be determined in advance on a simple chart. For example, a "paper doll" (body outline) can be constructed and insulin sites marked by the child. After injection, the child places the date on the appropriate site. To keep in practice, it is a good idea for the parent to give two or three injections a week in areas that are difficult for the child to reach.

The same basic methodology is used when teaching children to give their own insulin injections (Figure 51.3). They should practise first on an orange or a doll, building confidence gradually. Other devices are available for insulin injection and may offer advantages to some children. Children who do not wish to give themselves injections can be taught to use a syringe-loaded injector (Inject-Ease). With the device, puncture is always automatic. Adolescents respond well to a self-contained and compact device resembling a pen, which eliminates conventional vials and syringes. Preloaded pens may also cause less pain, since the needle is not blunted by piercing the rubber top of the insulin vial.

Continuous subcutaneous insulin infusion. Many children are considered candidates for use of a portable insulin pump, and even some young children with unsatisfactory metabolic control can benefit from its use. The child and parents need to be taught to operate the device, including the mechanics of the pump, battery changes, and alarm systems. A number of devices are on the market that vary in the basal rates they are able to deliver and in the cost of the equipment. Families can investigate the various devices and select the model that best suits their needs.

Parents and children also need to learn the technical aspects of self-monitoring of blood glucose. Numerous blood glucose measurements (at least four times per day) are an essential part of infusion pump use. Intensive education and supervision are critical to obtaining maximum efficiency and control. This is particularly important if the family has been accustomed to a conventional insulin regimen. They must realize that simply wearing the pump will not normalize blood glucose. The pump is merely an insulin delivery device; frequent, routine blood glucose determinations are necessary to adjust the insulin delivery rate.

Fig. 51.3 School-age children are able to administer their own insulin.

The major concern with use of the insulin pump is **inflammation** from irritation or infection at the insertion site. The site should be cleaned thoroughly before the needle is inserted and then covered with a transparent dressing. The site should be changed and rotated every 48 to 72 hours (this may vary) or at the first sign of inflammation. Nurses working where pumps are part of the therapeutic regimen should become familiar with the operation of the specific device being used and the protocol of disease management.

Monitoring. Nurses should also be prepared to teach and supervise blood glucose monitoring. SMBG is associated with few complications, and although it does not necessarily lead to improved metabolic control, it provides a more accurate assessment of blood glucose levels than can be obtained with the historical urine testing. Blood glucose monitoring has the added advantage that it can be performed anywhere (see Atraumatic Care box: Minimizing Pain of Blood Glucose Monitoring).

ATRAUMATIC CARE

Minimizing Pain of Blood Glucose Monitoring

- To enhance blood flow to the finger, hold it under warm water for a few seconds before the puncture.
- When obtaining blood samples, use the ring finger or thumb (blood flows more easily to these areas) and puncture the finger just to the side of the finger pad (where there are more blood vessels and fewer nerve endings).
- To prevent a deep puncture, press the platform of the lancet device lightly against the skin and avoid steadying the finger against a hard surface.
- Use lancet devices with adjustable-depth tips. Begin with the shallowest setting.
- Use glucose monitors that require small blood samples to avoid repeated punctures.

Blood for testing can be obtained by using a mechanical bloodletting device. A mechanical device is recommended for children, although the child and family should learn to use both methods in the event of mechanical failure. Several lancet devices are available, and each provides a means for obtaining a large drop of blood for testing (Figure 51.4).

Fig. 51.4 Child using finger-stick device to obtain blood sample.

! NURSING ALERT

Caution children not to allow anyone else to use their lancet because of the risk of contracting blood-borne infections such as hepatitis B virus or HIV infection.

The blood sample may be obtained from fingertips or alternative sites such as the forearm. Alternative-site testing requires a meter that can test a small volume of blood. Not all meters are capable of this.

Signs of redness and soreness at the site of finger puncture should be examined by the nurse. It may be evidence of poor technique, poor hygiene, or poor skin healing relative to poor control. Many types of blood-testing meters are available for home use (Figure 51.5). Newer technology has brought about improvements in meter size and ease of use. The family should be shown features of several meters, including advantages and disadvantages, and allowed to choose equipment that best meets their needs.

Continuous glucose monitoring (CGM) technology incorporates a subcutaneously inserted sensor, an attached transmitter and, in the case of real-time CGM, a display unit as a stand-alone unit or be incorporated into an insulin pump. Flash glucose monitoring (FGM) also measures glucose concentration in the interstitial fluid; blood glucose levels are not displayed on a continuous basis but on a monitoring device that displays the glucose level when the sensor is "flashed" with a reader device on demand. The sensor can be worn continuously for up to 14 days (see Blood Glucose in the previous section) (Berard et al., 2018). If these types of monitors are used, children and families need education in their use. Cost can be a concern with the use of these, thus nurses should advocate to have costs covered for children with diabetes.

Signs of hyperglycemia. Severe hyperglycemia is most often caused by illness, growth, emotional upset, or missed insulin doses. Emotional stress from school examinations or a physical response to immunizations are examples that may contribute to causes of hyperglycemia. With careful glucose monitoring, any elevation can be managed by adjustment of insulin or food intake. Children and parents should understand how to adjust food, activity, and insulin at the time of illness or when the child is treated for an illness with a medication known to raise the blood glucose level (e.g., steroids). The hyperglycemia is managed by increasing insulin soon after the increased glucose level is noted. The health care team should be aware that adolescent girls often become hyperglycemic around the time of their menses and should be advised to increase insulin dosages if necessary.

Signs of hypoglycemia. Hypoglycemia is caused by imbalances of food intake, insulin, and activity. Ideally, hypoglycemia should be prevented, and parents need to be prepared to prevent, recognize, and treat the condition. They should be familiar with the signs of hypoglycemia and instructed in treatment, including care of the child with seizures. Early signs are adrenergic, including sweating and trembling (see Table 51.4), which help raise the blood glucose level, much like the reaction when an individual is startled or anxious. The second set of symptoms that follow an untreated adrenergic reaction is neuroglycopenic (also called *brain hypoglycemia*). These symptoms typically include difficulty with balance, memory, attention, or concentration; dizziness or lightheadedness; and slurred speech. Severe and prolonged hypoglycemia leads to seizures, coma, and possible death. Hypoglycemia can be managed effectively, as outlined in the Emergency box: Hypoglycemia.

Fig. 51.5 Child using blood glucose monitor and reagent strips to test blood for glucose.

+ EMERGENCY

Treatment of Mild to Moderate Hypoglycemia

Patient age	<5 years	5 to 10 years	>10 years
Amount of carbohydrate	5 g	10 g	15 g
Carbohydrate Source			
Glucose tablet (4 g)	1	2 or 3	4
Dextrose tablet (3 g)	2	3	5
Apple or orange juice; regular soft drink; sweet beverage (cocktails)	40 mL	85 mL	125 mL

Severe Reaction—Unresponsive, Unconscious, or Seizures

Administer glucagon as prescribed.

Follow with planned meal or snack when child is able to eat.

Nocturnal Reaction

Give child 10 to 15 g of a simple carbohydrate.

Source: Wherrett, D. K., Ho, J., Huot, C., et al. (2018). Diabetes Canada 2018 clinical practice guidelines for the prevention and management of diabetes in Canada: Type 1 diabetes in children and adolescents. *Canadian Journal of Diabetes, 42*(Suppl 1), S234–S246.

Parents need to plan for anticipated stress or exercise that could trigger a hypoglycemic event. In addition, gastroenteritis may decrease insulin needs slightly as a result of poor appetite, vomiting, or diarrhea. If the blood glucose level is low, the family should be aware of the increased need for simple carbohydrates and liquids.

Hygiene. All aspects of personal hygiene should be emphasized for the child with diabetes. The child should be cautioned against wearing shoes without socks, wearing sandals, or walking barefoot. Correct nail and extremity care tailored to the individual child (with the guidance of a podiatrist) can help the child begin using health practices that last a lifetime. Eyes should be checked once a year unless the child wears glasses, and then as directed by the ophthalmologist. Regular dental care is emphasized, and cuts and scratches should be treated with plain soap and water unless otherwise indicated. Diaper rash in infants and candidal infections in teens may indicate poor diabetes control.

Physical activity. Exercise is an important component of the treatment plan. If the child is more active at one time of the day than at another time, food or insulin can be altered to meet that activity pattern. The child who is active in team sports will need a snack about a half-hour before the anticipated activity. Races or other competition may call for a slightly higher food intake than at practice times.

Food intake will usually need to be repeated for prolonged activity periods, often as frequently as every 45 minutes to 1 hour. Families should be informed that if increased food is not tolerated, decreased insulin is the next course of action. If the timing of the exercise is changed so that the supper meal is delayed, the insulin in the second or third dose of the day may be moved back to precede the mealtime. Sugar may sometimes be needed during exercise periods for quick response. Elevated blood glucose levels after extreme activity may represent the body's adrenergic response to exercise. If the blood glucose level is elevated (13 mmol/L or higher) before planned exercise, urinary ketones should be checked and the activity may need to be postponed until the blood glucose is controlled.

Record keeping. Electronic or written home records are an invaluable aid to diabetes self-management. The nurse and family can devise a method to chart insulin administered, blood glucose values, and other factors and events that affect diabetes control. The child and family should be encouraged to observe for patterns of blood glucose responses to events such as exercise. If lapses in management occur (such as eating a candy bar), the child should be encouraged to note this and not be criticized for the transgression.

Self-management. Self-management is the key to close control. Being able to make changes when they are needed rather than waiting until the next contact with health care providers is important for self-management and gives the individual and family the feeling they have control over the disease. Psychologically this helps family members feel that they are useful and participating members of the team. Allowing the child to learn to look at records objectively promotes independence in self-management. As children grow and assume more responsibility for self-management, they develop confidence in their ability to manage their disease and confidence in themselves as persons. They learn to respond to the disease and to make more accurate interpretations and changes in treatment when they become adults.

Puberty is associated with decreased sensitivity to insulin that normally would be compensated for by an increased insulin secretion. Health care providers should anticipate that pubertal patients will have more difficulty maintaining glycemic control. Patients should be taught to give themselves additional doses of rapid-acting insulin (5 to 10% of their daily dose) when their blood glucose levels are increased. The use of supplemental rapid-acting insulin is preferred to withholding food.

Camping and other special group activities are also useful to children with diabetes. At diabetes camp, children learn that they are not alone. As a result, they become more independent and resourceful in other settings. Useful information about such camps and organizations, as well as resources for children with diabetes, their families, and health care providers, can be obtained from Diabetes Canada (see Additional Resources at the end of this chapter).

Several organizations assist with education about diabetes and support for individuals with diabetes. These include the Juvenile Diabetes Research Foundation Canada and the Canadian Diabetes Educator Certification Board (see Additional Resources).

Child or adolescent and family support. Just as the physiological responses affect the child, the parents and other family members of the child with newly diagnosed DM experience various emotional responses to the crisis. Care in the acute setting is short but may create fear and frustration. The prospect of a chronic illness in their child can engender all the feelings and concerns faced by parents of children with other chronic illnesses (see Chapter 41). The threat of complications and death is always present, as well as the continuing drain on emotional and financial resources.

Certain fears may develop as a result of past experiences with the disease. A severe insulin reaction with seizures can contribute to fear of repetition. If parents observe a seizure or the adolescent has one in a public place, the desire to maintain better control is reinforced. They must understand how to prevent complications and how to handle them calmly and coolly if they occur, and they must understand the complexities of the body, the disease, and its complications. Young children usually adjust well to issues related to the disease. With toddlers and preschoolers, insulin injections and glucose testing may be difficult at first. However, they usually accept the procedures when the parents use a matter-of-fact approach, without calling attention to a "hurt," and treat the procedures like any other routine part of the child's life. After receiving an injection, giving the child some positive attention, such as reading to the child or engaging in some other pleasant activity, is one way to help children who initially refuse injections to accept them.

In the years before adolescence, children probably accept their condition most easily. They are able to understand the basic concepts related to their disease and its treatment. They are able to test blood glucose and urine, recognize food groups, give injections, keep records, and distinguish fear or excitement from hypoglycemia. They understand how to recognize, prevent, and treat hypoglycemia. However, they still need considerable parental involvement.

Adolescents appear to have the most difficulty adjusting. Adolescence is a time of stress in trying to be accepted by one's peers, and having diabetes can be viewed as being different and as an obstacle to such acceptance. Some adolescents are more upset about not being able to have a chocolate bar than about injections, diet, and other aspects of management. If children can accept the difference as a part of life—in other words, that each person is different in some way—then, with adequate parental support, they should be able to adjust well (see Clinical Reasoning Case Study: Type 1 Diabetes Mellitus).

CLINICAL REASONING CASE STUDY

Type 1 Diabetes Mellitus

Shelly, a 14-year-old adolescent with a 3-year history of type 1 DM, has been admitted to the pediatric critical care unit for treatment of DKA. This is her fifth hospital admission for DKA in the past year. Shelly's parents are divorced, and she has four younger siblings, none of whom has diabetes. Shelly's mother has maintained two jobs for the past 5 years and frequently leaves Shelly in charge of the household. In anticipation of her discharge, you are planning a patient education program for Shelly and her mother. What important issues regarding Shelly's diabetes management must you consider to plan the education program?

1. Evidence: Is there sufficient evidence to draw conclusions about Shelly's recurrent episodes of DKA?
2. Assumptions: Describe an underlying assumption about each of the following:
   a. Type 1 DM in adolescence
   b. Type 1 DM and menses
   c. Emotional stress and elevated blood glucose levels
   d. Blood glucose monitoring for insulin management
3. What priorities for nursing care should be established for Shelly and what is the rationale for these priorities?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to Shelly.

DKA, Diabetic ketoacidosis; *DM,* diabetes mellitus.

Diabetes Mellitus Type 2

Type 2 DM arises because of insulin resistance, in which the body fails to use insulin properly, combined with relative (rather than absolute) insulin deficiency leading to predominant insulin resistance. People with type 2 DM can range from predominantly insulin resistant with relative insulin deficiency to predominantly deficient in insulin secretion with some insulin resistance. In North America, the incidence of type 2 diabetes has been increasing over the past 20 years in both the adult and pediatric populations (Panagiotopoulos et al., 2018).

Factors that put nonpubertal and pubertal children at greater risk of developing type 2 DM include obesity (body mass index [BMI] greater than ninety-fifth percentile for age and gender) or being a member of a high-risk ethnic group, such as those of African, Arab, Asian, Latin American, Indigenous, or South Asian descent, which are disproportionately affected. Type 2 DM is a highly heritable condition, with 90% of children and adolescents affected having a first- or second-degree relative who also has type 2 diabetes. A significant proportion of children with type 2 diabetes live below the poverty line or come from low-resourced homes (Panagiotopoulos et al., 2018). In a recent national Canadian diabetes incidence study, the mean age of diagnosis of type 2 DM in children was 13.7 years. However, 8% of all newly diagnosed children with type 2 diabetes were less than 10 years of age. Among Indigenous, White, and Asian children with type 2 diabetes, 11%, 8.8%, and 8.7%, respectively, presented at less than 10 years of age. Thus, consideration should be given for screening at a younger age in those at high risk (Panagiotopoulos et al., 2018).

Screening and Diagnostic Evaluation. Signs or symptoms of insulin resistance include hypertension, dyslipidemia, and impaired fasting glucose test results. The physical signs of insulin resistance and metabolic syndrome are acanthosis nigricans (AN) (hyperpigmentation and thickening of the skin in the neck and axillary regions), polycystic ovarian syndrome (PCOS), hypertension, dyslipidemia, and steatohepatitis. While these signs do not cause type 2 DM, they are associated with glucose intolerance and early-onset type 2 diabetes. Although research has not proven that AN is a definitive marker, neck observation for AN is a useful community screening tool that is acceptable to most children.

Screening of fasting or random plasma glucose and A_{1C} is recommended as routine in assessment for type 2 DM, but an OGTT is more likely to have a higher detection rate. A 2-hour OGTT is suggested as an initial screening test in children and youth with three or more risk factors and should be done in patients with a discrepancy between the A_{1C} and fasting or random blood glucose results (Panagiotopoulos et al., 2018). Screening for type 2 diabetes should be done every 2 years in children and adolescents with three or more of risk factors beginning at 8 years of age or in pubertal children who have two or more risk factors (Panagiotopoulos et al., 2018).

The microvascular complications of type 2 DM have been identified at diagnosis, suggesting undiagnosed long-term hyperglycemia. Children may also present with acute decompensation in DKA and/or hyperosmolar hyperglycemic state. These risk factors emphasize the importance of a systematic screening program in children at high risk for type 2 diabetes to help prevent an acute, life-threatening presentation and the development of chronic complications.

Therapeutic Management. The management of type 2 DM is similar to that for type 1 DM. The pediatric interprofessional team needs to consult with the family about lifestyle, focusing on healthy eating and physical activity. Psychological issues such as depression and smoking need to be addressed and interventions offered. The target A_{1C} for most children with type 2 diabetes should be equal to or less than 7.0%; however, there is evidence to suggest that achieving an A_{1C} of less than 6.0% within the first 6 months of diagnosis may reduce the risk of treatment failure (Panagiotopoulos et al., 2018). Children with severe metabolic decompensation (DKA, hemoglobin A_{1C} greater than 9.0%) and hyperglycemia who need insulin can be successfully weaned once the glycemic goals are reached, especially if their lifestyle has improved. In children with type 2 diabetes who are metabolically stable (A_{1C} less than 9.0% and no or minimal symptoms), metformin should be initiated in conjunction with healthy behaviour interventions. Once-a-day basal insulin is often effective in achieving metabolic control (Panagiotopoulos et al., 2018).

Short-term complications of type 2 DM in children include DKA and a hyperosmolar state. Children with both conditions at onset have high morbidity and mortality rates. Early-onset type 2 diabetes in adolescents has been associated with severe and early-onset microvascularization, which includes retinopathy, neuropathy, and nephropathy, thus these individuals need to be monitored for this. Hypertension is present in 36% of individuals with type 2 diabetes; thus this also needs monitoring and potential intervention. Other potential complications that require monitoring include dyslipidemia, steatohepatitis, and PCOS (Panagiotopoulos et al., 2018). Children should be screened at diagnosis of type 2 DM and then on an annual basis with measures similar to screening for type 1 DM (see Table 51.2).

Risk Reduction for Type 2 Diabetes. Some strategies toward decreasing the risk of type 2 DM in children include the following:

- Being breastfed
- Weight loss (decreasing obesity)
- Enhanced sleep
- Nutrition—decreasing consumption of sugar-sweetened beverages
- Increase physical activity and limit screen time.
- In children with obesity, consider using medications to assist in weight loss, and bariatric surgery (Panagiotopoulos et al., 2018).

The rates of DM are higher in Indigenous populations. Some specific recommendations to decrease rates among Indigenous children include the following (Crowshoe et al., 2018):

- Set up culturally based and community-run diabetes prevention programs in Indigenous communities.
- Indigenous health care providers can provide type 2 DM opportunistic screening.
- In Indigenous communities, promote traditional values, diets (using *Canada's Food Guide*), activities, and lifestyles; group activities with elders may work most effectively.
- Teach a healthy lifestyle as part of the curriculum in schools and at day care such as Head Start; provide national community-based programs for Indigenous people that focus on early childhood development.
- Community leaders can act as role models and provide appropriate safe environments for physical and other recreational activities.

KEY POINTS

- The endocrine system has three components: the cells, which send chemical messages via hormones; target cells, which receive the messages; and the environment through which the chemicals are transported from the sites of synthesis to the sites of cellular action.
- Pituitary dysfunction is manifested primarily by growth disturbance.
- The main physiological action of thyroid hormone (TH) is to regulate the basal metabolic rate and control the processes of growth and tissue differentiation.
- Disorders of thyroid function include hypothyroidism, autoimmune thyroiditis, goitre, and hyperthyroidism.
- Therapy for hyperthyroidism is directed at slowing the rate of hormone secretion and may include medication therapy, thyroidectomy, or radioiodine therapy.
- Classic forms of hypoparathyroidism in childhood are idiopathic (deficient production of parathyroid hormone [PTH]) and pseudohypoparathyroidism (increased PTH production with end-organ unresponsiveness to PTH).
- The adrenal cortex secretes three important groups of hormones: glucocorticoids, mineralocorticoids, and sex steroids.
- Disorders of adrenal function include acute adrenocortical insufficiency, chronic adrenocortical insufficiency, Cushing syndrome, and congenital adrenal hyperplasia (CAH).
- Five categories of Cushing syndrome are pituitary, adrenal, ectopic, iatrogenic, and food dependent.
- Management of CAH includes assignment of a sex, administration of cortisone, and, possibly, reconstructive surgery.
- DM is categorized as type 1 diabetes and type 2 diabetes.
- The focus of treatment for type 1 DM is insulin replacement, diet, and exercise.
- Education of families includes explanation of diabetes, meal planning, administering insulin injections, monitoring general hygienic practices, promoting exercise, record keeping, and observing for complications.
- The focus of treatment for type 2 DM is weight reduction, diet, exercise, and possible medication administration.

Integumentary Conditions

Cheryl Sams

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Describe the distribution and configuration of the various skin lesions.
2. List the benefits of a moist environment for wound healing.
3. Contrast the manifestations of and therapies for bacterial, viral, and fungal infections of the skin.
4. Compare the skin manifestations related to age in children.
5. Outline a care plan to prevent and treat diaper dermatitis.
6. Outline a care plan for a child with atopic dermatitis.
7. Formulate a teaching plan for an adolescent with acne.
8. Describe the methods for assessing a burn wound.
9. Discuss the physical and emotional care of a child with a severe burn wound.
10. Describe strategies to reduce the risk of sunburn.

INTEGUMENTARY ANATOMY AND PHYSIOLOGY

The skin is the largest organ in the body and provides a protective covering. The skin is composed of stratified epithelial cells, which are thickest on the palms and soles. The outer epidermal layer starts with the following stratum: corneum lucidum, granulosum, spinsum, and germinativum (Figure 52.1). The skin is pigmented by melanocytes in the germinativum layer, which darken the skin (in response to sunlight) to varying degrees. Blood vessels are located in the dermis. The dermis, which lies directly beneath the epidermis, consists of connective tissue containing white collagenous and yellow elastic fibres, blood vessels, nerves, lymph vessels, hair follicles, and sweat glands.

The skin has four functions:

- To provide sensory input—the sensations of pain, temperature, touch, and pressure—and to discriminate between the sensations through a nervous system pattern to the cerebral cortex
- For protection—the skin forms an elastic, resistant covering for protection against the external environment, inhibiting excessive water loss and that of essential electrolytes and providing an acid mantle to protect skin from irritants and bacterial invasions.
- Thermoregulation and the prevention of heat loss by processes of conduction, convection, radiation, and evaporation (which occurs as either insensible water loss or visual water loss as perspiration)
- To act as a warning system for danger by sending information to the brain about the external environment

The appendages of the skin are protective and include hair, nails, and glands. Hair is composed of individual units of follicles that contain cuticle, cortex, and medulla with attached arrector pili muscles that are smooth fibre bundles. Nails are composed of hard keratin; modified layers of horny epidermal cells arise from proximal nail folds and adhere to nail beds. Skin glands include sebaceous glands, which produce sebum for skin surface lubrication and minimizes fluid loss; secretion increases at puberty and late in pregnancy and decreases in advancing age.

INTEGUMENTARY DYSFUNCTION

Skin Lesions

Lesions of the skin result from a variety of etiological factors. Skin lesions can involve (1) contact with injurious agents (infective organisms, toxic chemicals, and physical trauma), (2) hereditary factors, (3) external factors such as allergens, or (4) systemic diseases, such as measles, lupus erythematosus, and nutritional deficiency diseases. Responses to these agents or factors are highly individualized. An agent that is harmless to one individual may be damaging to another, and a single agent may produce varying degrees of response. Contact dermatitis, such as poison ivy, is seen only when the noxious agent is found in the environment.

An important factor in the etiology of skin manifestations is the child's age. Infants are subject to "birthmark" malformations and atopic dermatitis (AD) that appear early in life, and acne is a characteristic skin disorder of puberty.

Pathophysiology of Dermatitis. More than half of the dermatological conditions in children are forms of dermatitis. This implies a sequence of inflammatory changes in the skin that are grossly and

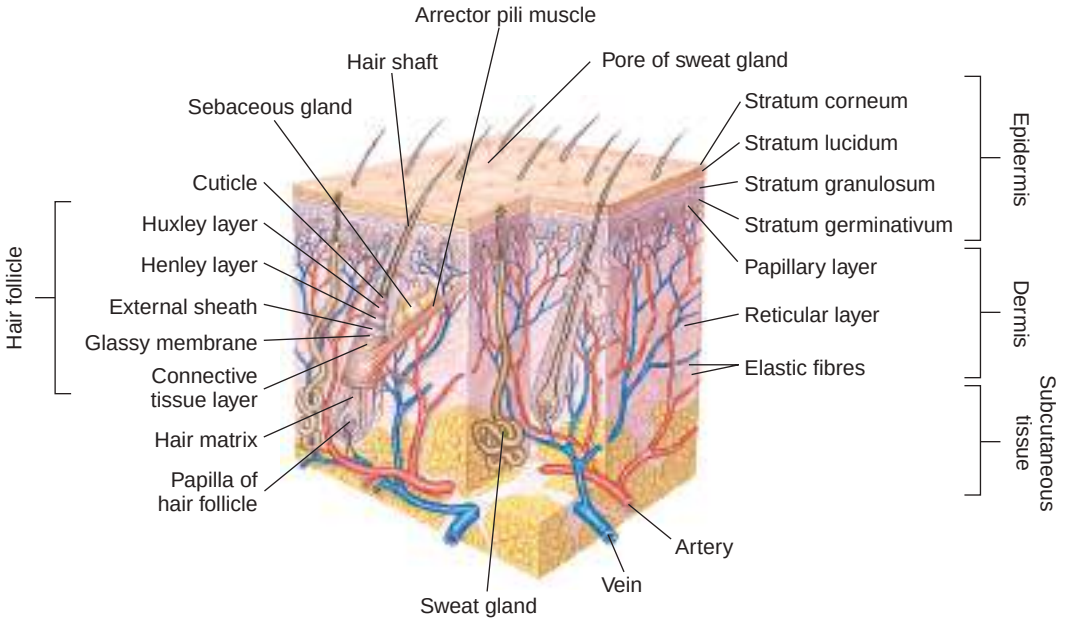

Fig. 52.1 Anatomical structures of the skin. (From Ball, J. W., Dains, J. E., Flynn, J. A., et al. [2015]. *Seidel's guide to physical examination* [8th ed., p. 115]. Mosby [Fig. 8-1]).

microscopically similar but diverse in course and causation. Acute responses produce intercellular and intracellular edema, the formation of intradermal vesicles, and an initial infiltration of inflammatory cells into the epidermis. In the dermis there is edema, vascular dilation, and early perivascular cellular infiltration. The location and manner of these reactions produce the lesions characteristic of each disorder. The changes are usually reversible, and the skin ordinarily recovers without blemish unless complicating factors such as ulceration from the primary irritant, scratching, and infection are introduced or underlying vascular disease develops. In chronic conditions, permanent effects are seen that vary according to the disorder, the general condition of the affected individual, and the available therapy.

Diagnostic Evaluation. Although the history and subjective symptoms of skin lesions are explored first, the obvious objective characteristics of the lesions are often noted simultaneously. Many skin lesions are easily diagnosed after careful inspection.

History and subjective symptoms. Many cutaneous lesions are associated with local symptoms. The most common local symptom is itching (*pruritus*), which varies in intensity. Pain or tenderness often accompanies some skin lesions. Other skin sensations such as burning, prickling, stinging, or crawling are also described. Alterations in local feeling include absence of sensation (*anaesthesia*); excessive sensitiveness (*hyperesthesia*); diminished sensation (*hypesthesia* or *hypoesthesia*); or abnormal sensation, such as burning or prickling (*paresthesia*). These symptoms may remain localized or migrate, may be constant or intermittent, and may be aggravated by a specific activity, such as exposure to sunlight.

It is important to determine whether the child has an allergic condition such as asthma or hay fever or history of a previous skin disease. AD, often associated with allergies, frequently begins in infancy. Important questions for the parent include when the lesion or symptom first appeared; whether it occurred with ingestion of a food or other substance, including any medication; and whether the condition was related to activity such as contact with plants, insects, or chemicals.

Objective findings. The distribution, size, morphological characteristics, and arrangement of skin lesions provide significant information. Extrinsic causes usually result from physical, chemical, or allergic irritants or from an infectious agent such as bacteria, fungi, viruses, or animal parasites. Skin manifestations are also produced by intrinsic causes such as an infection (measles or chicken pox), medication sensitization, or other allergic phenomena.

Types of lesions. Skin lesions assume distinct characteristics that are related to the pathological process. Nurses should become familiar with the common terms used to describe skin lesions because these terms are used in the processes of record keeping and communication. These terms include the following:

Erythema—A reddened area caused by increased amounts of oxygenated blood in the dermal vasculature

Ecchymoses (bruises)—Localized red or purple discolorations caused by extravasation of blood into dermis and subcutaneous tissues

Petechiae—Pinpoint, tiny, and sharp circumscribed spots in the superficial layers of the epidermis

Primary lesions—Skin changes produced by a causative factor; primary lesions in pediatric skin disorders include macules, papules, vesicles, patches, bullae, plaque, wheals, nodules, pustules, and cysts (Figure 52.2)

Secondary lesions—Changes that result from alteration in the primary lesions, such as those caused by rubbing, scratching, medication, or involution and healing (Figure 52.3)

Distribution pattern—The pattern in which lesions are distributed over the body, whether local or generalized, and the specific areas associated with the lesions

Configuration and arrangement—The size, shape, and arrangement of a lesion or groups of lesions (e.g., *discrete, clustered, diffuse,* or *confluent*)

Laboratory studies. If a skin issue is related to a systemic disease such as collagen or immunodeficiency disease, laboratory studies are performed to identify the condition. Diagnostic techniques include microscopic examination, cultures, skin scrapings or biopsy, cytodiagnosis, patch testing, **Wood light** examination, allergic skin testing, and other laboratory tests, such as blood count and sedimentation rate.

Macule—flat; nonpalpable; circumscribed; less than 1 cm in diameter; brown, red, purple, white, or tan in colour
Examples: Freckles; flat moles; rubella; rubeola

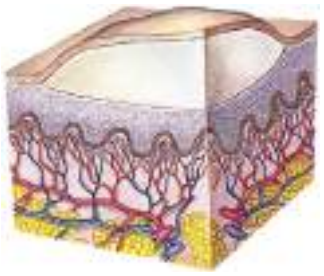
Plaque—elevated; flat topped; firm; rough; superficial papule greater than 1 cm in diameter; may be coalesced papules
Examples: Psoriasis; seborrheic and actinic keratoses

Patch—flat; nonpalpable; irregular in shape; macule that is greater than 1 cm in diameter
Examples: Vitiligo; port-wine marks

Wheal—elevated, irregularly shaped area of cutaneous edema; solid, transient, changing, variable diameter; pale pink with lighter centre
Examples: Urticaria; insect bites

Papule—elevated; palpable; firm; circumscribed; less than 1 cm in diameter; brown, red, pink, tan, or bluish red in colour
Examples: Warts; drug-related eruptions; pigmented nevi

Nodule—elevated; firm; circumscribed; palpable; deeper in dermis than papule; 1 to 2 cm in diameter
Examples: Erythema nodosum; lipomas



Vesicle—elevated; circumscribed; superficial; filled with serous fluid; less than 1 cm in diameter
Examples: Blister; varicella

Pustule—elevated; superficial; similar to vesicle but filled with purulent fluid
Examples: Impetigo; acne; variola

Bulla—vesicle greater than 1 cm in diameter
Examples: Blister; pemphigus vulgaris

Cyst—elevated; circumscribed; palpable; encapsulated; filled with liquid or semisolid material
Example: Sebaceous cyst

Fig. 52.2 Primary skin lesions. (From Seidel, H. M., et al. [Eds.]. [2006]. *Mosby's guide to physical examination* [6th ed., pp. 183–185]. Mosby [Table 8-4].)

Wounds

Wounds are structural or physiological disruptions of the skin that activate normal or abnormal tissue repair responses. Wounds are classified as acute or chronic. *Acute wounds* are those that heal uneventfully within 2 to 3 weeks. *Chronic wounds* are those that do not heal in the expected time frame or are associated with complications. Cofactors that disrupt or delay wound healing include compromised perfusion, malnutrition, and infection. In children, most wounds are acute and can be prevented from becoming chronic wounds through appropriate nursing care. Wounds are also classified as surgical and nonsurgical and then further

Scale—heaped-up keratinized cells; flaky exfoliation; irregular; thick or thin; dry or oily; varied size; silver, white, or tan in colour
Examples: Psoriasis; exfoliative dermatitis

Crust—dried serum, blood, or purulent exudate; slightly elevated; size varies; brown, red, black, tan, or straw in colour
Examples: Scab on abrasion; eczema

Lichenification—rough, thickened epidermis; accentuated skin markings caused by rubbing or irritation; often involves flexor aspect of extremity
Example: Chronic dermatitis

Scar—thin to thick fibrous tissue replacing injured dermis; irregular; pink, red, or white in colour; may be atrophic or hypertrophic
Example: Healed wound or surgical incision

Keloid— irregularly shaped, elevated, progressively enlarging scar; grows beyond boundaries of wound; caused by excessive collagen formation during healing
Example: Keloid from ear piercing or burn scar

Excoriation—loss of epidermis; linear or hollowed-out crusted area; dermis exposed
Examples: Abrasion; scratch

Fissure—linear crack or break from epidermis to dermis; small; deep; red
Examples: Athlete's foot; cheilosis

Erosion—loss of all or part of epidermis; depressed; moist; glistening; follows rupture of vesicle or bulla; larger than fissure
Examples: Varicella; variola following rupture

Ulcer—loss of epidermis and dermis; concave; varies in size; exudative; red or reddish blue
Examples: Decubiti; stasis ulcers

Fig. 52.3 Secondary skin lesions. (From Seidel, H. M., et al. [Eds.]. [2006]. *Mosby's guide to physical examination* [6th ed., pp. 186–188]. Mosby [Table 8-5].)

classified in the same manner as burns: superficial, partial thickness, or full thickness (complex wounds that include muscle or bone).

Epidermal Injuries. Abrasions are the most common epidermal wounds in children, usually in the form of a skinned knee or elbow. In most injuries the margins of the abraded area are superficial, involving only the outer layers of epidermis, although the central portion may extend into the dermis. Epithelial tissue is composed of labile cells, which are constantly destroyed and replaced throughout the lifespan. Thus epidermal injuries usually result in rapid, uneventful healing and recovery.

Injury to Deeper Tissues. Tissues composed of permanent cells such as muscle and nerve cells are unable to regenerate. These tissues repair themselves by substituting fibrous connective tissue for the injured tissue. This fibrous tissue, or *scar*, serves as a patch to preserve or restore the continuity of the tissue. Wounds involving permanent cells include surgical incisions, lacerations, pressure injuries, evulsions, and full-thickness burns.

Assessment of the wound is important to detect for early signs of pressure injury development. Factors that contribute to pressure injury formation include impaired mobility, protein malnutrition, edema, incontinence, sensory loss, anemia, infection, failure to turn the child, and intubation. Assessment scales such as Braden QD (Chamblee et al., 2018; Liao et al., 2018) help in evaluation of the severity of the pressure injury. (See Chapter 44 for prevention and treatment of pressure injuries; see Additional Resources for the RNAO best practice guidelines on treating pressure injuries and for the Braden QD assessment tool.)

General Therapeutic Management. Some wounds demand aggressive therapy but, typically, the major aim of treatment is to prevent further damage, eliminate the cause, prevent complications, and provide relief from discomfort while tissues undergo healing. Factors that contribute to the development of dermatitis and that prolong the course of the disease should be eliminated when possible. For example, the most common causative agents of dermatitis in infants, children, and adolescents are environmental factors (soaps, bubble baths, shampoos, rough or tight clothing, wet diapers, blankets, and toys) and the natural elements (such as dirt, sand, heat, cold, moisture, and wind). Dermatitis may also result from home remedies and medications.

Wound care management has shifted from interventions aimed at maintaining a dry environment to those that promote a moist, crust-free environment that enhances the migration of epithelial cells across the wound and facilitates remodelling. An acute full-thickness wound kept in a moist environment usually re-epithelializes in 12 to 15 days; the same wound when kept open to the air heals in about 25 to 30 days.

Dressings. Moist wound healing increases the rate of collagen synthesis and re-epithelialization and decreases pain and inflammation. It also creates an environment for autolytic debridement of necrotic tissue, which creates a clean wound bed and enhances granulation. However, a balance must be achieved between creating a moist wound bed and maintaining a dry periwound area that protects the skin and wound from maceration. The dressing type and frequency of dressing changes help to achieve this balance. The frequency of dressing changes is based on the presence of infection, the type of dressing, the location of the wound, and the amount of drainage.

Topical therapy. Topical applications may be applied to treat a disorder, reduce itching, decrease external stimuli, or apply external heat or cold. The emollient action of soaks, baths, and lotions provides a soothing film over the skin surface that reduces external stimuli. Ordinarily, lukewarm or cool applications offer the greatest relief.

! NURSING ALERT

Application of heat tends to aggravate most conditions, and its use is usually reserved for reducing specific inflammatory processes, such as folliculitis and cellulitis.

Ointments in a petrolatum base provide protection from moisture. Therefore, this type of ointment is indicated around gastrostomy tubes, in skin folds, and in the diaper area. Creams are absorbed by the skin and are used for areas where a nongreasy "feel" is desired, such as the face and hands.

Topical corticosteroid therapy. Glucocorticoids are the therapeutic medications used most frequently for skin disorders. Corticosteroids are applied directly to the affected area, are essentially nonsensitizing, and have only minor adverse effects. As with the use of any steroids, their use in large amounts may mask signs of infection, and symptoms may be exacerbated after termination of the medication. The concentrations available without prescription are not adequate for stubborn skin conditions such as psoriasis and may further aggravate inflammation caused by fungus or bacteria. Most parents and children should be counselled that it is both effective and economical to apply only a thin film and to massage it into the skin. Parents and children should also be advised to use the application for no more than 5 to 7 days, because these agents may cause depigmentation and other changes in the skin.

Other topical therapies. Other topical treatments include chemical cautery (especially useful for warts), cryosurgery, electrodesiccation (chiefly used for warts, granulomas, and nevi), ultraviolet (UV) therapy (primarily used in psoriasis and acne), laser therapy (especially for birthmarks), and acne therapies such as dermabrasion and chemical peels. New medications called *topical immunomodulators* are effective in reducing the itching of AD (eczema) and preventing "flares."

Systemic therapy. Systemic medications may be used as an adjunct to topical therapy in some dermatological disorders. The medications most frequently used are corticosteroids, antibiotics, and antifungal medications. Corticosteroids are valuable because of their capacity to inhibit inflammatory and allergic reactions. Dosage is carefully adjusted and gradually tapered to the minimum dosage that is effective and tolerated, as prolonged use may temporarily suppress growth.

Antibiotics are used in severe or widespread skin infections. However, because these medications tend to produce hypersensitivity in some patients, they are used with caution. Antifungal medications are the only means for treating systemic fungal infections.

Nursing Care. It is important for nurses to not only describe but also assess skin lesions and the associated wounds. The colour, shape, and distribution of lesions and wounds are important to note. Individual lesions are described according to standard terminology. Sometimes two descriptors are used for a particular characteristic, such as maculopapular rash. To confirm or amplify the findings made by inspection, the nurse may gently palpate the skin to detect characteristics such as temperature, moisture, texture, elasticity, and edema. Wounds need to be assessed for depth of tissue damage, evidence of healing, and signs of infection.

! NURSING ALERT

Signs of wound infection are as follows:

- Increased erythema, especially beyond the wound margin
- Edema
- Purulent exudate
- Pain
- Increased temperature

The frequency of wound assessment depends on the severity and complexity of the wound. The wound bed is assessed for colour, drainage, odour, necrosis, granulation tissue, fibrin slough, undermining and condition of the wound edges, and the colour and condition of the surrounding skin.

Therapeutic programs are designed to include general measures such as rest, protection, and relief of discomfort, and specific treatments such as medication and physical techniques. Only a few skin diseases are contagious; thus it is usually not necessary to isolate the affected

child, except from persons in danger of acquiring a secondary infection, such as a child receiving large doses of corticosteroids or other immunosuppressant medications or a child with an immune deficiency disorder. However, if the skin manifestation is caused by a viral **exanthema**, such as measles or chicken pox, the child should be prevented from exposing other susceptible children.

Wound care. Parents can generally manage small skin lesions or wounds at home. The parents should be instructed to wash their hands and then wash the wound gently with mild soap and water or normal saline. They should be cautioned to avoid povidone-iodine, alcohol, and hydrogen peroxide because these products are toxic to wounds.

! NURSING ALERT

Do not put anything in a wound that you would not put in the eye. The safest solution is normal saline.

Open wounds are covered with a dressing, such as a commercial adhesive bandage, although larger wounds may benefit from the use of occlusive dressings. If a dressing needs to be secured, a nonalcohol skin barrier can be applied to protect the skin, or the wound can be "picture framed" with hydrocolloid dressing and dressing tape can be secured to the hydrocolloid. This method of securing the dressing protects the skin when the tape is removed. Montgomery straps or stretch netting can also be used to secure dressings and to avoid the use of tape.

! NURSING ALERT

Advise parents that the yellow gel forming under hydrocolloid dressings may look like pus and has a distinct odour (somewhat fruity) but is normal leakage.

Dressings need to be removed carefully to protect intact skin and the epithelial surface of the wound. When removing transparent or hydrocolloid dressings, the nurse or parent should raise one edge of the dressing and pull parallel to the skin to loosen the adhesive.

Lacerations present a special challenge. The injured child and family are usually distressed by the bleeding. In particular, scalp lacerations tend to bleed profusely. The initial nursing intervention is to apply pressure to the area and to attempt to calm the child before further examination. Unless there is bleeding from a severed artery, the wound is cleansed with a forced jet of sterile tepid water or saline (via syringe) and examined for extent, depth, and presence of foreign material such as dirt, glass, or fabric fragments.

The location of the wound facilitates assessment. Wounds over bony areas may contain bone chips, and clear fluid seeping from severe head wounds may indicate cerebrospinal fluid. A pressure dressing is applied for transfer to medical care. After the child is in a medical facility, the child is prepared for treatment.

Puncture wounds that do not require a tetanus booster are soaked in warm water and soap for several minutes. Causing the wound to rebleed may be helpful. An adhesive bandage can be applied if desired. Puncture wounds of the head, chest, or abdomen or those that could still contain a portion of the puncturing object must be evaluated carefully.

Parents should be cautioned against opening blisters or kissing a wound "to make it better." The wound can easily become contaminated from germs in the human mouth. If scabs form, they need to be allowed to slough off without assistance; picking or early removal may cause scarring and secondary infection. Parents should be advised to seek medical help if there is evidence of infection.

Relief of symptoms. Most therapeutic regimens for skin lesions are directed toward relief of pruritus, the most common subjective complaint. Cooling the affected area and increasing the skin pH with cool baths or compresses and alkaline applications such as baking soda baths are helpful in reducing the itching. Clothing and bed linen should be soft and lightweight to decrease irritation from friction and stimulation.

During treatment, both the affected and unaffected skin should be protected from damage and secondary infection. Preventing scratching is important. Older children can refrain from scratching or rubbing, although they may need to be reminded to do so. Small children may require the use of devices such as mittens (especially during sleep) or special coverings. Keeping fingernails clean, short, and trimmed reduces the risk of secondary infection.

Antipruritic medications, such as diphenhydramine (Benadryl) or hydroxyzine (Atarax), may be prescribed for severe itching, especially if it disturbs the child's rest. Pain and discomfort are usually managed with nonpharmacological measures and mild analgesia. Severe pain requires more potent medication. Occlusive dressings over wounds reduce pain. For suturing wounds a topical anaesthetic or intradermal buffered lidocaine should be used (see Pain Management, Chapter 34).

! NURSING ALERT

Provide written instructions and demonstrate to parents the correct amount of topical medication to apply (e.g., size of a pea; thin film to cover). If more than one preparation is applied, mark the containers with numbers so the parents remember the correct order of application. Stress that more is not necessarily better with some medications, such as steroids.

Home care and family support. Dermatological conditions always involve the family; few situations require hospitalization and most care is delivered at home. Because family members must carry out the treatment plan, their assistance is essential. Regimens that are simple to accomplish in the clinic, hospital, or primary health care provider's office may be frustrating and baffling at home. The family may also need assistance in adapting equipment available for home therapy.

It is important that the child and family be given explanations that are as detailed as possible about both the expected and unexpected results of treatment, including any ill effects that might occur. If unexplained reactions develop, the family should be directed to discontinue treatment and report the reactions to the appropriate person. The use of over-the-counter medicines is discouraged unless the preparations have been discussed and approved by the health care provider.

INFECTIONS OF THE SKIN

Bacterial Infections

Normally, the skin harbours a variety of bacterial flora, including the major pathogenic varieties of staphylococci and streptococci. The degree of pathogenicity of the organism depends on its invasiveness and toxicity, the integrity of the skin, and the immune and cellular defences of the host. Children with congenital or acquired immunodeficiency disorders (such as acquired immunodeficiency syndrome [AIDS]), those in a debilitated condition, those receiving immunosuppressant therapy, and those with a generalized malignancy such as leukemia or lymphoma are at risk for developing bacterial infections. Common bacterial skin disorders are outlined in Table 52.1.

TABLE 52.1 Bacterial Infections

Disorder and Organism	Manifestations	Management	Comments
Impetigo contagiosa—*Staphylococcus* (Figure 52.4)	Begins as a reddish macule Becomes vesicular Ruptures easily, leaving superficial, moist erosion Tends to spread peripherally in sharply marginated irregular outlines Exudate dries to form heavy, honey-coloured crusts Pruritus common Systemic effects—Minimal or asymptomatic	Careful removal of undermined skin, crusts, and debris by softening with 1:20 Burow solution compresses Topical application of bactericidal ointment Systemic administration of oral or parenteral antibiotics (penicillin) in severe or extensive lesions	Tends to heal without scarring unless secondary infection Autoinoculable and contagious Common in toddlers and preschoolers May be superimposed on eczema
Pyoderma—*Staphylococcus*, streptococcus	Deeper extension of infection into dermis Tissue reaction more severe Systemic effects—Fever, lymphangitis	Soap and water cleansing Wet compresses Bathing with antibacterial soap as prescribed Washcloths or towels should not be shared Mupirocin to nares and lesions as prescribed Systemic antibiotics	Autoinoculable and contagious May heal with or without scarring
Folliculitis (pimple), furuncle (boil), carbuncle (multiple boils)—*Staphylococcus aureus*	Folliculitis—Infection of hair follicle Furuncle—Larger lesion with more redness and swelling at a single follicle Carbuncle—More extensive lesion with widespread inflammation and "pointing" at several follicular orifices Systemic effects—Malaise, if severe	Skin cleanliness Local warm, moist compresses Topical application of antibiotic medications Systemic antibiotics in severe cases Incision and drainage of severe lesions, followed by wound irrigation with antibiotics or suitable drain implantation	Autoinoculable and contagious Furuncle and carbuncle tend to heal with scar formation Never squeeze a lesion
Cellulitis—*Streptococcus,* staphylococcus, *Haemophilus influenzae* (Figure 52.5)	Inflammation of skin and subcutaneous tissues with intense redness, swelling, and firm infiltration Lymphangitis "streaking" frequently seen Involvement of regional lymph nodes common May progress to abscess formation Systemic effects—Fever, malaise	Oral or parenteral antibiotics Rest and immobilization of both affected area and child Hot, moist compresses to area Marking the edges of the erythema to determine and track spreading of the infection	Hospitalization may be necessary for child with systemic symptoms Otitis media may be associated with facial cellulitis
Staphylococcal scalded skin syndrome—*S. aureus*	Macular erythema with "sandpaper" texture of involved skin Epidermis becoming wrinkled (in 2 days or less), and large bullae appearing	Systemic administration of antibiotics Gentle cleansing with saline, Burow solution, or 0.25% silver nitrate compresses	Infants subject to fluid loss; impaired body temperature regulation; and secondary infection, such as pneumonia, cellulitis, and septicemia Heals without scarring

Fig. 52.4 Impetigo contagiosa. (From Weston, W. L., Lane, A. T., & Morelli, J. G. [2002]. *Color textbook of pediatric dermatology* [3rd ed.]. Mosby.)

Fig. 52.5 Cellulitis of cheek from puncture wound. (From Weston, W. L., Lane, A. T., & Morelli, J. G. [2002]. *Color textbook of pediatric dermatology* [3rd ed.]. Mosby.)

Because of the characteristic "walling-off" process of the inflammatory reaction (abscess formation), staphylococci are more difficult to treat, and the local infected area is associated with an increase in bacteria all over the skin surface that serves as a source of continuing infection. In recent years, the number of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) infections has risen. There is also increasing concern about evolving resistant forms of MRSA due to overuse of antibacterials. Outbreaks of MRSA in Canada have been seen among athletes, prisoners, military recruits, children who attend day care centres, injection drug users, and other groups of people who live in crowded settings or routinely share contaminated items. Indigenous populations have high rates of community-acquired MRSA infections that are mostly skin and soft-tissue infections and are more virulent, resulting in significant morbidity and mortality. This increased prevalence is in part due to household overcrowding and a lack of indoor piped water, which directly affects this community's ability to maintain adequate personal and environmental hygiene (Irvine & Canadian Paediatric Society [CPS], First Nations, Inuit and Métis Health Committee, 2012/2020).

Nursing Care. The major nursing interventions related to bacterial skin infections are to prevent the spread of infection and to prevent complications. Impetigo contagiosa and MRSA infections can easily spread by self-inoculation; as a result the child must be cautioned against touching the involved area. Hand hygiene is mandatory before and after contact with an affected child. Good hand hygiene practice should be emphasized to both the child and family. Many children with AD are colonized with MRSA in the nares and under the fingernails. Thus for many bacterial infections, and for MRSA infection in particular, the child should be provided with washcloths and towels separate from those of other family members. The child's pyjamas, underwear, and other clothes should be changed daily and washed in hot water. Razors used for shaving should be discarded after each use and not shared. Caregivers should be instructed to seek medical attention if a child develops a fever or other signs of illness, or if a local lesion does not improve within 48 hours of starting treatment. Families also should be instructed to perform regular cleaning of contact surfaces in the home with a standard household cleaner or detergent (Irvine & CPS, First Nations, Inuit and Métis Health Committee, 2012/2020).

Children and parents are often tempted to squeeze follicular lesions. They must be warned that squeezing will not hasten the resolution of the infection and that there is a risk for making the lesion worse or spreading the infection. No attempt should be made to puncture the surface of the pustule with a needle or sharp instrument. For example, a child with a stye (an abscess on the inner or outer part of the eyelid caused by a bacterial infection) may waken with the eyelids of the affected eye sealed shut with exudate. The child or parents should be instructed to gently wipe the lid from the inner to the outer edge with warm water and a clean washcloth until the exudate is removed.

The child with limited cellulitis of an extremity is usually managed at home on a regimen of oral antibiotics and warm compresses. Children with more extensive cellulitis, especially around a joint with lymphadenitis or on the face, are usually admitted to the hospital for parenteral antibiotics, followed by continued treatment at home. Nurses are responsible for teaching the family to administer the medication and apply compresses.

Viral Infections

Viruses are intracellular parasites that produce their effect by using the intracellular substances of the host cells. Composed of only a deoxyribonucleic acid (DNA) or ribonucleic acid (RNA) core enclosed in an antigenic protein shell, viruses are unable to provide for their own metabolic needs or to reproduce themselves. After a virus penetrates a cell of the host organism, it sheds the outer shell and disappears within the cell, where the nucleic acid core stimulates the host cell to form more virus material from its intracellular substance. In a viral infection the epidermal cells react with inflammation and vesiculation (as in herpes simplex) or by proliferating to form growths (warts).

Many of the communicable viral diseases of childhood are associated with rashes, and each rash is characteristic. The type of lesion and the configuration of rubeola, rubella, and chicken pox are described in Table 35.7. Other common viral disorders of the skin are outlined in Table 52.2.

Dermatophytoses (Fungal Infections)

The dermatophytoses (ringworm) are infections caused by a group of closely related filamentous fungi that invade primarily the stratum corneum, hair, and nails. These are superficial infections that live on, not in, the skin. Dermatophytoses are designated by the Latin word *tinea,* with further designation relating to the area of the body where they are found (e.g., *tinea capitis* [ringworm of the scalp]). Table 52.3 outlines common dermatophytoses.

Nursing Care. When teaching families how to care for a child with ringworm, the nurse should emphasize good health and hygiene. Because of the infectious nature of the disease, affected children should not exchange with other children grooming items, headgear, scarves, or other articles of apparel that have been in proximity to the infected area. Affected children should have their own towels and wear a protective cap at night to avoid transmitting the fungus to bedding, especially if they sleep with another person. Because the infection can be acquired by animal-to-human transmission, all household pets should be examined for the disorder. Other sources of infection are seats with headrests (such as theatre seats), seats in public transportation vehicles, helmets, and gymnasium mats.

Both 2% ketoconazole and 1% selenium sulphide shampoos may reduce colony counts of dermatophytes. These shampoos can be used in combination with oral therapy to reduce the transmission of disease to others. The shampoo should be applied to the scalp for 5 to 10 minutes twice a week. The child may return to school once the therapy is initiated.

If the child is treated with the medication griseofulvin and symptoms subside, the child or parents may be tempted to decrease or discontinue the medication. The nurse should emphasize the importance of maintaining the prescribed dosage schedule and of taking the medication with high-fat foods for best absorption. They should also be informed of possible medication adverse effects, such as headache, gastrointestinal upset, fatigue, insomnia, and photosensitivity. For children who take the medication over many months, periodic testing is required to monitor leukopenia and assess liver and renal function.

Systemic Mycotic (Fungal) Infections

Mycotic (systemic or deep fungal) infections have the capacity to invade the viscera as well as the skin. The most common infections are the lung diseases, which are usually acquired by inhalation of fungal spores. These fungi produce a variable spectrum of disease, and some are common in certain geographic areas. They are not transmitted from person to person but appear to reside in the soil, from which their spores are airborne. The cutaneous lesions caused by deep fungal infections are granulomatous and appear as ulcers, plaques, nodules, fungating masses, and abscesses. The course of deep fungal diseases is chronic with slow progression that favours sensitization (Table 52.4).

TABLE 52.2 Viral Infections

Infection	Manifestations	Management	Comments
Verruca (warts) Cause—Human papillomavirus (various types)	Usually well-circumscribed, grey or brown, elevated, firm papules with a roughened, finely papillomatous texture Occur anywhere, but usually appear on exposed areas such as fingers, hands, face, and soles May be single or multiple Asymptomatic	Not uniformly successful Local destructive therapy, individualized according to location, type, and number—surgical removal, electrocautery, curettage, cryotherapy (liquid nitrogen), caustic solutions (lactic acid and salicylic acid in flexible collodion, retinoic acid, salicylic acid plasters), X-ray treatment, laser	Common in children Tend to disappear spontaneously Course unpredictable Most destructive techniques tend to leave scars Autoinoculable Repeated irritation will cause to enlarge Apply topical anaesthetic EMLA
Verruca plantaris (plantar wart)	Located on plantar surface of feet and, because of pressure, is practically flat; may be surrounded by a collar of hyperkeratosis	Apply caustic solution to wart and wear foam insole with hole cut to relieve pressure on wart; Soak 20 minutes after 2–3 days; repeat until wart comes out	Destructive techniques tend to leave scars, which may cause difficulties with walking Apply topical anaesthetic EMLA
Herpes simplex virus Type I (cold sore, fever blister) Type II (genital)	Grouped, burning, and itching vesicles on inflammatory base, usually on or near mucocutaneous junctions (lips, nose, genitalia, buttocks) Vesicles dry, forming a crust, followed by exfoliation and spontaneous healing in 8–10 days May be accompanied by regional lymphadenopathy	Avoidance of secondary infection Burow solution compresses during weeping stages Topical therapy (penciclovir) to shorten duration of cold sores Oral antiviral (acyclovir) for initial infection or to reduce severity in recurrence Valacyclovir, an oral antiviral, used for episodic treatment of recurrent genital herpes; reduces pain, stops viral shedding, and has a more convenient administration schedule than acyclovir	Heal without scarring unless secondary infection Type I cold sores prevented by using sunscreens protecting against UVA and UVB light to prevent lip blisters Aggravated by corticosteroids Positive psychological effect from treatment May be fatal in children with depressed immunity
Varicella-zoster virus (herpes zoster; shingles)	Caused by same virus that causes varicella (chicken pox) Virus has affinity for posterior root ganglia, posterior horn of spinal cord, and skin; crops of vesicles usually confined to dermatome following along course of affected nerve Usually preceded by neuralgic pain, hyperesthesias, or itching May be accompanied by constitutional symptoms	Symptomatic Analgesics for pain Mild sedation sometimes helpful Local moist compresses Drying lotions sometimes helpful Ophthalmic variety: use systemic corticotropin (adrenocorticotropic hormone) or corticosteroids Acyclovir Lidocaine (Lidoderm) topical anaesthetic	Pain in children usually minimal Postherpetic pain does not occur in children Chicken pox may follow exposure; isolate affected child from other children in a hospital or school May occur in children with depressed immunity; can be fatal
Molluscum contagiosum Cause—Pox virus Small, benign tumours	Flesh-coloured papules with a central caseous plug (umbilicated) Usually asymptomatic	Cases in well children resolve spontaneously in about 18 mo Treatment reserved for troublesome cases Apply topical anaesthetic EMLA and remove with curette Use tretinoin gel 0.01% or cantharidin (Cantharone) liquid Curettage or cryotherapy	Common in school-age children Spread by skin-to-skin contact, including autoinoculation and fomite-to-skin contact

EMLA, Eutectic mix of lidocaine and prilocaine; *UVA,* ultraviolet A; *UVB,* ultraviolet B.

SKIN DISORDERS RELATED TO CHEMICAL OR PHYSICAL CONTACTS

Contact Dermatitis

Contact dermatitis is an inflammatory reaction of the skin to chemical substances, natural or synthetic, that evokes a hypersensitivity response or direct irritation. The initial reaction occurs in an exposed region, most commonly the face and neck, backs of the hands, forearms, male genitalia, and lower legs. Early in the reaction, there is usually a sharp delineation between inflamed and normal skin that ranges from a faint, transient erythema to massive bullae on an erythematous swollen base. Itching is a constant symptom.

The cause may be a primary irritant or a sensitizing agent. A *primary irritant* is one that irritates any skin. A *sensitizing agent* produces an irritation on those individuals who have met the irritant or something chemically related to it, have undergone an immunological

TABLE 52.3 Dermatophytoses (Fungal Infections)

Disease and Organism	Manifestations	Management	Comments
Tinea capitis—*Trichophyton tonsurans, Microsporum audouinii, Microsporum canis* (Figure 52.6, A)	Lesions in scalp but may extend to hairline or neck Characteristic configuration of scaly, circumscribed patches or patchy, scaling areas of alopecia Generally asymptomatic, but severe, deep inflammatory reaction may occur that manifests as boggy, encrusted lesions (kerions) Pruritic Microscopic examination of scales is diagnostic	Oral griseofulvin Oral ketoconazole for difficult cases Selenium sulphide shampoos Topical antifungal medications (e.g., clotrimazole, haloprogin, miconazole)	Person-to-person transmission Animal-to-person transmission Rarely, permanent loss of hair *M. audouinii* transmitted from one human being to another directly or from personal items; *M. canis* usually contracted from household pets, especially cats Atopic individuals more susceptible
Tinea corporis—*Trichophyton rubrum, Trichophyton mentagrophytes, M. canis, Epidermophyton* organisms (see Figure 52.6, B)	Generally round or oval, erythematous scaling patch that spreads peripherally and clears centrally; may involve nails (tinea unguium) Diagnosis—Direct microscopic examination of scales Usually unilateral	Oral griseofulvin Local application of antifungal preparation such as tolnaftate, haloprogin, miconazole, clotrimazole; apply 2.5 cm beyond periphery of lesion; continual application 1–2 wk after no sign of lesion	Usually of animal origin from infected pets Majority of infections in children caused by *M. canis* and *M. audouinii*
Tinea cruris ("jock itch")—*Epidermophyton floccosum, T. rubrum, T. mentagrophytes*	Skin response similar to that in tinea corporis Localized to medial proximal aspect of thigh and crural fold; may involve scrotum in males Pruritic Diagnosis—Same as for tinea corporis	Local application of tolnaftate liquid Wet compresses or sitz baths may be soothing	Rare in preadolescent children Health education regarding personal hygiene
Tinea pedis ("athlete's foot")—*T. rubrum, Trichophyton interdigitale, E. floccosum*	On intertriginous areas between toes or on plantar surface of feet Lesions vary: Maceration and fissuring between toes Patches with pinhead-sized vesicles on plantar surface Pruritic Diagnosis—Direct microscopic examination of scrapings	Oral griseofulvin Local applications of tolnaftate liquid and antifungal powder containing tolnaftate Acute infections—Compresses or soaks followed by application of glucocorticoid cream Elimination of conditions of heat and perspiration by clean, light socks and well-ventilated shoes; avoidance of occlusive shoes	Most frequent in adolescents and adults; rare in children, but occurrence increases with wearing of plastic shoes Transmission to other individuals rare Ointments not successful
Candidiasis (moniliasis)—*Candida albicans*	Grows in moist areas Inflamed areas with white exudate, peeling, and easy bleeding Pruritic Diagnosis—Characteristic appearance	Esophagitis: oral or intravenous (IV) fluconazole; IV amphotericin, voriconazole, or micafungin Skin lesions: topical nystatin, miconazole, or clotrimazole Vulvovaginal: topical clotrimazole, miconazole, butoconazole, terconazole, or tioconazole	Common form of diaper dermatitis (see Figure 52.12) Oral form common in infants Vaginal form in older females May be disseminated in immunosuppressed children

Fig. 52.6 **A:** Tinea capitis. **B:** Tinea corporis. Both infections are caused by *Microsporum canis*, the "kitten" or "puppy" fungus. (From Habif, T. P. [2004]. Clinical dermatology: A color guide to diagnosis and therapy [4th ed.]. Mosby.)

TABLE 52.4 Systemic Mycoses

Disorder and Organism	Skin Manifestations	Systemic Manifestations	Management	Comments
North American blastomycosis—*Blastomyces dermatitidis*	Chronic granulomatous lesions and microabscesses in any part of body Initial lesion a papule; undergoes ulceration and peripheral spread	Pulmonary symptoms, such as cough, chest pain, weakness, and weight loss May have skeletal involvement, with bone destruction and formation of cutaneous abscesses	Intravenous (IV) administration of amphotericin B	Usual portal of entry is lungs Source of infection unknown Noninfectious Pulmonary infections may be mild and self-limited and require no treatment Progressive disease often fatal
Cryptococcosis—*Cryptococcus neoformans (Torula histolytica)*	Usually on face; acneiform, firm, nodular, painless eruption	Central nervous system (CNS) manifestations—Headache, dizziness, stiff neck, and signs of increased intracranial pressure Low-grade fever, mild cough, lung infiltration	IV amphotericin B; may be administered intrathecally for CNS involvement 5-Fluorocytosine for meningitis Excision and drainage of local lesions	Acquired by inhalation of dust but may enter through skin Prognosis serious Noninfectious Increased incidence in persons receiving corticosteroids with lymphoreticular malignancies, or type 2 diabetes
Histoplasmosis—*Histoplasma capsulatum*	Not distinctive or uniform, but most appear as punched-out or granulomatous ulcers	General systemic symptoms may include pallor, diarrhea, vomiting, irregular spiking temperature, hepatosplenomegaly, and pulmonary symptoms Any tissue of body may be involved with related symptoms	IV amphotericin B for severe cases Oral ketoconazole	Organism cultured from soil, especially where contaminated with fowl droppings Fungus enters through skin or mucous membranes of mouth and respiratory tract Endemic in St. Lawrence Valley region where 20 to 30% of the population test positive on a yearly basis Disseminated diseases most common in infants and children

change, and have become sensitized. Prior exposure is not necessarily a factor in the reaction. A sensitizer irritates in relatively low concentrations only persons who are allergic to it.

In infants, contact dermatitis occurs on the convex surfaces of the diaper area (see Diaper Dermatitis, later in chapter). Other agents that produce contact dermatitis include plants (poison ivy, oak, or sumac), animal irritants (wool, feathers, and furs), metal (nickel found in jewellery and the snaps on sleepers and denim), vegetable irritants (oleoresins, oils, and turpentine), synthetic fabrics (e.g., shoe components), dyes, cosmetics, perfumes, and soaps (including bubble baths).

The major goal in treatment is to prevent further exposure of the skin to the offending substance. Provided there is no further irritation, the skin's normal recuperative powers will often produce healing without treatment. Otherwise, treatment of contact dermatitis is based on severity. Mild cases are treated with topical steroids. Mild to moderately severe cases may require a 2-week course of strong topical corticosteroids. Very severe cases require systemic corticosteroids.

Nursing Care. Nurses frequently detect evidence of contact dermatitis during routine physical assessments. Skin manifestations in specific areas suggest limited contact, such as around the eyes (mascara), areas of the body covered by clothing but not protected by undergarments (wool), or areas of the body not covered by clothing (UV injury). Generalized involvement is more likely to be caused by bubble bath or soap. Often nurses can determine the offending agent and counsel families regarding management. However, if the lesions persist, are extensive, or show evidence of infection, medical evaluation is indicated.

Poison Ivy, Oak, and Sumac

Contact with the dry or succulent portions of any of three poisonous plants (ivy, oak, and sumac) produces localized, streaked or spotty, oozing and painful impetiginous lesions. The offending substance in these plants is an oil, *urushiol*, that is extremely potent. Sensitivity to urushiol is not inborn but is developed after one or two exposures and may change over a lifetime. All parts of the plants contain the oil, including dried leaves and stems. Even smoke from burning brush piles can produce a reaction. Some people may react to the skin of mango, which contains uroshiol.

Animals do not seem to be affected by the oil; however, dogs or other animals that have run or played in the plants may carry the sap on their fur, and animals that eat the plants can transfer the oil in their saliva. Shoes, tools, and toys can transfer the oil. Golf balls that have been in the rough are another source of contact.

Urushiol takes effect as soon as it touches the skin. It penetrates through the epidermis and bonds with the dermal layer, where it initiates an immune response. The full-blown reaction is evident after about 2 days, with redness, swelling, and itching at the site of contact. Several days later, streaked or spotty blisters oozing serum from damaged cells produce the characteristic impetiginous lesions (Figure 52.7). The lesions dry and heal spontaneously, and itching stops by 10 to 14 days.

Nursing Care. As soon as an exposure is realized, there is no time to waste. The earlier the skin is cleansed, the greater the chance of removing the urushiol before it attaches to the skin. The exposed skin can be cleansed with isopropyl alcohol or vinegar followed by water. A shower with soap and warm water should follow. Harsh soap is contraindicated because it removes protective skin oils and dilutes the urushiol, allowing it to spread; hard scrubbing irritates the skin. Clothes, tools, shoes, and any other objects that had contact with the plants should be cleaned with alcohol and then water.

Treatment of the lesions includes calamine lotion, soothing Burow solution compresses, or oatmeal baths to relieve discomfort. Topical corticosteroid gel is effective for prevention or relief of inflammation, especially when applied before blisters form. Oral corticosteroids may be needed for severe reactions, and a sedative such as diphenhydramine may be ordered. Every effort needs to be made to prevent the child from scratching the lesions. Although the lesions do not spread by contact with the blister serum or from scratching, they can become secondarily infected.

Medication Reactions

Adverse reactions to medications are seen more often in the skin than in any other organ, although any organ of the body can be affected. The reaction may be a result of toxicity related to medication concentration, individual intolerance to the average dosage of the medication, or an allergic or idiosyncratic response. The manifestations

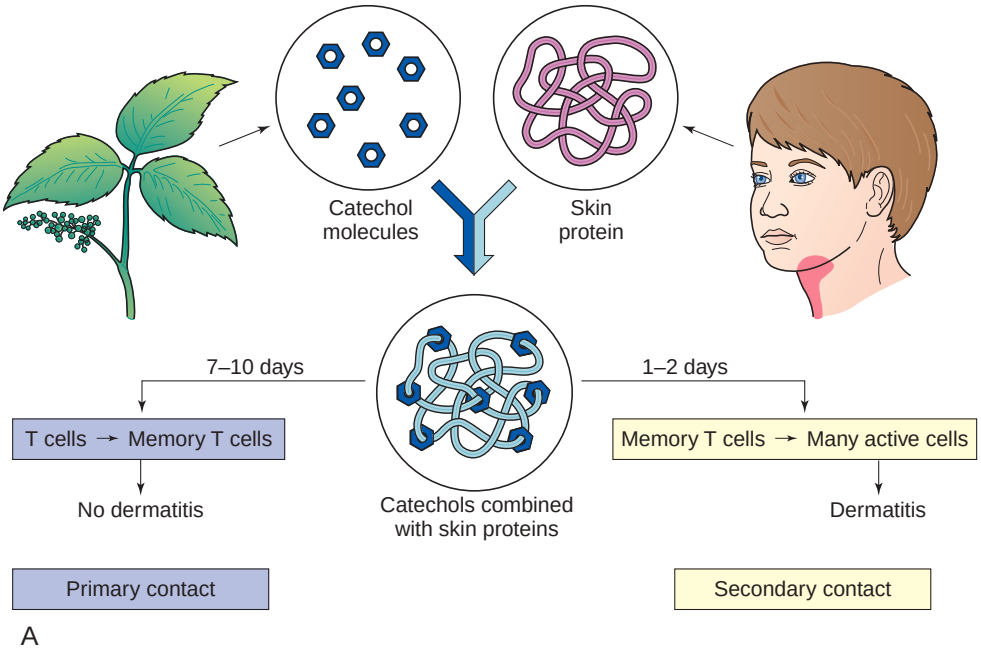


Fig. 52.7 **A:** Development of allergic contact dermatitis. **B:** Poison ivy lesions; note the "streaked" blisters surrounding one large blister. (**A**, from McCance, K., & Huether, S. [2010]. *Pathophysiology: The biological basis for disease in adults and children* [6th ed.]. Mosby. **B**, from Habif, T. P. [2010]. *Clinical dermatology: A color guide to diagnosis and therapy* [5th ed.]. Mosby.)

may be associated with adverse effects or secondary effects of a medication, either of which are unrelated to its primary pharmacological actions.

Although any medication is capable of producing a reaction in the susceptible individual, some medications have a tendency to produce a particular reaction consistently, and others are more likely to produce an untoward effect. Many are allergenic responses that occur after a previous administration of the medication, even a topical application. Other factors influence a medication response in a particular individual. For example, the incidence increases with the amount and number of medications given.

! NURSING ALERT

Intravenous (IV) medications are more likely to cause a reaction than oral medications. Stop the medication, but maintain the infusion with normal saline.

Manifestations of medication reactions may be delayed or immediate. A period of 7 days is usually required for a child to develop sensitivity to a medication that has never been administered previously. With prior sensitivity the manifestations appear almost immediately. Rashes are the most common manifestation of adverse medication reactions in children. However, individual medication reactions may vary from a single lesion to extensive, generalized epidermal necrosis such as that seen in Stevens-Johnson syndrome. Cutaneous manifestations can resemble almost any skin disease and can appear in almost any degree of severity. With few exceptions, the distribution of a medication eruption is widespread because it results from a circulating agent, appears as an inflammatory response with itching, is sudden in onset, and may be associated with constitutional symptoms such as fever, malaise, gastrointestinal upsets, anemia, or liver and kidney damage.

In most cases treatment for simple cutaneous reactions consists of discontinuing the medication. Sometimes a decision is made to continue the medication, such as an antibiotic in an infant or small child, until the cause of the rash is clearly indicated. In urticarial-type eruptions antihistamines may be ordered, and for widespread and severe lesions corticosteroids are beneficial. Severe anaphylactic reactions are a medical emergency (see Anaphylaxis, Chapter 47).

Nursing Care. The most effective means of management is prevention. Parents always remember a severe reaction in their child; a careful history will elicit evidence of a previous medication reaction. The history should include the medication's name, the nature of the reaction, dosage, and how soon after administration the reaction occurred.

Nurses who suspect that a rash is caused by a medication should withhold any further dose and report the eruption to the primary health care provider. Frequent offenders in medication reactions are penicillin and sulphonamides, and nurses must be alert to this possibility. However, even commonplace medications, including Aspirin, barbiturates, chemical agents in some foods, flavouring agents, and preservatives, are capable of producing an undesired response. Persons who have severe reactions should wear a medical identification bracelet in case of emergency or inadvertent administration of the offending medication.

SKIN DISORDERS RELATED TO ANIMAL CONTACTS

Arthropod Bites and Stings

Bites and stings account for a significant amount of mild to moderate discomfort in children. Most bites and stings are managed by simple symptomatic measures, such as compresses, calamine lotion, and prevention of secondary infection. *Arthropods* include insects and arachnids, such as mites, ticks, and spiders. Most arthropods in Canada, including tarantulas, are relatively harmless. Although all spiders produce venom that is injected via fangs, some are unable to pierce the skin and others produce venom that is insufficiently toxic to be harmful. Only two spiders—the brown recluse and the black widow—inject venom deadly enough to require immediate attention. Children bitten by these arachnids must receive medical attention as soon as possible. The black widow bite causes local, regional, or generalized pain associated with nonspecific symptoms and autonomic effects such as sweating, muscle cramps, and vomiting. Antivenoms are an important treatment for black widow spider bites. Muscle relaxants, analgesics or sedatives, and steroids are also used to treat the manifestations. The brown recluse spider bite causes pain and erythema that can become a necrotic ulcer. Systemic reactions include fever, nausea and vomiting, and joint pain. These bites are treated with antibiotics, corticosteroids, and analgesics. Wounds may require skin grafts.

When a hymenopteran (bees in particular) stings, its barbed stinger penetrates the skin. As long as the stinger remains in the skin, the muscles push the stinger deeper and the venom is pumped into the wound. The best approach is to remove the stinger as quickly as possible and to get away from the vicinity of other insects to prevent further injury. Children who have become sensitized to hymenopteran bites may have a severe systemic response that can be life-threatening. One sting can produce generalized urticaria, respiratory difficulty (from laryngeal edema), hypotension, and death. Intramuscular administration of epinephrine provides immediate relief and must be available for emergency use.

Hypersensitive children should wear a medical identification bracelet. They should also have a kit that contains epinephrine and a hypodermic syringe. Families should be reminded to check the expiration date on the kit and to replace an outdated one. They should determine whether someone at the school should be designated to inject the epinephrine in case of an emergency.

Skin lesions caused by other arthropods are outlined in Table 52.5, along with manifestations and management.

Scabies

Scabies is an endemic infestation caused by the scabies mite, *Sarcoptes scabiei*. Lesions are created as the impregnated female burrows into the stratum corneum of the epidermis (never into living tissue) to deposit her eggs and feces. Although it can affect individuals at any socioeconomic level, individuals who live in overcrowded conditions are at much higher risk for scabies (Banerji & CPS, First Nations, Inuit and Métis Health Committee, 2015/2018). The inflammatory response and intense itching occur after the host becomes sensitized to the mite, approximately 30 to 60 days after initial contact. If the person has been previously sensitized to the mite, the response occurs within 48 hours after exposure. After this time, the areas over which the mite has travelled will begin to itch and develop the characteristic eruption (Box 52.1). Consequently, mites will not necessarily be located at all sites of eruption.

There is great variability in the type of lesions. Infants often develop an eczematous eruption; therefore the observer must look for discrete papules, burrows, or vesicles.

Nursing Care. The treatment of scabies is the application of a scabicide. Currently, permethrin 5% cream (Elimite) is the medication of choice. Alternative medications are benzyl benzoate (10 to 12.5% for children), which has high efficacy and is less expensive and is widely

TABLE 52.5 Skin Lesions Caused by Arthropods

Mechanism and Characteristics	Manifestations	Management
Insect Bites—Flies, Gnats, Mosquitoes, Fleas		
Mechanism: Foreign protein in insects' saliva introduced when skin is penetrated for a blood-sucking meal *Distribution*: Almost everywhere—Fleas, mosquitoes, ants Suburbs and rural areas—Bees Urban areas—Hornets, wasps, yellow jackets	Hypersensitivity reaction Papular urticaria Firm papules; may be capped by vesicles or excoriated Little or no reaction in nonsensitized person	*Treatment:* Use antipruritic medications and baths. Administer antihistamines. Prevent secondary infection. *Prevention:* Avoid contact. Remove focus, such as treating furniture, mattresses, carpets, and pets, where insects may live. Apply insect repellent when exposure is anticipated.
Hymenopterans—Bees, Wasps, Hornets, Yellow Jackets, Fire Ants		
Mechanism: Injection of venom through stinging apparatus Venom contains histamine, allergenic proteins, and often a spreading factor, hyaluronidase Severe reactions caused by hypersensitivity or multiple stings	Local reaction—Small red area, wheal, itching, and heat Systemic reactions—May be mild to severe, including generalized edema, pain, nausea and vomiting, confusion, respiratory embarrassment, and shock	*Treatment:* Carefully scrape off stinger or pull out stinger as quickly as possible. Cleanse with soap and water. Apply cool compresses. Apply common household product (e.g., lemon juice, paste made with Aspirin or baking soda). Administer antihistamines. Severe reactions—Administer epinephrine, corticosteroids; treat for shock. *Prevention:* Teach child to wear shoes; to avoid wearing bright clothing, flowery prints, shiny jewellery, or perfumed grooming products (cologne, scented hairspray), which might attract the insect; and to avoid places where the insect may be contacted. Hypersensitive children should wear medical identification bracelet to indicate allergy and therapy needed; family should keep emergency medication and be taught its administration.
Ticks		
Mechanism: In process of sucking blood, head and mouth parts are buried in skin *Characteristics:* Feed on blood of mammals Significant in humans because of pathological organism carried May be vectors of various infectious diseases, such as Rocky Mountain spotted fever, Q fever, tularemia, relapsing fever, Lyme disease, tick paralysis Must attach and feed for 1–2 hr to transmit disease Usual habitat is wooded area	Tick usually attached to skin, head embedded Produce firm, discrete, intensely pruritic nodules at site of attachment May cause urticaria or persistent localized edema	*Treatment:* Grasp tick with tweezers (forceps) as close as possible to point of attachment. Pull straight up with steady, even pressure; if bare hands, use a tissue to touch tick during removal; wash hands thoroughly with soap and water. Remove any remaining part (e.g., head) with sterile needle. Cleanse wounds with soap and disinfectant. Veterinarian offices sell tick removers to make removal more effective. *Prevention:* Teach children to avoid areas where prevalent. Inspect skin (especially scalp) after being in wooded areas. See discussion on Lyme disease later in chapter.

BOX 52.1 Clinical Manifestations of Scabies

Lesion

Children—Minute greyish brown, threadlike (mite burrows), pruritic
- Black dot at end of burrow (mite)

Infants—Eczematous eruption, pruritic

Distribution

Generally in intertriginous areas—Interdigital, axillary-cubital, popliteal, inguinal

Children older than 2 years of age—Primarily hands and wrists

Children younger than 2 years—Primarily feet and ankles

BOX 52.2 Clinical Manifestations of Pediculosis

- Pruritus (caused by crawling insects and insect saliva on skin)
- Nits observable on hair shaft (see Figure 52.8)

Distribution
- Occipital area
- Behind ears
- Nape of neck
- Eyebrows and eyelashes (occasionally) (caused by pubic lice)

used outside of North America; and 1% lindane cream or lotion. Lindane can be neurotoxic and is not recommended for use in Canada (Banerji & CPS, First Nations, Inuit and Métis Health Committee, 2015/2018).

Ivermectin is an oral medication and can be used to treat scabies in patients with secondary excoriation for whom topical scabicides are irritating and not well tolerated or whose infestation is refractory; it is only available under special Health Canada permission. Safety and efficacy of ivermectin for children under 5 years or weighing less than 15 kg have not been established.

Nurses instructing families in the use of scabicides should emphasize the importance of following directions carefully. Permethrin is applied to all skin surfaces from the neck down to the toes (not just areas with rash, but also areas between the fingers and toes, the umbilicus, and the cleft of the buttocks). Infants should have the cream applied to their faces as well. The cream should remain on the skin for 8 to 9 hours for children under 6 years and 8 to 14 hours for older children and is then removed by bathing.

Because of the length of time between infestation and physical symptoms (30 to 60 days), all persons who were in close contact with the affected child need treatment. This may include intimate friends, babysitters, grandparents, and immediate family members. The objective is to treat as thoroughly as possible the first time. Enough medication for the entire family should be prescribed, with 60 mL allowed for each adult and 30 mL for each child.

All clothes, bedding, and towels used by the infested person before treatment should be washed in hot water and dried in a hot dryer. Families need to know that although this treatment will kill the mite that causes scabies, it will not eliminate the rash and the itch until the stratum corneum is replaced in approximately 2 to 3 weeks. For itching, oral antihistamines can be taken and soothing ointments or lotions can be applied. Antibiotics may be given for secondary infection (Banerji & CPS, First Nations, Inuit and Métis Health Committee, 2015/2018).

Pediculosis Capitis

Pediculosis capitis (head lice) is an infestation of the scalp by *Pediculus humanus capitis*, a common parasite in school-age children. The adult louse lives only about 48 hours when away from a human host, and the lifespan of the average female is 1 month. The female lays her eggs at night at the junction of a hair shaft and close to the skin because the eggs need a warm environment. The *nits*, or eggs, hatch in approximately 7 to 10 days. Itching is usually the only symptom. Common areas involved are the occipital area, behind the ears, and the nape of the neck (Box 52.2).

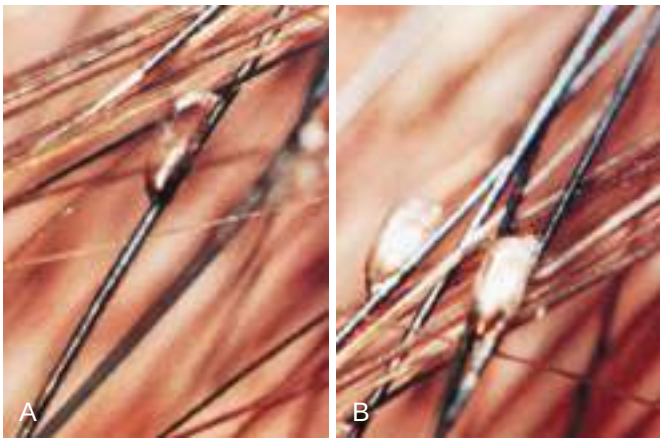

Fig. 52.8 A: Empty nit case. **B:** Viable nits. (From *The contemporary approach to the control of head lice in schools and communities* [1991]. SmithKline Beecham.)

Diagnostic Evaluation. Diagnosis is made by observation of the white eggs (nits) firmly attached to the hair shafts (Figure 52.8). Because of their brief lifespan and mobility, adult lice are more difficult to locate. Nits must be differentiated from dandruff, lint, hair spray, and other items of similar size and shape. Scratch marks or inflammatory papules, caused by secondary infection, may also be found on the scalp in the vulnerable areas.

Therapeutic Management. Treatment consists of the application of **pediculicides** and manual removal of nit cases. The medication of choice for infants and children is permethrin 1% cream rinse (Nix), which kills adult lice and nits. This product and preparations of pyrethrin with piperonyl butoxide (RID or A-200 Pyrinate) can be obtained without a prescription and can be used on children 2 months of age and older. Most experts advise a second treatment at 7 to 10 days to ensure a cure (Cummings et al., 2018). However, pyrethrin products are contraindicated for individuals with contact allergy to ragweed or turpentine. Two noninsecticidal products are available for treatment of head lice: isopropyl myristate 50% and ST-cyclomethicone 50%, for age 4 years and older; and dimeticone solution, which is a concentration of silicone oil, for age 2 years and older (Cummings et al., 2018).

Because of concerns that head lice may be developing resistance to chemical shampoos and that repeated exposure of children to strong chemicals on the scalp may be unhealthy, effective nonchemical control measures are essential. Daily removal of nits from the child's hair with a

metal nit comb at least every 2 or 3 days is a control measure to use after treatment with a pediculicide.

Nursing Care. An important nursing role is educating parents about pediculosis. Nurses should emphasize that *anyone* can get pediculosis; it has no respect for age, socioeconomic level, or cleanliness. Lice do not jump or fly, but they can be transmitted from one person to another on personal items and are more likely to infect people with straight hair and to infect girls. Because lice live close to the scalp, nits are unlikely to hatch at room temperature and environmental cleaning is not warranted. Children need to be cautioned against sharing combs, hair ornaments, hats, caps, scarves, coats, and other items used on or near the hair. Children who share lockers are more likely to become infested, and slumber parties place children at risk. In day care centres, children's clothing items should be stored in separate cubicles and sharing of clothing items should be discouraged. Lice are not carried or transmitted by pets.

Nurses or parents should carefully inspect children who scratch their head more than usual for bite marks, redness, and nits. The hair is systematically spread with two flat-sided sticks or tongue depressors, and the scalp is observed for any movement that indicates a louse. A more effective and faster method is to comb wet hair with a fine-toothed lice comb to detect lice. Nurses should wear gloves when examining the hair. Lice are small and greyish tan, have no wings, and are visible to the naked eye. The nits, or eggs, appear as tiny whitish oval specks adhering to the hair shaft about 6 mm from the scalp. The adherent nature of the nits distinguishes them from dandruff, which falls off readily. Empty nit cases, indicating hatched lice, are translucent rather than white and are located more than 6 mm from the scalp (see Figure 52.8).

If evidence of infestation is found, it is important to treat the child according to the directions on the label of the pediculicide. Parents should read the directions carefully before beginning treatment. The child should be made as comfortable as possible during the application process because the pediculicide must remain on the scalp and hair for several minutes. Playing "beauty parlour" or "barber shop" during the shampoo is a useful strategy. The child lies supine, with the head over a sink or basin, and covers their eyes with a dry towel or washcloth. This prevents medication, which can cause chemical conjunctivitis, from splashing into the eyes. If eye irritation occurs, the eyes must be flushed well with tepid water. It is not necessary to remove the nits after treatment because only live lice cause infestation. However, because none of the pediculicides is 100% effective in killing all the eggs, the makers of some pediculicides recommend manual removal of the nits after treatment. An extra-fine-tooth comb that is included in many commercial pediculicides or is available at pharmacies facilitates manual removal. If the comb is ineffective in removing the nit cases, the examiner should remove them by scraping them off the strands of hair with their fingernails.

Live lice only survive for up to 48 hours away from the host, but nits are shed into the environment and are capable of hatching in 7 to 10 days; retreatment may be required. Spraying with insecticide is not recommended because of the danger to children and animals. Families should also be advised that the pediculicide is relatively expensive, especially when several members of the household require treatment. Families may be inclined to try home remedies such as vinegar or petroleum jelly to treat the lice, but most are ineffective.

Families should be instructed to machine wash all objects that were in intimate contact with the head (e.g., hats, pillowcases, brushes and combs) in hot water and dry in a hot dryer for at least 15 minutes or store items in airtight plastic bags for 14 days; excessive cleaning is not required (Cummings et al., 2018).

Prevention. Nurses need to provide educational programs regarding prevention, transmission, detection, and treatment of pediculosis. Excluding children with nits or live lice from school or child care has no rational medical basis and is not recommended (Cummings et al., 2018).

Fig. 52.9 A bed bug biting a human.

Bed Bugs

Bed bugs, or Cimicidae, are small, biting insects that feed off the blood of warm-blooded animals and birds, preferring human blood. Bed bug infestations are becoming increasingly common in Canada because of the increase in travelling (Government of Canada, 2020). Cimicidae invade homes by travelling on objects such as clothing, televisions, and mattresses, where they hide in along the folds and on box springs.

Clinical Manifestations. Cimicidae reproduce quickly and travel easily. The insects are 6 mm in length, with wingless, oval bodies that redden with blood intake (Figure 52.9). The tiny eggs are whitish ovals and are clustered in crevices. They feed at night and bite all over the human body, particularly in the face, neck, and upper body. Cimicidae can survive up to 6 months without feeding. When the insect injects saliva into the skin, it creates localized red, itchy, flat or raised lesions, often linear in a group of three. Some individuals are more sensitive or allergic and react more with welts. Cimicidae do not transmit infection but an infection can develop from scratching the lesions. The bites do not require treatment and disappear quickly. It is important to not scratch and keep the skin clean in order to avoid infection. Antihistamines or creams can help relieve the itchiness and antibiotics can be prescribed if there is secondary infection present.

FAMILY-CENTRED CARE

How to Eliminate Cimicidae in the Home

- Check with the local health department or a pesticide control company to confirm Cimicidae presence.
- Inspect mattress, frame, and underside of beds.
- Vacuum with a nozzle daily in the house along any crevices such as baseboards and other crevices and immediately dispose of vacuum contents into a closed plastic bag and block the hose with a paper towel.
- Wash linens in the hottest water possible and cover pillows and mattresses with plastic.
- Remove all unnecessary clutter.
- Seal cracks and crevices.
- Monitor daily, using double-sided carpet sticky tape to catch Cimicidae.
- Inspect any objects coming into the house.
- When travelling, keep luggage off the floor and wrap in plastic. Pull the bed away from the wall, tuck in linen, and keep blankets off the floor.
- Consult professional pesticide services and choose the least risky option to humans and the environment.

Modified from Toronto Public Health. (2008). *Bed bug information for tenants*. http://www.toronto.ca/legdocs/mmis/2008/hl/bgrd/backgroundfile-11158.pdf.

Cimicidae are very difficult to get rid of (see Family-Centred Care box: How to Eliminate Cimicidae in the Home). Various chemicals or nonchemicals are usually needed to eliminate these insects. Available products will usually contain the active ingredients pyrethrin or other pyrethroids or diatomaceous earth. Outdoor products should not be used indoors (Government of Canada, 2020).

Rickettsial Diseases

Rickettsiae, the organisms responsible for a number of disorders (Table 52.6), are transmitted to human beings via arthropods. Mammals become infected only through the bites of infected lice, fleas, ticks, and mites, all of which serve as both infectors and reservoirs. Rickettsiae are intracellular parasites, similar in size to bacteria that inhabit the alimentary tract of a wide range of natural hosts. Rickettsial diseases are more common in temperate and tropical climates where humans live in association with arthropods. Infection in humans is incidental (except epidemic typhus) and not necessary for the survival of the rickettsial species. However, after the organism invades a human, it causes a disease that varies in intensity from a benign, self-limited illness to a disease that is fulminating and fatal.

Lyme Disease

Lyme disease is a tick-borne disease in Canada that is increasing in incidence although still relatively rare (Onyett & CPS, Infectious Diseases and Immunization Committee, 2019/2020; 2014). In 2009, Lyme disease became a nationally reportable disease in Canada. The number of reported Canadian cases has increased from 128 in 2009 to an estimated 2 636 cases in 2019 (Government of Canada, 2021a). Migratory birds can bring infected ticks into nonendemic areas, and people may also become infected while travelling to other endemic areas in North America and Europe. Lyme disease is caused by the spirochete *Borrelia burgdorferi*, which enters the skin and bloodstream through the saliva and feces of ticks, especially the deer tick. In 2016, most cases of Lyme disease were reported in Ontario, Nova Scotia, and Quebec. Most of the endemic ticks are found in the southern and central areas of the provinces (Government of Canada, 2021a).

Peak incidence for Lyme disease is in children 5 to 9 years of age and in older persons (55 to 59 years of age) (Onyett & CPS, Infectious Diseases and Immunization Committee, 2019/2020). The disease may initially appear in any of three stages:

TABLE 52.6 Eruptions Caused by Rickettsiae

Disorder, Organism, and Host	Manifestations	Management	Comments
Rocky Mountain spotted fever—*Rickettsia rickettsii* *Arthropod*—Tick *Transmission*—Tick *Mammal source*—Wild rodents, dogs	*Gradual onset*—Fever, malaise, anorexia, myalgia *Abrupt onset*—Rapid temperature elevation, chills, vomiting, myalgia, severe headache Maculopapular or petechial rash primarily on extremities (ankles and wrists) but may spread to other areas, characteristically on palms and soles	*Control*—Protection from tick bite by wearing proper apparel, tick repellent Tetracycline or chloramphenicol Vigorous supportive therapy	Usually self-limited in children Onset in children may resemble that of any infectious disease. Severe disease is rare in children. Disease has been reported in Canada, particularly in the south Inspect children and dogs regularly if they play in wooded areas. See Table 52.5 for management of ticks.
Epidemic typhus—*Rickettsia prowazekii* *Arthropod*—Body louse *Transmission*—Infected feces into broken skin *Mammal source*—Humans	Abrupt onset of chills, fever, diffuse myalgia, headache, malaise Maculopapular rash becoming petechial 4–7 days later, spreading from trunk outward	*Control*—Immediate destruction of vectors Tetracycline or chloramphenicol Supportive treatment	Patient should be isolated until deloused See Pediculosis Capitis section for management of pediculosis. Excreta from infected lice also in dust; disinfect patient's clothing, bedding, and possessions and wash in hot water
Endemic typhus—*Rickettsia typhi* *Arthropod*—Rat fleas or lice *Transmission*—Flea bite; inhaling or ingesting flea excreta *Mammal source*—Rats	Headache, arthralgia, backache followed by fever; may last 9–14 days Maculopapular rash after 1–8 days of fever; begins in trunk and spreads to periphery; rarely involves face, palms, soles	*Control*—Eliminate rat reservoir, insect vectors, or both Tetracycline or chloramphenicol Supportive treatment	Rare in Canada and found mainly in warm climates Shorter duration than epidemic typhus Mild, seldom fatal illness Difficult to distinguish from epidemic typhus
Rickettsial pox—*Rickettsia akari* West Nile fever *Arthropod*—Mosquitoes *Transmission*—Mosquito bite *Mammal source*—Birds	Maculopapular rash following primary lesion; eschar at site of bite; most children do not have symptoms or get sick If illness is present, symptoms appear in 2 to 15 days; fever, headache, and body aches, mild rash, or swollen lymph nodes If illness is present in person with lower immunity, risk of meningitis and encephalitis	*Control*—Eradication of rodent reservoir and mosquitoes Tetracycline or chloramphenicol Supportive treatment	Self-limited nonfatal disease In most parts of Canada, the risk of humans becoming infected with West Nile virus starts in mid-April until hard frost in October, with the most risk mid-July to early September. Mosquitoes are often most active at dawn (first light) and dusk (just before dark). In 2019, 43 cases have been reported in Canada (Government of Canada, 2021b).

Fig. 52.10 Lyme disease. Note annular red rings in erythema chronicum migrans. (From Weston, W. L., & Lane, A. T. [2007]. *Color textbook of pediatric dermatology* [4th ed.]. Mosby.)

- *Stage 1* consists of the tick bite at the time of inoculation, followed in 3 to 31 days by the development of erythema migrans at the site of the bite (Figure 52.10).
- *Stage 2*, the most serious stage of the disease, is characterized by systemic involvement of neurological, cardiac, and musculoskeletal systems that appears several weeks after the cutaneous phase is completed.
- *Stage 3*, or the late stage, includes musculoskeletal pain that involves the tendons, bursae, muscles, and synovia. Arthritis may occur, and late neurological conditions include deafness and chronic encephalopathy.

Diagnostic Evaluation. Diagnosis is best made clinically during the early stages by recognizing the characteristic rash, erythema migrans. Serological testing may be used to establish the diagnosis in later stages of the disease.

Therapeutic Management. Early and appropriate treatment is essential to prevent complications. Children are treated with oral antibiotics; amoxicillin is recommended for children younger than 8 years of age. Most experts treat individuals with early Lyme disease for 14 to 21 days. Persons who have removed ticks from themselves should be monitored closely for signs and symptoms of tick-borne diseases for 30 days; in particular they should be monitored for erythema migrans, a red expanding skin lesion at the site of the tick bite that may suggest Lyme disease. People who develop a skin lesion or viral infection–like illness within 1 month of an attached tick should seek prompt medical attention. Treatment of erythema migrans most often prevents development of later stages of Lyme disease.

Nursing Care. The major thrust of nursing care should be educating parents to protect their children from exposure to ticks. Children should avoid tick-infested areas or wear light-coloured clothing so that ticks can be spotted easily, tuck pant legs into socks, and wear a long-sleeved shirt tucked into pants when in wooded areas. Parents and children need to perform regular tick checks when they are in infested areas (with special attention to the scalp, neck, armpits, and groin areas). Parents should also be alert for signs of the skin lesion, especially if their children have been in tick-infested areas. Insect repellents containing diethyltoluamide (DEET) and picardin can protect against ticks, but parents should use these chemicals cautiously (Onyett & CPS, Infectious Diseases and Immunization Committee, 2019/2020). DEET must not be used in children under 6 months of age. As well, products with citronella or lavender oil should not be used on infants (Onyett & CPS, Infectious Diseases and Immunization Committee, 2019/2020). All insecticides should be approved in Canada. Although there have been reports of serious neurological complications in children resulting from frequent and excessive application of DEET repellants, the risk is low when they are used properly. Products with DEET should be applied sparingly according to label instructions and not applied to a child's face or hands or to any areas of irritated skin.

After the child returns indoors, treated skin should be washed with soap and water. If a tick is found, it should be removed carefully with tweezers by gripping the head and mouth parts as closely to the skin as possible and pulling straight out or with a veterinarian tick remover. The tick should be kept in case the child develops Lyme symptoms so the tick can be identified. The area should be washed with soap and disinfected with alcohol or other disinfectant (Government of Canada, 2019).

Animal Bites

Animal bites are common in childhood. Most animal bites to children are caused by dogs. Small children are likely to be bitten or scratched on the head, face, and neck because they tend to put their heads near the animal's head and flail their arms rather than protecting their heads. Dog bites are most common is children aged 5 to 9 years (Public Health Agency of Canada [PHAC], 2012). Injuries vary in intensity from small puncture wounds to complete evulsion of tissue that is associated with significant crush injury.

Cat bites are less frequent, although cat scratches are common. Cat scratch disease usually follows the scratch or bite of an animal (a cat or kitten in 90% of cases) and is caused by *Bartonella henselae,* a gram-negative bacterium. The usual manifestations are a painless, nonpruritic erythematous papule at the site of inoculation, followed by regional lymphadenitis. The disease is usually a benign, self-limiting illness that resolves spontaneously in 4 to 6 weeks (American Academy of Pediatrics [AAP], Committee on Infectious Diseases & Pickering, 2015).

Therapeutic Management. General wound care consists of rinsing the wound with copious amounts of saline or lactated Ringer's solution under pressure via a large syringe and washing the surrounding skin with mild soap. A clean pressure dressing is applied, and the extremity is elevated if the wound is bleeding. Medical evaluation is advised because of the danger of tetanus and rabies. Prophylactic antibiotics are indicated for puncture wounds and wounds in areas where infection could result in cosmetic (face) or functional impairment (hand).

Treatment of cat scratch disease is primarily supportive. Some experts recommend a 5-day course of oral azithromycin to hasten recovery (AAP, Committee on Infectious Diseases & Pickering, 2015). Antibiotics do not shorten the duration or prevent progression to suppuration but may be helpful in severe forms of the disease. Analgesics may be given for discomfort.

Nursing Care. The most important aspect related to animal bites is prevention. Children should understand animal behaviour and develop respect for animals. Parents should monitor their children's behaviour with pets and instruct them not to tease or surprise dogs, invade their territory, interfere with their feeding or sleeping, take their toys, or interact with sick or injured dogs or dogs with pups.

TABLE 52.7 Miscellaneous Skin Disorders

Disease and Causative Agent	Local Manifestations	Management	Comments
Urticaria—Usually allergic response to medications or infection	Development of wheals Vary in size and configuration and tend to appear quickly, spread irregularly, and fade within a few hours May be constant or intermittent, sparse or profuse, small or large, discrete or confluent May be acute, chronic, or recurrent in acute attacks	Local soothing and antipruritic applications Antihistamines Epinephrine or ephedrine Cortisone in severe cases Severe upper respiratory tract involvement may require tracheostomy	Known etiological agents should be avoided May be accompanied by malaise, fever, lymphadenopathy Severe cases may involve mucous membranes, internal organs, and joints Obstruction to air passages constitutes medical emergency (see Chapter 45)
Intertrigo—Mechanical trauma and aggravating factors of excessive heat, moisture, and sweat retention	Red, inflamed, moist, partially denuded, marginated areas, the shape of which is determined by location Appears where opposing skin surfaces rub together, such as intergluteal folds, groin, neck, and axilla Excessive moisture and obesity are often factors	Affected areas kept clean and dry Skin folds kept separated with a generous supply of nonmedicated powder Expose to air and light Remove excess clothing	A form of diaper irritation Prevent recurrence by keeping susceptible areas clean and dry Frequently associated with overheating from too much clothing; common in patients with a tracheostomy with short necks and copious secretions
Psoriasis—Unknown; hereditary predisposition; may be triggered by stress	Round, thick, dry, reddish patches covered with coarse, silvery scales over trunk and extremities; first lesions commonly appear in scalp; facial lesions more common in children than in adults Affected cells proliferate at a much more rapid rate than normal cells	Tar preparations in combination with UVB light or natural sunlight Topical corticosteroids Topical vitamin D analog *calcipotriene* Phenol and saline solutions followed by a tar shampoo to remove scales Keratolytic agents (salicylic acid) Acitretin Emollients may provide relief	Uncommon in children younger than 6 years Patients are otherwise healthy Coal tar acts synergistically with UVB light Keratolytic agents enhance absorption of corticosteroids Humidifiers may help in winter
Alopecia*			
Alopecia areata	Sudden onset of asymptomatic, noninflammatory, round, bald patches in hairy parts of body	Psychological support Inducement of allergic contact dermatitis to stimulate growth of hair Minoxidil (peripheral vasodilator)	Family history in 10 to 26% of cases Some concern regarding medication therapy safety Refer to support groups*
Traumatic alopecia	Traction alopecia around scalp margins from tight hair styles (e.g., braids, pony tails, corn rows)	Counselling regarding hair styling, use of hair cosmetics, hot combs, rollers	More prevalent in Black children and adolescents Prolonged traction can produce fibrosis of hair root and permanent loss
Trichotillomania	Compulsive hair pulling	Determine and treat cause	Chronic hair pulling may require psychological therapy
Tinea capitis	See Table 52.3	See Table 52.3	See Table 52.3
Erythema multiforme (Stevens-Johnson syndrome)—Unknown; associated with ingestion of some medications; often follows upper respiratory tract infection	Erythematous papular rash Lesions enlarge by peripheral expansion, develop central vesicle Involves most skin surfaces except scalp May extend to mucous membranes, especially oral, ocular, and urethral	Symptomatic and supportive Maintain adequate intake of fluids (oral or intravenous), calories, and protein Moist wound care, hydrogels such as Vaseline, or Aquaphor Appropriate treatment of complications Diligent monitoring of urine volume and specific gravity, hemoglobin and hematocrit, serum electrolyte levels, total body weight	Rash often preceded by fever and malaise Complications include renal failure and severe eye disease Respiratory involvement in a number of cases Self-limiting, but recovery may extend for weeks; skin lesions may subside without scarring; mucous membrane lesions may persist for months Recurrence rate, 20%; mortality rate as high as 10% High mutation rate

MISCELLANEOUS SKIN DISORDERS

A number of miscellaneous skin lesions occur in children (Table 52.7). Some occur as a result of congenital disorders and are inherited as an autosomal dominant trait. *Ichthyoses* are a heterogeneous group of disorders characterized by scaling that create challenging issues in treatment. These disorders are not discussed in detail here because of their wide variability.

SKIN DISORDERS ASSOCIATED WITH SPECIFIC AGE GROUPS

Several common dermatological conditions are confined to children in specific age groups. These conditions include diaper, atopic, and seborrheic dermatitis, which occurs predominantly in infants, and acne, which is most common in adolescence.

Diaper Dermatitis

Diaper dermatitis is common in infants and is one of several acute inflammatory skin disorders caused either directly or indirectly by wearing diapers. The peak age of occurrence is 9 to 12 months of age, and the incidence is greater in formula-fed infants than in breastfed infants.

Pathophysiology and Clinical Manifestations. Diaper dermatitis is caused by prolonged and repetitive contact with an irritant (e.g., urine, feces, soaps, detergents, ointments, friction). Although the irritant in the majority of cases is urine and feces, a combination of factors contributes to irritation. Prolonged contact of the skin with diaper wetness produces higher friction, greater abrasion damage, increased transepidermal permeability, and increased microbial counts. The irritant quality of urine is related to an increase in pH from the breakdown of urea in the presence of fecal urease. The increased pH promotes the activity of fecal enzymes, principally the proteases and lipases, which act as irritants. Fecal enzymes also increase the permeability of skin to bile salts, another potential irritant in feces.

The eruption of diaper dermatitis is manifested primarily on convex surfaces or in folds. The lesions represent a variety of types and configurations. Eruptions involving the skin in most intimate contact with the diaper, such as the convex surfaces of buttocks, inner thighs, mons pubis, and scrotum but sparing the folds, are likely to be caused by chemical irritants, especially from urine and feces (Figure 52.11). Other causes are detergents or soaps from inadequately rinsed cloth diapers or the chemicals in disposable wipes. Perianal involvement is usually the result of chemical irritation from feces, especially diarrheal stools.

Fig. 52.11 Irritant diaper dermatitis. Note sharply demarcated edges. (From Habif, T. P. [1996]. *Clinical dermatology: A color guide to diagnosis and therapy* [3rd ed.]. Mosby.)

Candida albicans infection produces perianal inflammation and a maculopapular rash with satellite lesions that may cross the inguinal fold (Figure 52.12).

Nursing Care. Nursing interventions are aimed at altering the three factors that produce dermatitis: wetness (hydration), pH, and fecal irritants. The most significant factor amenable to intervention is the moist environment created in the diaper area. Changing the diaper as soon as it becomes wet eliminates a major factor, and removing the diaper to expose healthy skin to air facilitates drying. The use of a hair dryer or heat lamp is not recommended because these devices can cause burns.

Guidelines for controlling diaper rash are presented in the Family-Centred Care box: Controlling Diaper Rash. A common misconception about using cornstarch on skin is that it promotes the growth of *C. albicans*. Neither cornstarch nor talc promotes the growth of fungi under conditions normally found in the diaper area. Cornstarch is more effective in reducing friction and tends to cake less than talc when the skin is wet. On the basis of these properties and its safety in terms of inhalation injury, cornstarch is the preferred product. Talc should not be used.

Fig. 52.12 Candidiasis of diaper area. Note beefy red central erythema with satellite pustules. (From Paller, A. S., & Mancini, A. J. [2011]. *Hurwitz clinical pediatric dermatology* [4th ed.]. Saunders.)

FAMILY-CENTRED CARE

Controlling Diaper Rash

Keep skin dry.*
- Use superabsorbent disposable diapers to reduce skin wetness.
- If using cloth diapers, use only overwraps that allow air to circulate; avoid rubber pants.
- Change diapers as soon as soiled—especially with stool—whenever possible, preferably once during the night.
- Expose healthy or only slightly irritated skin to air, not heat, to dry completely.

Apply ointment, such as zinc oxide or petrolatum, to protect skin, if skin is very red or has moist, open areas.
- Avoid removing skin barrier cream with each diaper change; remove waste material and reapply skin barrier cream.
- To completely remove ointment, especially zinc oxide, use mineral oil; do not wash vigorously.

Avoid overwashing the skin, especially with perfumed soaps or commercial wipes, which may be irritating.
- A moisturizer or nonsoap cleanser may be used, such as cold cream or Cetaphil, to wipe urine from skin.
- Gently wipe stool from skin using water and mild soap.

*Powder helps to keep the skin dry, but talc is dangerous if breathed into the lungs. Plain cornstarch and cornstarch-based powder are safer. When using any powder product, first shake it in to your hand, and then apply to the diaper area. Store the container away from the infant's reach; keep the container closed when not in use.

Atopic Dermatitis (Eczema)

Eczema or *eczematous inflammation of the skin* refers to a descriptive category of dermatological diseases and not to a specific etiology. Atopic dermatitis (AD) is a type of pruritic eczema that usually begins during infancy and is associated with allergy with a hereditary tendency (*atopy*). AD manifests in three forms based on the child's age and the distribution of lesions:

1. *Infantile (infantile eczema)*—Usually begins at 2 to 6 months of age; generally undergoes spontaneous remission by 3 years of age
2. *Childhood*—May follow the infantile form; occurs at 2 to 3 years of age; 90% of children have manifestations by age 5 years
3. *Preadolescent and adolescent*—Begins at about 12 years of age; may continue into the early adult years or indefinitely

The diagnosis of AD is based on a combination of history and morphological findings (Box 52.3). Often the dermatological manifestations appear subsequent to scratching from the intense pruritus. For example, infants rub their faces against bed linen, and their crawling (a form of scratching) results in irritation of knees and elbows (Figure 52.13). Lesions disappear if the scratching is stopped.

The majority of children with infantile AD have a family history of eczema, asthma, food allergies, or allergic rhinitis, which strongly supports a genetic predisposition. The cause is unknown but appears to be related to abnormal function of the skin, including alterations in perspiration, peripheral vascular function, and heat tolerance. Manifestations of the chronic disease improve in humid climates and get worse in the fall and winter, when homes are heated and environmental humidity is lower. The disease can be controlled but not cured. Research has shown that itching and scratching in infants with this disorder create sleep disturbances and can lessen quality of life (Mayba & Gooderham, 2017).

Therapeutic Management. The major goals of management are to (1) hydrate the skin, (2) relieve pruritus, (3) prevent and minimize flare-ups or inflammation by avoiding triggers, and (4) prevent and control secondary infection. The general measures for managing AD focus on reducing pruritus and other aspects of the disease. Management strategies include avoiding exposure to skin irritants or allergens; avoiding overheating; avoiding skin moisture loss and improving skin hydration; and administrating medications such as antihistamines, topical immunomodulators, topical steroids, and (sometimes) mild sedatives as indicated. Products with coal tar are available and are an effective topical treatment (Canadian Dermatology Association, 2021b).

There are a number of ways to enhance skin hydration and prevent dry, flaky skin, depending on the child's skin characteristics and individual needs. A tepid bath with a mild soap, no soap, or an emulsifying oil or oatmeal baths, followed immediately by application of an emollient (within 3 minutes), assists in trapping moisture and preventing its loss. Bubble baths and harsh soaps should be avoided. Some lotions are not effective, and emollients should be chosen carefully to prevent excessive skin drying. Aquaphor, Cetaphil, and Eucerin are acceptable lotions for skin hydration. A nighttime bath, followed by emollient application and dressing in soft cotton pyjamas, may help alleviate most nighttime pruritus. Sometimes colloid baths, such as the addition of 500 mL of cornstarch to a tub of warm water, provide temporary relief of itching and may help the child sleep if given before bedtime.

Cool wet compresses are soothing to the skin and provide antiseptic protection. A soft cloth with several layers is soaked in water or Burow solution. The compress is left on the skin for 20 to 30 minutes. If the cloth starts to dry, more fluid is added to keep it very wet. After removal of the cloth, the skin is patted dry and the medicated treatment or emollient applied. Bleach baths in a solution of bleach and clear, warm water for 5 to 10 minutes twice weekly can be effective in individuals susceptible to frequent infections, which can worsen eczema. Phototherapy can also be part of effective management of AD (Canadian Dermatology Association, 2021b). Adverse effects with phototherapy when used short term include erythema, skin pain, pruritus, and pigmentation. Longer-term adverse effects include predisposition to cutaneous malignancies (Leung & Sicherer, 2020).

Oral antihistamine medications such as hydroxyzine or diphenhydramine usually relieve moderate or severe pruritus. Nonsedating antihistamines such as loratadine (Claritin) or fexofenadine (Allegra) may be preferred for daytime pruritus relief. Because pruritus increases at night, a mildly sedating antihistamine may be needed.

Occasional flare-ups require the use of topical steroids to diminish inflammation. Low-, moderate-, or high-potency topical corticosteroids are prescribed, depending on the degree of involvement, the area of the

BOX 52.3 Clinical Manifestations of Atopic Dermatitis

Distribution of Lesions

Infantile form—Generalized, especially cheeks, scalp, trunk, and extensor surfaces of extremities (see Figure 52.13)

Childhood form—Flexural areas (antecubital and popliteal fossae, neck), wrists, ankles, and feet

Preadolescent and adolescent form—Face, sides of neck, hands, feet, face, and antecubital and popliteal fossae (to a lesser extent)

Appearance of Lesions

Infantile Form

Erythema
Vesicles
Papules
Weeping
Oozing
Crusting
Scaling
Often symmetrical

Childhood Form

Symmetrical involvement
Clusters of small erythematous or flesh-coloured papules or minimally scaling patches
Dry and may be hyperpigmented
Lichenification (thickened skin with accentuation of creases)
Keratosis pilaris (follicular hyperkeratosis) common

Adolescent or Adult Form

Same as childhood manifestations
Dry, thick lesions (lichenified plaques) common
Confluent papules

Other Physical Manifestations

Intense itching
Unaffected skin dry and rough
Children of African descent are likely to exhibit more papular or follicular lesions than are White children
May exhibit one or more of the following:

- Lymphadenopathy, especially near affected sites
- Increased palmar creases (many cases)
- Atopic pleats (extra line or groove of lower eyelid)
- Prone to cold hands
- Pityriasis alba (small, poorly defined areas of hypopigmentation)
- Facial pallor (especially around nose, mouth, and ears)
- Bluish discoloration beneath eyes ("allergic shiners")
- Increased susceptibility to unusual cutaneous infections (especially viral)

Fig. 52.13 Infantile atopic dermatitis with oozing and crusting of lesions. (From Weston, W. L., Lane, A. T., & Morelli, J. G. [2002]. *Color textbook of pediatric dermatology* [4th ed.]. Mosby.)

body to be treated, the child's age, the potential for local adverse effects (striae, skin atrophy, and pigment changes), and the type of vehicle to be used (e.g., cream, lotion, ointment). Patients receiving topical corticosteroid therapy for chronic conditions should be evaluated for risk factors for suboptimal linear growth and reduced bone density. Topical immunomodulators, a new nonsteroidal treatment for AD, are best used at the beginning of a flare-up just as the skin becomes red and itches. Two immunomodulator medications used in children with AD are tacrolimus and pimecrolimus. Immunomodulators specifically inhibit the cells of the immune system in the skin. They are very effective at reducing itch and preventing flare-ups if applied regularly. Both medications can be used freely on the face without producing steroid adverse effects.

If secondary skin infections occur in children with AD, these infections are managed with appropriate systemic antibiotics. In some patients with moderate to severe AD, the disease may require systemic treatment (Canadian Dermatology Association, 2021b).

Nursing Care. Assessment of the child with AD includes a family history for evidence of atopy, a history of previous involvement, and any environmental or dietary factors associated with the present and previous exacerbations. The skin lesions are examined for type, distribution, and evidence of secondary infection. Parents should be interviewed regarding the child's behaviour, especially in relation to scratching, irritability, and sleeping patterns. Exploration of the family's feelings and methods of coping is also important.

The nursing care of the child with AD can be challenging. Controlling the intense pruritus is imperative if the disorder is to be successfully managed, since scratching leads to new lesions and may cause secondary infection. In addition to the medical regimen, other measures can be taken to prevent or minimize the scratching. Fingernails and toenails need to be cut short, kept clean, and filed frequently to prevent sharp edges. Gloves or cotton stockings can be placed over the hands and pinned to shirtsleeves. One-piece outfits with long sleeves and long pants also decrease direct contact with the skin. If gloves or socks are used, the child needs time to be free from such restrictions. An excellent time to remove gloves, socks, or other protective devices is during the bath or after the child receives sedative or antipruritic medication.

Conditions that increase itching should be eliminated when possible. Woolen clothes or blankets, rough fabrics, and furry stuffed animals should be removed from the child's environment. Because heat and humidity cause perspiration (which intensifies itching), proper dress for climatic conditions is essential. Pruritus is often precipitated by exposure to the irritant effects of certain components of common products such as soaps, detergents, fabric softeners, perfumes, and powders. Most children experience less itching when soft cotton fabrics are worn next to the skin. During cold months, affected children should wear overcoats, hats, gloves, and snowsuits made of synthetic fabrics

(not wool). Exposure to latex products, such as gloves and balloons, should also be avoided.

Preventing infection is usually accomplished by preventing scratching. Baths are given as prescribed, the water kept tepid, and soaps (except as indicated) and bubble baths avoided, along with oils or powders. Skin folds and diaper areas need frequent cleansing with plain water. A room humidifier or vaporizer may benefit children with extremely dry skin. The skin lesions should be examined for signs of infection—usually honey-coloured crusts or pustules with surrounding erythema. Any signs of infection need to be reported to the health care provider.

The family should be given explicit instructions on the preparation and use of soaks, special baths, and topical medications, including the order of application if more than one is prescribed. It is important to emphasize that one thick application of topical medication is *not* equivalent to several thin applications, and that excessive use of a medication (particularly steroids) can be hazardous. If children have difficulty remaining still for a 10- or 15-minute soak, bath, or dressing application, these can be carried out at naptime or when the child is engrossed in watching television, listening to a story, or playing with tub toys.

When a hypoallergenic diet is prescribed, parents need to be given the reason for the diet and the guidelines for avoiding hyperallergenic foods. Consultation with a dietitian is recommended. Because hypoallergenic diets take time before visible effects are apparent, parents need reassurance that results may not be seen immediately.

During acute phases, emotional stress can become intense for the family. They need time to discuss negative feelings and to be reassured that these feelings are normal. They can be referred to psychosocial services if further support is needed. Stress tends to aggravate the severity of the condition. Therefore, efforts to relieve as much anxiety as possible in both the parents and the child have a beneficial emotional and physical effect. Parents should be assured that the disease is not contagious; however, the child may have repeated exacerbations and remissions. Spontaneous and permanent remission takes place at approximately 2 to 3 years of age in most children with the infantile disorder.

Seborrheic Dermatitis

Seborrheic dermatitis is a chronic, recurrent, inflammatory reaction of the skin. It occurs most commonly on the scalp (cradle cap) but may involve the eyelids (blepharitis), external ear canal (otitis externa), nasolabial folds, and inguinal region. The cause is unknown, although it is more common in early infancy, when sebum production is increased. The lesions are characteristically thick, adherent, yellowish, scaly, oily patches that may or may not be mildly pruritic. Unlike AD, seborrheic dermatitis is not associated with a positive family history for allergy and is common in infants shortly after birth and in adolescents after puberty. Diagnosis is made primarily on the basis of the appearance and the location of the crusts or scales.

Nursing Care. Cradle cap may be prevented with adequate scalp hygiene. Frequently, parents omit shampooing the infant's hair for fear of damaging the "soft spots," or fontanels. The nurse should discuss how to shampoo the infant's hair and emphasize that the fontanel is like skin anywhere else on the body—it does not puncture or tear with mild pressure.

When seborrheic lesions are present, the treatment is directed at removing the crusts. Parents should be taught the appropriate procedure to clean the scalp. Education may need to include a demonstration. Shampooing should be done daily with a mild soap or commercial baby shampoo; medicated shampoos are not necessary, but an antiseborrheic shampoo containing sulphur and salicylic acid may be used. Shampoo is applied to the scalp and allowed to remain on the scalp until the crusts soften. Then the scalp is thoroughly rinsed. A fine-tooth comb or a soft facial brush helps remove the loosened crusts from the strands of hair after shampooing.

Acne

Acne vulgaris is the most common skin condition treated during adolescence. Acne is caused by testosterone, a hormone present in males and females that increases during puberty. It stimulates the sebaceous glands of the skin to enlarge and increase in number or produce oil and plug the pores. Whiteheads, blackheads, and pimples are present in teenage acne.

Half of the adolescent population experiences acne by the end of the teenage years. Although the disorder can appear before the age of 10 years, the peak incidence occurs in middle to late adolescence (at age 16 to 17 years in girls and 17 to 18 years in boys). It is more common in boys than in girls. The degree to which an individual is affected may range from nothing more than a few isolated comedones to a severe inflammatory reaction. Some studies have indicated that the earlier the acne is present the worse the acne will be (Canadian Dermatology Association, 2021a). Although the disease is self-limited and not life-threatening, it can have great significance to the adolescent. Health care providers should not underestimate the impact that acne has on teens. Canadian researchers discovered that even having mild acne can create feelings of low self-esteem, depression, and thoughts of self-harm. Acne often coincides with the start of puberty, which can add to feelings of uncertainty about self-image and can contribute to emotional issues (Vallerand et al., 2018).

Numerous factors affect the development and course of acne. Its distribution in families and a high degree of concordance in identical twins suggest hereditary factors. Premenstrual flares of acne occur in nearly 70% of adolescent girls, suggesting a hormonal cause. Studies do not indicate a clear association between stress and acne, but adolescents commonly cite stress as a cause for acne outbreaks. Cosmetics containing lanolin, petrolatum, vegetable oils, lauryl alcohol, butyl stearate, and oleic acid can increase comedone production. Exposure to oils in cooking grease can be a precursor in adolescents who work over fast-food restaurant hot oils. There is no known link between dietary intake and the development or worsening of acne.

Pathophysiology. Contributors to acne development include sebum secretion, abnormal desquamation of follicles, bacterial growth, and inflammation. *Comedogenesis* (formation of comedones) results in a noninflammatory lesion that may be either an *open comedone* ("blackhead") or a *closed comedone* ("whitehead"). Inflammation occurs with the proliferation of *Propionibacterium acnes*, which draws in neutrophils, causing inflammatory papules, pustules, nodules, and cysts.

Therapeutic Management. Successful management of acne depends on a collaborative effort between the health care provider, the adolescent, and the parents. Unlike many other dermatological conditions, acne lesions resolve slowly, and improvement may not be apparent for at least 6 weeks. Individual comedones can take several weeks to months to resolve, and papules and pustules usually resolve in about 1 week. The multifactorial causes of acne necessitate a combined approach for successful treatment. Treatment consists of general measures of care and specific treatments determined by the type of lesions involved.

Improvement of the adolescent's overall health status is part of the general management. Adequate rest, moderate exercise, a well-balanced diet, reduction of emotional stress, and elimination of any foci of infection are all part of general health promotion. Dirt or oil on the surface of the skin does not cause acne. Gentle cleansing with a mild cleanser once

or twice daily is usually sufficient. Antibacterial soaps are ineffective and may be too drying when used in combination with topical acne medications. There is no evidence that preparations containing alcohol or hexachlorophene decrease acne, because surface bacteria are not involved in the pathogenesis (Kim, 2020). For some adolescents hygiene of the hair and scalp appears to be related to the clinical activity of the acne. Acne on the forehead may improve with brushing the hair away from the forehead and more frequent shampooing. Use of any oily creams, cosmetics, and hair products needs to be avoided.

Medications. Treatment success depends on commitment from the adolescent. Before prescribing treatment, the health care provider should determine the adolescent's level of comfort and readiness to begin treatment.

Tretinoin (Retin-A) is the only medication that effectively interrupts the abnormal follicular keratinization that produces microcomedones, the invisible precursors of the visible comedones. Tretinoin alone is usually sufficient for management of comedonal acne (Kim, 2020). Tretinoin is available as a cream, gel, or liquid. This medication can be extremely irritating to the skin and requires careful patient education for optimal usage. The patient should be instructed to begin with a pea-sized dot of medication, which is divided into the three main areas of the face and then gently rubbed into each area. The medication should not be applied for at least 20 to 30 minutes after washing, to decrease the burning sensation. The avoidance of sun and the daily use of sunscreen must be emphasized, since sun exposure can result in severe sunburn. Adolescents should be advised to apply the medication at night and to use a sunscreen with a sun protection factor (SPF) of at least 15 in the daytime. Topical *benzoyl peroxide* is an antibacterial medication that inhibits the growth of *P. acnes* organisms. It is effective against both inflammatory and noninflammatory acne and is an effective first-line agent. This medication is available as a cream, lotion, gel, or wash. The patient should be informed that the medication may have a bleaching effect on sheets, bedclothes, and towels. The adolescent can be reassured that skin bleaching will not occur. Accommodation to the medication can be gained with a gradual increase in the strength and frequency of application.

When inflammatory lesions accompany the comedones, a *topical antibacterial medication* may be prescribed. These agents are used to prevent new lesions and to treat pre-existing acne. Clindamycin, erythromycin, metronidazole, and azelaic acid and the combination of either benzoyl peroxide and erythromycin or benzoyl peroxide and glycolic acid are all choices for topical antibacterial therapy. The combination of 5% benzoyl peroxide and 3% erythromycin are especially beneficial, although the exact mechanism of the action is not known (Kim, 2020). *Systemic antibiotic therapy* is used when moderate to severe acne does not respond to topical treatments. Oral antibiotics such as tetracycline, erythromycin, minocycline, and doxycycline are considered safe to use (Kim, 2020). A gel combining 0.25% tretinoin and 1.2% clindamycin phosphate is more effective in treating acne than tretinoin or clindamycin alone (Kim, 2020).

Young women with mild to moderate acne may respond well to topical treatment and the addition of an *oral contraceptive pill (OCP)*. OCPs reduce the endogenous androgen production and decrease the bioavailability of the woman's circulating androgens. Both of these actions result in decreased acne.

Isotretinoin, 13-cis-retinoic acid (Accutane), is a potent and effective oral medication that is reserved for severe cystic acne that has not responded to other treatments. Isotretinoin is the only agent available that affects factors involved in the development of acne. However, treatment with isotretinoin should be managed only by a dermatologist. Adolescents with multiple, active, deep dermal or subcutaneous cystic and nodular acne lesions are treated for 20 weeks. Multiple adverse effects can occur, including dry skin and mucous membranes, nasal irritation, dry eyes, decreased night vision, photosensitivity, arthralgia, headaches, mood changes, aggressive or violent behaviours, depression, and suicidal ideation. Adolescents taking this medication should be monitored for depression, depressive symptoms, and suicidal ideation (Kim, 2020). The medication should be given only at the recommended doses for no longer than the recommended duration. The most significant adverse effects of this medication are the teratogenic effects on a fetus. Isotretinoin is absolutely contraindicated in pregnant patients. Health Canada has instituted a pregnancy prevention program for users of isotretinoin that requires patients' written consent, two negative pregnancy tests before starting treatment, monthly tests during treatment and 1 month after stopping, and the use of two reliable methods of birth control through this period (Government of Canada, 2016). Patients receiving isotretinoin should also be monitored for elevated liver enzymes and cholesterol and triglyceride levels. Significant elevation may require discontinuation of the medication.

Nursing Care. Because acne is a common skin condition and its appearance may seem mild, the health care provider may underestimate the relative importance of the disease to the adolescent. The nurse should assess the individual adolescent's level of distress, current management, and perceived success of any regimen before initiating a referral. If adolescents do not perceive the acne to be a concern, they may lack motivation to follow the treatment plan.

The nurse can provide ongoing support for the adolescent when a treatment plan is initiated. The family is also encouraged to support the adolescent in the adolescent's efforts. Use of medications and basic skin care information should be discussed in detail with the adolescent. Written instructions should accompany the verbal discussion. Information that dispels myths regarding the use of abrasive cleansing products can prevent unnecessary costs and trauma to the skin.

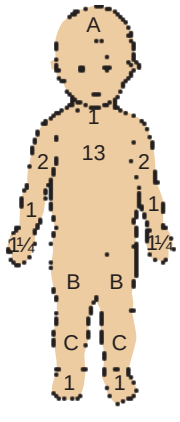
Teenagers need education about the factors that aggravate and damage the skin, such as too vigorous scrubbing. In addition, picking, squeezing, and manual expression with fingernails break down the ductal walls of lesions and cause the acne to worsen. Mechanical irritation, such as vinyl helmet straps that rub areas predisposed to acne, can also cause the development of lesions.

THERMAL INJURY

Burns

Burn injuries are usually attributed to extreme heat sources but may also result from exposure to cold, chemicals, electricity, or radiation. Most burns are relatively minor and do not require definitive medical treatment. However, burns involving a large body surface area, critical body parts, or the older-person or pediatric population often benefit from treatment in specialized burn centres.

In 2013, in 17 of the larger emergency departments in Canada, 1 682 individuals with burn injuries were identified, which represented 1.2% of all reported injuries; of these, 708 were in children and adolescents (Crain et al., 2017). Overall, boys and children under 5 years of age had the highest risk of burn injuries. In Canada, over time, there has been a significant reduction in burn injuries. This decrease is likely due to burn safety programs and improved burn treatments and hospital admission protocols.

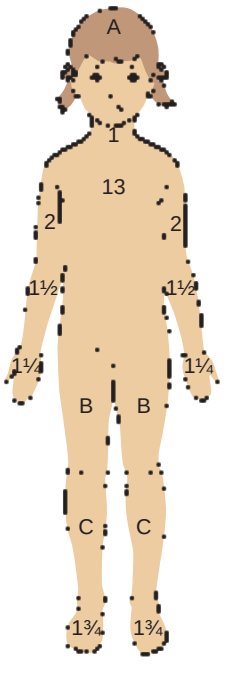


Younger children comprise a higher proportion of scalds and contact burns, which may be related to social and biological risk factors such as spending more time at home (where most burns occur) and having younger, thinner skin, which is more prone to burning

(Crain et al., 2017). In an eastern Ontario study, researchers reported that children living in rural areas sustained more burn wounds from exposure to flames and contact with hot surfaces compared to children from urban areas, for whom exposure to hot liquids was the main cause of burns (Garland et al., 2018). Indigenous children have higher rates of burn injuries, although adequate data tracking and collection are lacking on this issue. Children who live on reserve have an increased risk of death from fire because there tends to be a higher proportion of smokers in the home, housing is substandard and wood-framed, wood stoves are used for heating, working smoke detectors are underused, fire rescue equipment and personnel have long distances to travel, and trained firefighters are in short supply (Banerji & CPS, First Nations, Inuit, and Metis Health Committee, 2012/2020).

Characteristics of Burn Injury. The extent of tissue destruction in burns is determined by the intensity of the heat source, the duration of contact or exposure, the conductivity of the tissue involved, and the rate at which the heat energy is dissipated by the skin. A brief exposure to high-intensity heat from a flame can produce burn injuries similar to those induced by long exposure to less intense heat in hot water. The physiological responses, therapy, prognosis, and disposition of the injured child are all directly related to the *amount of tissue destroyed*. Therefore, the severity of the burn injury is assessed on the basis of the percentage of *total body surface area (TBSA)* burned and the *depth* of the burn. Among children in the school-age group or younger age groups, a burn that is 10% of TBSA can be life-threatening if not treated correctly. Other important factors in determining the seriousness of the injury are the location of the wounds, the child's age and general health, the causative agent, the presence of respiratory involvement, and any associated injury or condition.

Type of injury. Most burns result from contact with thermal agents such as a flame, hot surfaces, or hot liquids. Among young children there is a high incidence of electrical injuries caused by household current as these children may insert conductive objects into electrical outlets and bite or suck on connected electrical cords. Direct contact with high- or low-voltage current is the most frequent mechanism of injury. Such contact can also occur in lightning strikes. The resistance of the tissue and the path of the electric current are responsible for the damage incurred. Electric current travels through the body following the path of least resistance, which involves the tissues, fluid, blood vessels, and nerves. A more localized burn is produced if skin resistance is high at the area of contact, and a more systemic pattern of injury is produced if skin resistance is low. Often compared with a crush injury, serious electrical trauma results from current passing through vital organs, muscle compartments, and nerve or vascular pathways. Loss of limbs, cardiac fibrillation, respiratory collapse, and burns are common occurrences after exposure to electrical energy. Criteria for hospital admission include a history of loss of consciousness, electrocardiographic (ECG) changes, 10% TBSA affected, or the need for monitoring an affected extremity. Cardiac monitoring is included in standard burn care when ECG changes are identified on admission.



Chemical burns are seen in the pediatric population and can cause extensive injury. The severity of injury is related to the chemical agent (acid, alkali, or organic compound) involved and the duration of contact. The mechanism of injury differs from that in other burns in that there is a chemical disruption and alteration of the physical properties of the exposed body area. Noxious agents exist in many cleaning products commonly found in the home. In addition to concern for localized damage, the potential for systemic toxicity must be addressed. Of particular concern is the exposure of the eyes to chemical agents, the ingestion of caustic substances, and inhalation of toxic gases produced from chemicals.

RELATIVE PERCENTAGES OF AREAS AFFECTED BY GROWTH

A

AREA	BIRTH	AGE 1 YR	AGE 5 YR
A = ½ of head	9½	8½	6½
B = ½ of one thigh	2¾	3¼	4
C = ½ of one leg	2½	2½	2¾

RELATIVE PERCENTAGES OF AREAS AFFECTED BY GROWTH

B = ½ of one thigh	4½	4½	4¾
C = ½ of one leg	3	3¼	3½

Fig. 52.14 Estimation of distribution of burns in children. **A:** Children from birth to age 5 years. **B:** Older children.

Extent of injury. The extent of a burn is expressed as a percentage of the TBSA. This is most accurately estimated by using specially designed age-related charts (Figure 52.14). It is more efficient to use a chart designed to assign body proportions to children of different ages.

Depth of injury. A thermal injury is a three-dimensional wound that is also assessed in relation to depth of injury. Traditionally the terms *first-*, *second-*, and *third-degree* have been used to describe the

		Wound Appearance	Wound Sensation	Course of Healing
Partial-Thickness Burn	1st Degree	Epidermis remains intact and without blisters Erythema; skin blanches with pressure	Painful	Discomfort lasts 48–72 hours. Desquamation occurs in 3–7 days.
Partial-Thickness Burn	2nd Degree	Wet, shiny, weeping surface Blisters Wound blanches with pressure	Painful Very sensitive to touch, air currents	Superficial partial-thickness burn heals in <21 days. Deep partial-thickness burn requires >21 days for healing. Healing rates vary with burn depth and presence or absence of infection.
Full-Thickness Burn	3rd Degree	Colour variable (i.e., deep red, white, black, brown) Surface dry Thrombosed vessels visible No blanching	Insensate (↓ pinprick sensation)	Autografting is required for healing.
Full-Thickness Burn	4th Degree	Colour variable Charring visible in deepest areas Extremity movement limited	Insensate	Amputation of extremities is likely. Autografting is required for healing.

Fig. 52.15 Classification of burn depth according to depth of injury. (From Black, J. M. [2008]. *Medical-surgical nursing: Clinical management for positive outcomes* [8th ed.]. Saunders.)

depth of tissue injury. However, with the current emphasis on wound healing, these have been replaced by more descriptive terms based on the extent of destruction to the epithelializing elements of the skin (Figure 52.15).

Superficial burns (*first degree*) are usually of minor significance. With these burns, there is often a latent period followed by erythema (Figure 52.16). Tissue damage is minimal, the protective functions of the skin remain intact, and systemic effects are rare. Pain is the predominant symptom, and the burn heals in 5 to 10 days without scarring. A mild sunburn is an example of a superficial burn.

Partial-thickness burns (second degree) involve the epidermis and varying degrees of the dermis. These wounds are painful, moist, red, and blistered. Superficial partial-thickness burns involve the epidermis and part of the dermis. Dermal elements are intact, and the wound should heal in approximately 14 to 21 days with variable amounts of scarring. The wound is extremely sensitive to temperature changes, exposure to air, and light touch. Although classified as partial-thickness burns, deep dermal burns resemble full-thickness injuries in many respects except that sweat glands and hair follicles remain intact. The burn may appear mottled, with pink, red, or waxy white areas exhibiting blisters and edema formation. Systemic effects are similar to those encountered with full-thickness burns. Although many of these wounds heal spontaneously, healing time may extend beyond 21 days. These burn wounds often heal with extensive scarring.

Full-thickness burns (third degree) are serious injuries that involve the entire epidermis and dermis and extend into subcutaneous tissue (see Figure 52.15). Nerve endings, sweat glands, and hair follicles are destroyed. The burn varies in colour from red to tan, waxy white, brown, or black and is distinguished by a dry, leathery appearance (Figure 52.17). Normally, full-thickness burns lack sensation in the area of injury because of the destruction of nerve endings. However, most full-thickness burns have superficial and partial-thickness burned areas at the periphery of the burn, where nerve endings are intact and exposed. Excised **eschar** and donor sites also cause exposed nerve fibres. As the peripheral fibres regenerate, painful sensations return.

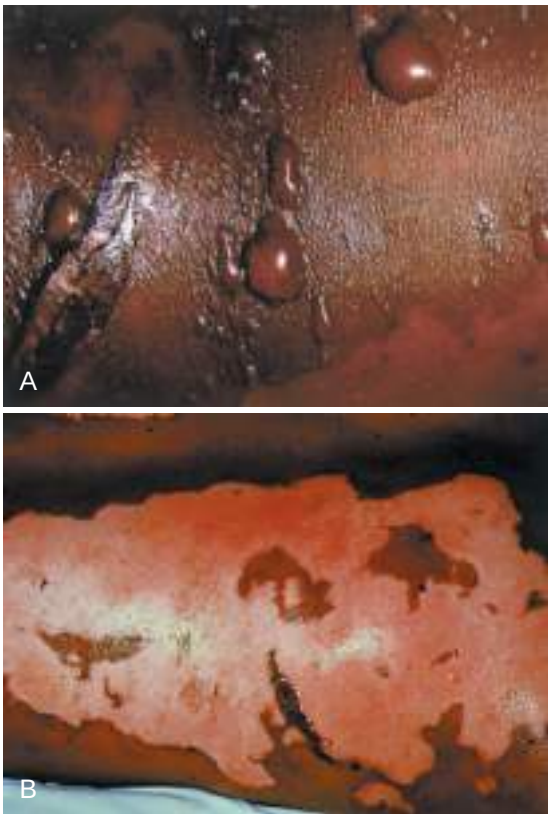

Fig. 52.16 Superficial burns on a Black child. **A:** Blisters intact. **B:** Blisters removed. (Courtesy Hillcrest Medical Center, Tulsa, OK.)

Consequently, children often experience severe pain related to the size and depth of the burn. Full-thickness wounds are not capable of re-epithelialization and require surgical excision and grafting to close the wound.

Fig. 52.17 Bottom to top: Deep partial-thickness burn (red area); full-thickness burn (white area); full-thickness burn with eschar (brown area). (Courtesy Hillcrest Medical Center, Tulsa, OK.)

Fourth-degree burns are full-thickness injuries that involve underlying structures such as muscle, fascia, and bone. The wound appears dull and dry, and ligaments, tendons, and bone may be exposed (Figure 52.18).

Severity of injury. Burns are classified as minor, moderate, or major, which is useful in determining the disposition of the patient for treatment. Burn patients are categorized as (1) those with a *major burn injury*, who require the services and facilities of a specialized burn centre; (2) those with a *moderate burn*, who may be treated in a hospital with expertise in burn care; and (3) those with *minor injuries*, who may be treated on an outpatient basis. The extent and depth of the burn, the causative agent, the body area involved, the patient's age, and concomitant injuries and illnesses determine the severity of the injury.

As the skin of infants is so thin, it is likely to sustain deeper injuries than those of older children. Children younger than 2 years of age, especially 6 months or younger, have a significantly higher mortality rate than that of older children with burns of similar magnitude. Acute or chronic illnesses or superimposed injuries also complicate burn care and response to treatment.

Fig. 52.18 Full-thickness burn with muscle and fascia involved. (Courtesy Hillcrest Medical Center, Tulsa, OK.)

Inhalation injury. Trauma to the tracheobronchial tree often follows inhalation of the heated gases and toxic chemicals produced during combustion. Although direct thermal injury to the upper airway may occur, heat damage below the vocal cords is rare. Inspired heated air is cooled in the upper airway before reaching the trachea. Reflex closure of the cords and laryngospasm also prevent full inhalation. However, evidence of direct thermal injury to the upper airway includes burns of the face and lips, singed nasal hairs, and laryngeal edema. Clinical manifestations may be delayed as long as 24 to 48 hours. Wheezing, increasing secretions, hoarseness, wet crackles, and carbonaceous secretions are signs of respiratory tract involvement. Upper airway obstruction is often associated with burn shock and fluid resuscitation. In such situations, endotracheal intubation may also be necessary to preserve a patent airway.

Inhalation of carbon monoxide is suspected when the injury has occurred in an enclosed space. Mucosal erythema and edema followed by sloughing of the mucosa are manifestations of respiratory tract injury. A mucopurulent membrane replaces the mucosal lining and seriously compromises respiration and ventilation. A significant increase in mortality has been observed when inhalation injury and pneumonia are both present. Deep burns, especially those encircling the thorax, may cause restriction of chest excursion as a result of edema and inelastic eschar formation. Young children are particularly at risk because of the pliability of the skeletal structure.

Pathophysiology. Thermal injuries produce both local and systemic effects that are related to the extent of tissue destruction. In superficial burns the tissue damage is minimal. In partial-thickness burns there is considerable edema and more severe capillary damage. With a major burn greater than 30% TBSA, there is a systemic response involving an increase in capillary permeability, allowing plasma proteins, fluids, and electrolytes to be lost. Maximum edema formation in a small wound occurs about 8 to 12 hours after injury. After a larger injury, hypovolemia, associated with this phenomenon, will slow the rate of edema formation, with maximum effect at 18 to 24 hours.

Another systemic response is anemia, caused by direct heat destruction of red blood cells (RBCs), hemolysis of injured RBCs, and trapping of RBCs in the microvascular thrombi of damaged cells. A long-term decrease in the number of RBCs may occur as a result of increased RBC fragility. Initially there is increased blood flow to the heart, brain, and kidneys, with decreased blood flow to the gastrointestinal tract. There is an increase in metabolism to maintain body heat, providing for the body's increased energy needs.

Complications. Thermally injured children are subject to a number of serious complications, both from the wound and from systemic alterations resulting from the injury. The immediate threat to life is related to airway compromise and profound shock. During healing, infection—both local and systemic sepsis—is the primary complication. Mortality associated with thermal trauma in children increases with the severity of injury and decreases as age advances.

A less apparent respiratory tract injury is inhalation of carbon monoxide. Carbon monoxide has a greater affinity for hemoglobin than does oxygen, thereby depriving peripheral tissues and oxygen-dependent organs (such as the heart and brain) of the oxygen needed for survival. Treatment is with 100% oxygen, which reverses the situation rapidly.

Pulmonary issues are a major cause of fatality in children with either thermal burns or complications in the respiratory tract. In the early stages after a burn, most respiratory infections result from health care–acquired exposure, immobility, and abdominal distension. Respiratory conditions include inhalation injuries, aspiration in unconscious

patients, bacterial pneumonia, pulmonary edema, pulmonary embolus, post-traumatic pulmonary insufficiency, and atelectasis.

A less common complication is pulmonary edema resulting from fluid overload or acute respiratory distress syndrome (ARDS) in association with Gram-negative sepsis. ARDS results from pulmonary capillary damage and leakage of fluid into the interstitial spaces of the lung. A loss of adherence to and interference with oxygenation are the consequences of pulmonary insufficiency in conjunction with systemic sepsis.

Sepsis is a critical concern in the treatment of burns and an ever-present threat following the shock phase. Decreased level of consciousness and lethargy are early signs of sepsis. Initially, burn wounds are relatively pathogen free unless they are contaminated with potentially infectious material, such as dirt or polluted water. However, dead tissue and exudate provide a fertile field for bacterial growth. On approximately the third postburn day, early colonization of the wound surface by a preponderance of Gram-positive organisms (primarily staphylococci) changes to predominantly Gram-negative opportunistic organisms, particularly *Pseudomonas aeruginosa*. By the fifth postburn day, bacterial invasion is well under way beneath the surface of the burn wound. Early surgical excision of eschar together with placement of autografts reduces the incidence of sepsis.

Therapeutic Management.

Emergency care. The initial management of the burn patient begins at the scene of injury. The first priority is to stop the burning process (see Emergency box: Burns). The child should then be transported immediately to the nearest medical facility for treatment and evaluation. The child and the family are usually extremely frightened and anxious; sensitivity to their emotional state and reassurance should be provided during the transport process.

EMERGENCY

Burns

Minor Burns

Stop the burning process:
- Apply cool water to the burn or hold the burned area under cool running water.
- Do not use ice.

Do not disturb any blisters that form, unless the injury is from a chemical substance.
Do not apply anything to the wound.
Cover with a clean cloth if there is risk of damage or contamination.
Remove burned clothing and jewellery.

Major Burns

Stop the burning process:
- Flame burns—smother the fire.
- Place victim in the horizontal position.
- Roll victim in a blanket or similar object; avoid covering the head.

Assess for an adequate airway and breathing.
If child is not breathing, begin mouth-to-mouth resuscitation.
Remove burned clothing and jewellery.
Cover wound with a clean cloth.
Keep victim warm.
Transport to medical aid.
Begin intravenous and oxygen therapy as prescribed.

Major burns with large amounts of denuded skin should not be cooled. Heat is rapidly lost from burned areas, and additional cooling leads to a drop in core body temperature and potential circulatory collapse. Wet dressings also promote vasoconstriction because of cooling, resulting in impaired circulation to the burned area and increased tissue damage. Chemical burns require continuous flushing with large amounts of water before transport to a medical facility. The use of neutralizing agents on the skin is contraindicated, since a chemical reaction is initiated and further injury may result. If the chemical is in powder form, the addition of water may spread the caustic agent. The powder should be brushed off if possible before flushing the area.

Assess the victim's condition. As soon as the flames are extinguished, the child is assessed. Circulation, airway, and breathing (CAB) are the primary concerns. Cardiopulmonary complications may result from exposure to electric current, inhalation of toxic fumes and smoke, hypovolemia, and shock. Emergency measures are instituted as appropriate.

Cover the burn. The burn wound should be covered with a clean cloth to prevent contamination, decrease pain by eliminating air contact, and prevent hypothermia. No attempt should be made to treat the burn. Application of topical ointments, oils, or other home remedies is contraindicated.

Transport the child to medical aid. The child with an extensive burn is not given anything by mouth, to avoid aspiration in the presence of paralytic ileus and upper airway edema and to prevent water intoxication. The child is transported to the nearest medical facility. If this cannot be accomplished within a relatively short period, intravenous (IV) access should be established, if possible, with a large-bore catheter. Oxygen is administered, if available, at 100%. A report of the initial assessment and any interventions implemented is given to the medical facility assuming care of the child.

Provide reassurance. Providing reassurance and psychological support to both the family and the child helps immeasurably during the period of postinjury crisis. Reducing anxiety conserves energy the family and child will need to cope with the physiological and emotional stress of injury.

Minor burns. Treatment of burns classified as minor can usually be managed adequately on an outpatient basis when it is determined that the parent is able to carry out instructions for care and observation. Patients with less than optimum circumstances may require close follow-up to ensure they are able to manage the treatment.

The wound is cleansed with a mild soap and tepid water. **Debridement** of the wound includes removal of any embedded debris, chemicals, and devitalized tissue. Removal of intact blisters remains controversial. Some authorities argue that blisters provide a barrier against infection; others maintain that blister fluid is an effective medium for the growth of microorganisms. However, blisters should be broken if the injury is due to a chemical agent to control absorption. Most health care providers favour covering the wound with an antimicrobial ointment to reduce the risk of infection and to provide some form of pain relief. The dressing consists of nonadherent fine-mesh gauze placed over the ointment and a light wrap of gauze dressing that avoids interference with movement. This helps keep the wound clean and protect it from trauma. The caregiver is instructed to wash the wound, reapply the dressing, and return the child to the office or clinic as directed for wound observation. The frequency of dressing changes may vary from every other day to once a day.

Some health care providers prefer an occlusive dressing, such as a hydrocolloid, which is placed over the wound after cleansing. Hydrogel dressings, which are soothing and nonadherent, may also be used. The dressing is changed when leakage occurs—at regular intervals or at least weekly. This method eliminates the discomfort associated with frequent dressing changes but impairs visualization of the wound surface.

If there is a high probability of infection or other complications or if there is difficulty in carrying out instructions, the caregiver may be directed to bring the patient in daily for dressing changes and inspection. Another option is to have a nurse make a home visit to inspect the wound and perform the dressing change. Frequent removal of the dressing is an effective mode of debridement. Soaking the dressing in tepid water or normal saline before removal helps loosen the dressing and debris and reduce discomfort. Burns of the face are usually treated by an open method. The wound is washed and debrided in the same manner, and a thin film of antimicrobial ointment is applied.

A tetanus history is obtained on admission. If there is no history of immunization, or if more than 5 years have passed since the last immunization, tetanus prophylaxis is administered. A mild analgesic such as acetaminophen is usually sufficient to relieve discomfort; the antipyretic effect of the medication also alleviates the sensation of heat.

Most minor burns heal without difficulty, but if the wound margin becomes erythematous, gross purulence is noted, or the child develops evidence of systemic reaction, such as fever or tachycardia, hospitalization is indicated. The child should also be evaluated for functional impairment, and the caregiver should be instructed in the exercise and ambulation program. After wound healing, an evaluation of scar maturation and range of motion will indicate any need for further therapy.

Major burns. The first priority is airway maintenance. Respiratory burns or the inhalation of noxious agents are suggested when there is a history of injury in an enclosed space; edema of the oral and nasal membranes; thermal injury to the face, nares, and upper torso; hyperemia; and blisters or evidence of trauma to the upper respiratory passages. When respiratory involvement is suspected or evident, 100% oxygen is administered and blood gas values, including carbon monoxide levels, are determined.

If the child exhibits changes in sensorium, air hunger, or other signs of respiratory distress, an endotracheal tube is inserted to maintain the airway. When severe edema of the face and neck is anticipated, intubation is performed before swelling makes intubation difficult or impossible. Controlled intubation is preferred to an emergency procedure. Intubation allows for the delivery of humidified oxygen, the removal of secretions from respiratory passages, and the provision of ventilatory support. When full-thickness burns encircle the chest, constricting eschar may limit chest wall excursion, and ventilation of the child becomes more difficult. Escharotomy of the chest relieves this constriction and improves ventilation.

Fluid replacement therapy. The objectives of fluid therapy are to (1) compensate for water and sodium lost to traumatized areas and interstitial spaces, (2) re-establish sodium balance, (3) restore circulating volume, (4) provide adequate perfusion, (5) correct acidosis, and (6) improve renal function.

Fluid replacement is required during the first 24 hours because of fluid shifts that occur after the injury. Various formulas are used to calculate fluid needs, and the one adopted depends on health care provider preference. Crystalloid solutions are used during this initial phase of therapy. Parameters such as vital signs (especially heart rate), urine output, adequacy of capillary filling, and state of sensorium determine adequacy of fluid resuscitation.

After the initial 24-hour period, theoretically there is a capillary seal, and capillary permeability is restored. Colloid solutions such as albumin, Plasma-Lyte, or fresh frozen plasma are useful in maintaining plasma volume. However, children with burn injuries usually require fluids in excess of their calculated maintenance and replacement volume. Reasons for this may include underestimation of burn size (particularly in pediatric patients), pulmonary injury that sequesters resuscitation fluid in the lung, electrical injury with greater tissue destruction than what is visible, and a delay in the initiation of fluid resuscitation. Irreversible burn shock that persists despite aggressive fluid resuscitation remains a significant cause of death in the immediate postburn period. Fluid balance may continue to be a concern throughout the course of treatment, especially when there is considerable evaporative loss from the wound.

Nutrition. The enhanced metabolic requirements and catabolism in children with severe burns make nutritional needs of paramount importance and often difficult to satisfy. To avoid protein breakdown, the diet must provide sufficient calories to meet the increased metabolic needs and enough protein. Hypoglycemia can result from the stress of the burn injury because the liver glycogen stores are rapidly depleted.

A high-protein, high-calorie diet is encouraged. Many children have poor appetites and are unable to meet energy requirements solely by oral feeding. Oral feedings are encouraged unless the child is intubated or has a paralytic ileus. Most children with burns in excess of 25% TBSA require supplementation with tube feeding. Early and continued nutritional support is an important part of therapy for seriously burned patients. Enteral feeding provides direct nourishment to the gastrointestinal tract and helps reverse the defective gut barrier that accompanies burn shock (Antoon, 2020). Children who require enteral supplementation must be monitored for feeding intolerance and tube malposition. The nurse should also monitor and report any abdominal distension, diarrhea, or electrolyte, and metabolic deviations. If nutritional requirements cannot be met entirely by the enteral route, parenteral hyperalimentation is used to supplement intake. However, enteral feeding increases blood flow in the intestinal tract, preserves gastrointestinal function, and minimizes bacterial translocation by decreasing mucosal atrophy of the intestines. These factors make enteral feeding the preferred route of nutritional support.

To facilitate growth and proliferation of epithelial cells, the administration of vitamins A and C is begun early in the postburn period. Zinc is also supplemented because of its important role in wound healing and epithelialization.

Medications. Antibiotics are usually not administered prophylactically. The administration of systemic antibiotics to control wound colonization is not indicated, since decreased circulation to the injured area prevents delivery of the medication to areas of deepest injury. Surveillance cultures and monitoring of the clinical course provide the most reliable indicators of developing infection. Appropriate antibiotics are instituted to treat the specific identified organism. Otitis media should not be overlooked as a source of fever in the pediatric population.

Some form of sedation and analgesia is required in the care of burned children. Fentanyl or alfentanil has a major advantage over morphine because of the short duration. Fentanyl can prevent oversedation after the procedure. For less painful procedures, premedication with oral morphine, oral ketamine, or milder opioids 15 minutes before the procedure may be sufficient. See discussion of management of burn pain in Chapter 34. Dosage monitoring is important because tolerance to opioids may develop. Analgesics are most effective when they are administered just before the onset of procedural pain.

The use of short-acting anaesthetic agents, such as propofol (Diprivan) and nitrous oxide, has proved beneficial in eliminating procedural pain. Pharyngeal reflexes remain intact, thus ensuring a patent airway. For any conscious or unconscious sedation, the child must be monitored continuously during the procedure (see Preoperative Care, Chapter 44, and Procedural Sedation and Analgesia, Chapter 34).

Management of the burn wound. After the initial period of shock and the restoration of fluid balance, the primary concern is the burn wound. The objectives of wound management include prevention of infection, removal of devitalized tissue, and closure of the wound.

The application of dressings and topical antimicrobial therapy reduce pain by minimizing the exposure to air.

Primary excision. In children with large, full-thickness burn wounds, excision is performed as soon as the patient is hemodynamically stable after initial resuscitation. Because the burn wound precipitates an exaggerated physiological response, many complications do not resolve until the eschar is excised and the wound is closed. Early excision of deep partial- and full-thickness burns reduces the incidence of infection and the threat of sepsis.

Debridement. Partial-thickness wounds require debridement of devitalized tissue to promote healing. Debridement is painful and requires analgesia and a sedative before the procedure. Medications given for pain need to be readily available during this procedure and may need to be titrated upward during the procedure. Hydroxyzine and diphenhydramine are often needed for itching that occurs after whirlpool and debridement. The itching becomes particularly bothersome as the burns heal.

Hydrotherapy is employed to cleanse the wound and involves soaking in a tub or showering at least once a day for no more than 20 minutes. The water loosens and removes sloughing tissue, exudate, and topical medications. Hydrotherapy helps to cleanse not only the wound but also the entire body and aids in maintenance of range of motion. Mesh gauze entraps the exudative slough and is readily removed during hydrotherapy. Any loose tissue is carefully trimmed away before the wound is redressed.

Topical antimicrobial medications. Methods used for managing the burn wound include the following:

Exposure—Wounds are left open to air; crust forms on partial-thickness wounds, and eschar forms on full-thickness burns.

Open—Topical antimicrobial medication is applied directly to the wound surface and the wound is left uncovered.

Modified—Antimicrobial medication is applied directly or impregnated into thin gauze and applied to the wound; gauze or net secures the area.

Occlusive—Antimicrobial medication is impregnated in gauze or applied directly to the wound; multiple layers of bulky gauze are placed over the primary layer and secured with gauze or net.

All of these methods provide wound coverage and employ some type of topical agent. Topical medications do not eliminate organisms from the wound but can effectively inhibit bacterial growth. To be effective, a topical application must be nontoxic, capable of diffusing through eschar, harmless to viable tissue, inexpensive, and easy to apply. A topical ointment should not encourage the development of resistant strains of bacteria and should produce minimal electrolyte derangement. Some topical agents are packaged and prepared on a fine-meshed gauze that allows ease of application. The gauze provides necessary protection for the wound, maximizes patient comfort, increases rate of healing, decreases the necessity for frequent dressing changes, and is cost effective. Examples include a nanocrystalline film of pure silver (Acticoat), a hydrofibre with ionic silver (Aquacel Ag), a flexible nylon mesh matrix with oat-beta glucan and silver (Glucan Silver Matrix), and a silicone foam dressing with silver (Mepilex Ag).

Biological skin coverings. Permanent coverage of extensive burns is a prolonged process that requires repeated operative procedures using general anaesthesia for atraumatic care in debridement and grafting. Early closure shortens the period of metabolic stress and decreases the likelihood of burn wound sepsis. In the acute phase, biological dressings cover and protect the wound from contamination, reduce fluid and protein loss, increase the rate of epithelialization, reduce pain, and facilitate movement of joints to retain range of motion.

Allograft (homograft) skin is obtained from human cadavers that are screened for communicable diseases. Allograft is particularly useful in the coverage of surgically excised deep partial- and full-thickness wounds in extensive burns when available donor sites are limited. Severe immunosuppression occurs in massively burned children, and the allograft becomes adherent. The allograft can remain in place until suitable donor sites become available. Typically, rejection is seen approximately 3 to 4 weeks after application (Antoon, 2020). The insufficient availability of tissue banks and suitable donors limits the use of allografts.

Xenograft from a variety of species, most notably pigs, is commercially available. In large burns, the porcine xenograft is commonly applied when extensive early debridement is indicated to cover a partial-thickness burn; this provides a temporary covering for the wound until an available autograft can be applied to the full-thickness areas (Antoon, 2020). Pigskin dressings are replaced every 1 to 3 days. They are particularly effective in children with partial-thickness scald burns of the hands and face because they allow relatively pain-free movement, which reduces contracture formation and has the added benefit of improving appetite and morale.

When applied early to a superficial partial-thickness injury, biological dressings stimulate epithelial growth and faster wound healing. However, biological dressings must be applied to clean wounds. If the dressing covers areas of heavy microbial contamination, infection occurs beneath the dressing. In the case of partial-thickness burns, such infection may convert the wound to a full-thickness injury.

Synthetic skin coverings are available for the management of partial-thickness burn wounds. Ideally, the dressing should provide the properties of human skin: adherence, elasticity, durability, and hemostasis. Synthetic skin substitutes are readily available, have an indefinite shelf life, and are relatively inexpensive. Synthetic dressings are composed of a variety of materials and can be used successfully in the management of superficial partial-thickness burns and donor sites. Examples include adherent elastic films, hydroactive materials, and colloidal suspensions that are usually permeable to air, vapour, and fluids.

Biobrane is a flexible silicone-nylon membrane bonded to collagenous peptides of porcine skin. Calcium alginate is another treatment for donor sites. As with biological dressings, it is important that the wound be free of debris before the dressing is applied. Body temperature elevation or evidence of purulence, erythema, or cellulitis around the wound edges may indicate that the wound has become infected beneath the dressing. If this occurs, prompt discontinuance of the synthetic dressing is indicated. All synthetic dressings are reputed to hasten wound healing and reduce discomfort.

Permanent skin coverings. Permanent coverage of deep partial- and full-thickness burns is usually accomplished with a split-thickness skin graft. This graft consists of the epidermis and a portion of the dermis removed from an intact area of skin by a special instrument, the *dermatome* (Figure 52.19). With extensive burns it is often difficult to find enough viable skin to cover the wounds; therefore, available donor sites and special techniques are used. Split-thickness skin grafts may be sheet graft or mesh graft.

Sheet graft. A sheet of skin, removed from the donor site, is placed intact over the recipient site and sutured in place; this is used in areas where cosmetic results are most visible (Figure 52.20).

Mesh graft. A sheet of skin is removed from the donor site and passed through a mesher, which produces tiny slits in the skin that allow the skin to cover 1.5 to 9 times the area of the sheet graft; this results in a less desirable cosmetic and functional outcome (Figure 52.21).

The donor site is dressed with synthetic wound coverings or fine-mesh gauze until the dressing separates at 10 to 14 days, when the wound is healed. Dressings are not changed on donor sites to avoid damage to newly healed, delicate epithelium. Healed donor sites are

Fig. 52.19 Removal of split-thickness skin graft with a dermatome.

Fig. 52.20 Sheet graft.

Fig. 52.21 Mesh graft.

available for reharvesting in patients with extensive burns and limited undamaged skin, but the quality of skin is decreased when multiple grafts are taken.

Artificial skin. The development of Integra, a product that allows the dermis to regenerate, has produced significant improvement in burn wound healing and decreased scar formation. It is applied to partial- and full-thickness burns. The two-layer membrane is made of collagen (a fibrous protein from animal tendons and cartilage) and silicone rubber (i.e., Silastic). The Silastic layer is peeled off after the dermis is formed. The application of artificial skin does not replace the grafting procedure, but it prepares the burn wound to accept an ultrathin autograft. Advantages include faster healing of the burn wound when integrity of the dermis is restored, faster healing of donor sites with the use of ultrathin grafts, and restoration of sweat glands and hair follicles. A disadvantage is its high cost.

Cultured epithelium. When burns are extensive and donor sites for split-thickness skin grafting are limited, it is possible to culture cells from a full-thickness skin biopsy and produce coherent sheets that can be applied to clean, excised full-thickness wounds. Epithelial cell culture grafts offer the possibility of an unlimited source of autograph in patients with extensive burns. Cultured epithelial auto grafts are effective in early wound closure. The child's own skin is fractionated and cultured in a porcine media to form a thin epithelial layer that is applied to the burn wound. This technique offers an improved rate of survival in patients with extensive burns and limited donor sites.

Prognosis. Children differ from adults in their responses to thermal injury, and the mortality rates in young children are significantly higher than those in older children and adults. Mortality is greatest for children younger than 48 months of age. Many children who do survive have long-term functional and cosmetic impairments.

Nursing Care. Because the care of burned children encompasses a broad range of skills, nursing care has been divided into segments that correspond with the major phases of burn treatment. The *acute phase*, also referred to as the *emergent* or *resuscitative phase*, involves the first 24 to 48 hours of care. The *management phase* extends from the completion of adequate resuscitation through wound coverage. The *rehabilitative phase* begins once the majority of the wounds have healed and rehabilitation has become the predominant focus of the care plan. This phase continues until all reconstructive procedures and corrective measures are accomplished (often a period of months or years).

Acute phase. The primary emphasis during the emergent phase is the treatment of burn shock and the management of pulmonary status. Monitoring of vital signs, output, fluid infusion, and respiratory parameters is ongoing in the hours immediately after injury. IV infusion is begun immediately and is regulated to maintain a urine output of at least 1 to 2 mL/kg in children weighing less than 30 kg; an output of 30 to 50 mL/hr is expected in children weighing more than 30 kg. Urine output and specific gravity, vital signs, laboratory data, and objective signs of adequate hydration guide the rate of fluid administration.

Children who are hospitalized with burns require constant observation and assessment for complications. Alterations in electrolyte balance produce clinical symptoms of confusion, weakness, cardiac irregularities, and seizures. Changes in respiratory function and gas exchange are reflected clinically by restlessness, irritability, increased work of breathing, and alterations in blood gas values. The loss of protective function of the skin exposes burned children to increased risk of hypothermia. Edema formation and circulatory impairment result in the loss of sensation and deep throbbing pain.

! NURSING ALERT

Evaluate the burned extremity and check the pulse every hour. If unable to palpate, use Doppler to ascertain loss of circulation and pulse. If the pulse is lost, escharotomy may be necessary to relieve the edema causing pressure on blood vessels, to restore adequate circulation.

Burn units maintain a pictorial record of the wound to record progress and for legal purposes (if child maltreatment is suspected). The burn wound is treated according to the protocol of the specific burn facility.

Throughout the acute phase of care, the psychosocial needs of the child and their family should not be overlooked. The child is frightened, uncomfortable, and often confused. The child may be isolated from familiar persons and surroundings; the overwhelming physical needs at this time are the primary focus of the staff and parents. In addition to feeling concern for their child, the family may experience guilt, which may be related to the fact that the parents did not or could not protect their child from injury. Consistency in the information presented and in the staff's attitude can create a sense of familiarity and stability during the acute phase of care. Consistent caregivers can also help decrease the patient's and family's anxiety and provide coordination of care. For example, when many teams of consultants and specialists are involved in the child's care, appointing one "spokesperson" decreases the confusion and enhances communication regarding the child's care.

Management and rehabilitative phases. After the patient's condition is stabilized, the management phase begins. The multidisciplinary team concentrates on preventing wound infections, closing the wound as quickly as possible, and managing the numerous complications. Although the rehabilitative phase begins when permanent wound closure has been achieved, rehabilitation issues are identified on admission and are included in the care plan throughout the hospital course.

Managing pain. The severe pain of the wound and resultant therapies, the anxiety generated by these experiences, sleep deprivation, itching related to wound healing, and the conscious and unconscious interpretations of traumatic events contribute to the psychological behaviours commonly observed in children with burns. It is always difficult to care for a child in pain, and inflicting pain on a helpless child is contrary to the empathic nature of nursing. Interventions to promote comfort may include medications, relaxation techniques, distraction therapy, behavioural techniques, operant conditioning such as tokens, a star chart, and family participation.

Children need age-appropriate explanations before all procedures. As stated earlier, consistency in caregivers is important. If this is not possible, a carefully developed, interprofessional care plan is necessary to provide consistency.

Care of the burn wound. The nurse has a major responsibility for cleansing, debriding, and applying topical medications and dressings to the burn wound. Pain medication should be administered so that the peak effect of the medication coincides with the procedure. Children who have an understanding of the procedure to be performed and some perceived control tend to demonstrate less anxious behaviour. Children also respond well to participating in decisions (see Atraumatic Care box: Reducing the Stress of Burn Care Procedures).

ATRAUMATIC CARE

Reducing the Stress of Burn Care Procedures

- Have all materials ready before beginning.
- Administer appropriate analgesics and sedatives.
- Remind the child of the impending procedure to allow sufficient time to prepare.
- Encourage the child to test and approve the temperature of the water.
- Allow the child to select the area of the body on which to begin.
- Allow the child to request a short rest period during the procedure.
- Encourage the child to remove the dressings if desired.
- Provide something constructive for the child to do during the procedure (e.g., holding a package of dressings or a roll of gauze).
- Inform the child when the procedure is near completion.
- Praise the child for their assistance.

Outer dressings are removed. Any dressings that have adhered to the wound can be more easily removed by applying tepid water or normal saline. Loose or easily detached tissue is debrided during the cleansing process. In dressing the wound, it is important that all areas be clean, that medication be amply applied, and that no two burned surfaces touch each other, such as fingers or toes, or ears touching the side of the head. If they are touching, the burned surfaces will heal together, causing deformity or dysfunction.

Topical medications may be applied directly to the wound with a tongue blade or gloved hand or impregnated into fine-mesh gauze before application. Dressings are then applied to assist in exudate absorption, wound debridement, and increased patient comfort. All dressings applied circumferentially should be wrapped in a distal-to-proximal manner. The dressing is applied with sufficient tension to remain in place but not so tightly as to impair circulation or limit motion. Elastic net or bandages are applied over dressings to prevent epithelial breakdown, decrease edema, stimulate circulation, and improve mobility. A stable dressing is especially important when the child is ambulatory.

Routine precautions, including the use of protective garments and barrier techniques, should be followed when caring for patients with thermal injuries. Frequent hand hygiene, including of the forearm, is the single most important element of the infection control program. Strict policies for cleaning the environment and patient care equipment should be implemented to minimize the risk of cross-contamination. All visitors and members of other departments should be oriented to the infection control policies, including the importance of hand hygiene and forearm washing and use of protective garb. Visitors should be screened for infection and contagious diseases before patient contact.

Preventing complications.

Acute care. The maintenance of body temperature is important to the child with burns. Core body temperature is supported when energy is conserved with an environmental temperature of 28° to 33°C. Large areas of the body should not be exposed simultaneously during dressing changes. Warmed solutions, linens, occlusive dressings, heat shields, a radiant warmer, and warming blankets assist in preventing hypothermia.

The chief danger during acute care is infection—wound infection, generalized sepsis, or bacterial pneumonia. Accurate and ongoing assessments of all parameters that provide clues to the early diagnosis and treatment of infection are essential. Symptoms of sepsis include a decreasing level of consciousness, a rising or falling white blood cell

count, hyperthermia progressing to hypothermia, increasing fluid requirements, hypoactive or absent bowel sounds, a rising or falling blood glucose level, tachycardia, tachypnea, and thrombocytopenia. Infection delays the loss of the progression of wound healing.

Children are reluctant to move if movement causes pain, and they are likely to assume a position of comfort. Unfortunately, the most comfortable position often encourages the formation of contractures and loss of function. Ongoing efforts to prevent contractures include maintaining proper body alignment, positioning and splinting involved extremities in extension, providing active and passive physiotherapy, and encouraging spontaneous movement when feasible. Frequent position changes are important to promote adequate bronchopulmonary hygiene and capillary perfusion to common pressure areas. Low–air loss beds are beneficial for patients with morbid obesity or those with posterior grafts. Special attention should be given to areas at risk for increased pressure, such as the posterior scalp, heels, sacrum, and areas exposed to mechanical irritation from splints and dressings.

Long-term care. The rehabilitative phase of care begins once wound coverage is achieved. Scar formation becomes a major issue as burn wounds heal (Figure 52.22). Contractile properties of the scar tissue can result in disabling contractures, deformity, and disfigurement.

Uniform pressure applied to the scar decreases the blood supply. When pressure is removed, blood supply to the scar is immediately increased; therefore, periods without pressure should be brief to avoid nourishment of the hypertrophic tissue. Continuous pressure to areas of scarring can be achieved by use of elastic bandages or commercially available pressure garments. Because these custom-made garments are often worn for months, revisions may be required as the child grows. It is much easier to prevent scarring and contracture of the wound than to resolve an existing problem. Splints and appliances may also be needed until wound maturation is achieved (Figure 52.23).

Fig. 52.23 Child in elasticized (Jobst) garment and "airplane" splints.

Scar tissue has certain significant properties, particularly for growing children. Intense itching occurs in healing burn wounds and scar tissue until the scar is no longer active. Itching is usually treated with H_1 and H_2 antagonists such as cetirizine and cimetidine (Tagamet); an H_1 antagonist alone; and frequent applications of a moisturizer, such as Vaseline Intensive Care Rescue, Aveeno Baby, Alpha Keri, or Eucerin. Massage therapy during the application of moisturizers is also beneficial to stretch scar tissue and aid in contracture prevention. Scar tissue has no sweat glands, thus children with extensive scarring may experience difficulty during hot weather. Caregivers should be alerted to this possibility and be prepared to institute alternative methods of cooling when necessary.

Scar tissue does not grow and expand as normal tissue does, which may create difficulties, especially in functional areas such as on the hands and over joints. Additional surgery is sometimes required to allow independent functioning in daily activities, to improve cosmetic appearance, or to restore anatomical integrity.

The nursing activities in the rehabilitative phase of treatment focus on the child's and family's adaptation to the burn injury and their ability to transition back into home and family life. The psychological pain and sequelae of severe burn injury are as intense as the physical trauma. The impact of severe burns taxes the coping mechanisms at all ages. Very young children, who suffer acutely from separation anxiety, and adolescents, who are developing an identity, are probably most affected psychologically. Toddlers cannot understand why the parents they love and who have protected them can leave them in such a frightening and unfamiliar place. Adolescents, in the process of achieving independence from the family, find themselves in a dependent role with a damaged body. Being different from others at a time when conformity with peers is so important is difficult to accept.

Anticipation of the return to school can be overwhelming and frightening. It is essential that health care providers recognize the importance of preparing teachers and classmates for the child's return. Teachers need to be provided with information to assist the child and family and to promote the child's optimal adjustment. Telephone calls, emails, videos, information packets, and visits by members of the health

care team offer opportunities to help with reintegration into the school environment—a focal point of the child's life.

Psychosocial support of the child. Children should begin early to do as much for themselves as possible and to be active participants in their care. Loss of control and perceived helplessness may result in acting-out behaviours. During illness, children may regress to a previous developmental level that allows them to deal with stress. As children begin to participate in their care, they gain confidence and self-esteem. Fears and anxieties diminish with accomplishment and self-confidence. If the child demonstrates nonadherence in the rehabilitative phase, a behaviour modification program can be initiated to promote or reward the child's accomplishment in care.

Children need to know that their injury and the treatments are not punishment for real or imagined transgressions and that the nurse understands their fear, anger, and discomfort. They also need body contact. This is often difficult to arrange for the child with massive burns. Stroking areas of unburned skin can be comforting. Even older children enjoy sitting on their parent's lap and being cuddled and hugged. This can be a reward or a comfort in times of stress, but most of all it should be kept in mind that it is a natural part of childhood.

Psychosocial support of the family. Recognizing and respecting each family's strengths, differences, and methods of coping enables the nurse to respond to their unique needs by implementing a family-centred approach to care. In the acute phase, all attention is focused on the child, and the parents can feel powerless and ineffectual. Most parents feel overwhelming guilt, whether or not the guilt is justified. They feel responsible for the injury. These feelings may impede the child's rehabilitation. Parents may indulge the child and allow noncompliant behaviours that affect physical and emotional recovery. Parents need to be informed of the child's progress and helped to cope with their feelings while supporting their child. The nurse can help them understand that it is not selfish to look after themselves and their own needs to meet their child's needs. It is important to recognize the parents' need to grieve the change in their child's normal appearance. Professional psychological help may be needed for parents whose response to the injury is severe or whose response to stress is manifested in destructive behaviour.

The parents are members of the interprofessional team and participate in the development of the care plan. It is important to facilitate their input; to consider all aspects of the physical, emotional, social, and cultural factors affecting the child and family; and to establish a realistic home therapy program. The family's willingness to assume responsibility for care and their ability to implement the therapeutic regimen needs to be assessed. Home, school, and other environmental factors should be explored; financial concerns and available community resources discussed; and a specific care plan for the child, with an anticipated follow-up program, developed.

Prevention of burn injuries. The best intervention is to prevent burns from occurring. See Chapter 35, Safety Promotion and Injury Prevention: Burns. Education related to fire safety and survival should begin with the very young. They can practise "stop, drop, and roll" to extinguish a fire. The fire escape route, including a safe meeting place away from the home in case of fire, also should be practised.

Community activities are also helpful in supporting burn survivors and preventing burns. There are various organizations that provide important burn prevention educational programs as well as financial and emotional support to the children with burn injuries and their families. An example is TOMA Foundation for Burned Children, which is a Canadian and American organization of firefighters who fundraise and work with interdisciplinary health care providers to provide support to burn victims and their families. There are also burn camps in most of the provinces for children who have sustained burn injuries.

Sunburn

Sunburn is a common skin injury caused by overexposure to ultraviolet radiation (UVR). The sun emits a continuous spectrum of visible and nonvisible light rays that range in length from very short to very long. The shorter, higher-frequency waves are more damaging than longer wavelengths, but much of the light is filtered out as it travels through the atmosphere. Of the light that does filter through, *ultraviolet A (UVA)* waves are the longest and cause only minimum burning, but they play a significant role in photosensitive and photoallergic reactions. They are also responsible for premature aging of the skin and potentiate the effects of *ultraviolet B (UVB)* waves. UVB waves are shorter and are responsible for tanning, burning, and most of the harmful effects attributed to sunlight, especially skin cancer.

Numerous factors influence the amount of UVR exposure. Maximum exposure occurs at midday (1000 to 1600), when the distance from the sun to a given spot on the earth is shortest. There is more exposure at higher altitudes and near the equator, and less when the sky is hazy (although the amount of UVR that does penetrate is easily underestimated). Window glass effectively screens out UVB but not UVA rays. Fresh snow, water, and sand reflect UVR, especially when the sun is directly overhead.

Sunburn is usually an epidermal burn, although severe sunburn can be a partial-thickness burn with blister formation. Treatment of sunburn involves stopping the burning process, decreasing the inflammatory response, and rehydrating the skin. Local application of cool tapwater soaks or immersion in a tepid-water bath (temperature slightly below 36.7°C for 20 minutes or until the skin is cool) limits tissue destruction and relieves the discomfort. After the cool applications, a bland oil-in-water moisturizing lotion can be applied. Partial-thickness sunburns are treated the same as those from any heat source (see earlier discussion on burns).

Nursing Care. Protection from sunburn is the major goal of nursing care. The harmful effects of the sun on the delicate skin of infants and children are currently receiving increased attention. To protect skin exposed to the sun for extended periods, skin should be covered with clothing and a broad-spectrum sunscreen should be applied. Children with fair skin, who usually burn and do not easily tan when out in the sun, or children with blond or red hair, freckles, or many moles, are at greatest risk of sustaining sun damage (Canadian Dermatology Association, 2021c) (see Family-Centred Care: Sun Protection Basics).

Canadian Dermatology Association–approved sun protection agents should be applied. Two types of products are available for sun protection: *topical sunscreens*, which partially absorb UVR, and *sun blockers*, which block out UVR by reflecting sunlight. The most frequently recommended sun blockers are zinc oxide and titanium dioxide ointments. Sunscreens are products containing a sun protection factor (SPF) based on an evaluation of its effectiveness against UVR. The SPF is a number, such as 15, which indicates that if individuals normally burn in 10 minutes without a sunscreen, use of a sunscreen with SPF 15 allows them to remain in the sun 15 times 10, or 150 minutes (2.5 hours) before acquiring the same degree of burns. The most effective sunscreens against UVB are p-aminobenzoic acid (PABA) and PABA-esters. However, many individuals are allergic to PABA, and use of sunscreens without PABA is encouraged, to prevent these reactions in children. The Canadian Dermatology Association provides an approved list of sunscreens on their website (see Additional Resources at the end of this chapter); approved products have the Canadian Dermatology Association logo on them. The Canadian Dermatology Association (2021c) also recommends use of a sunscreen that protects against UVA and UVB, with SPF 30 or higher, but if a

child develops a burn with SPF 30, the parent should try a higher SPF. Sunscreen should not be applied around a child's eyes, as it may sting and burn. Swimmers should use water-resistant sunscreens, and children can wear sun-protective bathing suits to protect their skin while swimming. Sunscreens should be applied liberally to a child's skin; lip balm with SPF 30 should be applied to a child's lips.

FAMILY-CENTRED CARE

Sun Protection Basics

The incidence of skin cancer is increasing in children, accounting for about 4% of pediatric malignancies. A resource to use for protecting children from harmful sun exposure is the Environment Canada UV (ultraviolet) Index level, with a scale from 1 to 11, which has associated precautions, including sunglasses, sunscreens, sun-protective clothing, and sun avoidance. Environment Canada predicts the maximum daily UV index levels, which measure the sun's burning UV rays on a daily basis, countrywide. This information is available on the Government of Canada's website at https://weather.gc.ca/forecast/public_bulletins_e.html?Bulletin=fpcn48.cwao.

Following are some practices to protect children from harmful UV exposure:

- Children's sunglasses must absorb at least 99% of UV radiation. Sunglasses with the label "Blocks 99% of UV rays" should be used. The glasses must have unbreakable plastic lenses with a wrap-around style that closely fits, to maximize UV and light protection. The glasses should be worn on cloudy as well as sunny days.
- Children should be allowed to choose their sunglasses. A child who wears prescription glasses should also wear prescription sunglasses.
- Avoid sun exposure between 1000 and 1400 hours. High altitude, sand, concrete, snow, and water increase UV exposure.
- Wear wide-brim hats and sun-protective clothing.
- Apply an adequate layer of sunscreen, preferably waterproof or water resistant, and reapply at regular intervals.

Source: Government of Canada. (2018). *Sun safety tips for parents*. http://healthycanadians.gc.ca/healthy-living-vie-saine/environment-environnement/sun-soleil/tips-parent-conseils-eng.php.

Sunscreens should be applied evenly to all exposed areas, with special attention to skin folds and areas that might become exposed as clothing shifts. Parents need to read labels of sunscreen products carefully for the SPF and follow the manufacturer's directions for application.

NURSING ALERT

Infants should be kept out of the sun or physically shaded from it. Infants should be covered as much as possible with tightly woven fabric, such as cotton, when in the sun. Small amounts of sunscreen can be applied to sun-exposed skin, such as on the back of the hands and face, in small amounts (Canadian Dermatology Association, 2021c).

Individuals who work in the community, such as teachers, day care workers, coaches, and youth-group leaders, as well as relatives should all be made aware of sun safety for children. Sunscreens must be applied *liberally and frequently*. Parents with children in day care can also work together with the day care staff regarding sun protection.

The increased incidence of indoor tanning beds is of particular concern for nurses and health teaching and promotion. Teenagers are frequent visitors to tanning parlours; the majority of users are females. The incidence of cutaneous malignant melanoma (CMM) has increased more than three-fold in the last 35 years (Taddeo et al., 2012/2018). Skin damage is cumulative, and the full impact and scope of damage caused by year-round indoor tanning may take years to develop into certain skin cancers. Ontario and other provinces have banned the use of commercial tanning facilities by children and adolescents under the age of 18 (Taddeo et al., 2012/2018).

Cold Injury

In cold injuries the nature of the body's heat-regulating mechanisms is such that the inner portion of the body, or *core*, produces heat, and the periphery, or outer area, conserves or dissipates heat. When the body attempts to conserve heat, the outer tissues are subjected to low temperatures, and local trauma may result.

Chilblain, redness and swelling of the skin, occurs when extremities, usually the hands, are exposed to cold temperatures and moisture. The response may vary but is characterized by intense vasodilation that increases the temperature of involved tissues above that of unaffected tissue and produces edematous, reddish blue patches that itch and burn. As warming takes place, the sensations become more intense, but ordinarily they subside in a few days.

Frostbite is the term used to describe tissue damage caused when excessive heat loss to local tissues allows ice crystals to form in tissues. The frostbitten part appears white or blanched, feels solid, and is without sensation. Rapid rewarming is associated with less tissue necrosis than slow thawing. It restores blood flow and shortens the period of cellular damage. Rewarming produces a flush (sometimes deep purple) and a return of sensation, which is extremely painful. Large blisters may appear in 24 to 48 hours after rewarming and begin to reabsorb within 5 to 10 days, followed by the formation of a hard black eschar. Superficial injury often heals without incident. Rewarming is accomplished by immersing the part in well-agitated water at 37.8° to 42.2°C. Discomfort is managed with analgesics and sedatives. Care of blistered skin is similar to that described for burns. It is seldom possible to estimate the extent of tissue loss until new skin layers are revealed after the eschar layer separates.

KEY POINTS

- A variety of factors can produce lesions of the skin.
- It is important for nurses to be able to describe skin lesions accurately.
- A moist environment promotes wound healing.
- Bacterial, viral, and fungal infections are common in childhood.
- Some skin diseases are transmitted by arthropod vectors, especially ticks.
- The most common skin infestations of childhood—scabies and pediculosis capitis—affect children of any age and from any social class.
- Contact dermatitis may involve a primary irritant or a sensitizing agent.
- The most common skin disorders of infancy are diaper dermatitis, seborrheic dermatitis, and AD.
- Acne, a disorder affecting many adolescents, is related to hormonal fluctuation, stimulation of the sebaceous glands, excessive sebum production, the formation of comedones, and the overgrowth of the *P. acnes* organism.
- Medication and gentle facial cleansing are the treatments of choice for acne.
- Burns are caused by thermal, chemical, electric, or radioactive agents.
- Burns are assessed on the extent, depth, and severity of the wound.
- Essentials of emergency care of burn injury include stopping the burning process, covering the burn, transporting the injured child to medical aid, and providing reassurance to the child and family.

- Management of minor burns consists of facilitating wound healing, relieving discomfort, and preventing complications.
- Management of major burns consists of facilitating wound healing, relieving discomfort, replacing destroyed skin, preventing or treating complications, and providing rehabilitation.
- Sunscreen is recommended for use when the skin is exposed to the damaging effects of the sun's rays.
- Thermal injuries to the skin can result from exposure to extreme cold.

Musculoskeletal or Articular Conditions

Natasha Bath
Originating US Chapter by *Marilyn J. Hockenberry*

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Outline a care plan for a child immobilized with an injury or a physically limiting condition.
2. Formulate a teaching plan for the parents of a child in a cast.
3. Explain the functions of the various types of traction.
4. Differentiate among the various congenital skeletal defects.
5. Design a teaching plan for the parents of a child with a congenital skeletal deformity.
6. Describe the therapies and nursing care of a child with scoliosis.
7. Outline a care plan for a child with osteomyelitis.
8. Differentiate between osteosarcoma and Ewing sarcoma.
9. Describe the nursing care of a child with juvenile arthritis.
10. Demonstrate an understanding of the management of systemic lupus erythematosus.

THE IMMOBILIZED CHILD

One of the most difficult aspects of illness in otherwise healthy children is the immobility it imposes. Children by nature are usually active, and immobility, however temporary, may have lasting effects on the child's developmental progress. The most frequent reasons for immobility are **congenital** defects (e.g., spina bifida), degenerative disorders (e.g., muscular dystrophy), and infections or injuries that impair the integumentary system (e.g., severe burns) (Chapter 52), the musculoskeletal system (e.g., multiple fractures, osteomyelitis), or the neurological system (e.g., spinal cord injury, Guillain-Barré syndrome, traumatic brain injury, and coma) (Chapter 54). At times therapeutic interventions such as traction and spinal fusion are responsible for prolonged immobilization, although the increasing trends in health care are early mobilization, rehabilitation, discharge, and outpatient treatment.

Physiological Effects of Immobilization

Many clinical studies have documented predictable consequences that occur after immobilization. Functional and metabolic responses to restricted movement can be noted in most of the body's systems. Each has a direct influence on the child's growth and development because homeostatic mechanisms thrive on normal use and need feedback to maintain dynamic equilibrium. Inactivity leads to a decrease in the functional capabilities of the whole body as dramatically as the lack of physical exercise leads to muscle weakness.

Disuse from illness, injury, or a sedentary lifestyle can limit function and potentially delay age-appropriate milestones. Most of the pathological changes that occur during immobilization arise from decreased muscle strength and mass, decreased metabolism, and bone demineralization, which are closely interrelated, with one change leading to or affecting the other. Some results of immobilization are primary and produce a direct effect; other pathophysiological consequences occur frequently but seem to be more indirect and are thus secondary effects. Many pathophysiological changes affect more than one body system, with the primary or secondary effect being demonstrated in both systems.

The major effects of immobilization are outlined briefly in Table 53.1 and are related directly or indirectly to decreased muscle activity, which produces numerous primary changes in the musculoskeletal system with secondary alterations in the cardiovascular, respiratory, metabolic, and renal systems. The musculoskeletal changes that occur during disuse are a result of alterations in gravity and stress on the muscles, joints, and bones. Muscle disuse leads to tissue breakdown and loss of muscle mass (**atrophy**). Muscle atrophy causes decreased strength and endurance, which may take weeks or months to restore.

The daily stresses on bone created by motion and weight bearing maintain the balance between bone formation (osteoblastic activity) and bone resorption (osteoclastic activity). During immobilization, more calcium leaves the bone, causing **osteopenia** (demineralization

TABLE 53.1 Summary of Physical Effects of Immobilization*

Primary Effects	Secondary Effects	Nursing Considerations
Muscular System		
Decreased muscle strength, tone, and endurance	Decreased venous return and decreased cardiac output	Use antiembolism stockings or intermittent compression devices to promote venous return (monitor circulatory and neurovascular status of extremities when such devices are used).
	Decreased metabolism and need for oxygen	Plan play activities to use uninvolved extremities.
	Decreased exercise tolerance	Place in upright position as often as possible.
	Bone demineralization	Perform passive range-of-motion exercises.
Disuse atrophy and loss of muscle mass	Catabolism Loss of strength	Have patient perform active and passive range-of-motion, stretching exercises.
Loss of joint mobility	Contractures, ankylosis of joints	Maintain correct body alignment. Use joint splints as indicated to prevent further deformity. Maintain range of motion.
Weak back muscles	Secondary spinal deformities	Maintain body alignment.
Weak abdominal muscles	Impaired respiration	See nursing considerations for respiratory system.
Skeletal System		
Bone demineralization—Osteoporosis, hypercalcemia	Negative calcium balance	With paralysis, use upright posture on tilt table.
	Pathological fractures	Handle extremities carefully when turning and positioning.
	Calcium deposits	Administer calcium-mobilizing medications (diphosphonates) and normal saline infusions as directed.
	Extraosseous bone formation, especially at hip, knee, elbow, and shoulder	
	Renal calculi	Ensure adequate fluid intake; monitor output. Acidify urine. Promptly treat urinary infections.
Negative calcium balance	Life-threatening electrolyte imbalance	Monitor serum calcium levels. Provide electrolyte replacement as indicated.
Metabolism		
Decreased metabolic rate	Slowing of all systems	Mobilize as soon as possible. Have patient perform active and passive resistance and deep breathing exercises.
	Decreased food intake	Ensure adequate food intake. Provide a high-protein diet.
Negative nitrogen balance	Decline in nutritional state	Encourage small frequent feedings with protein and preferred foods.
	Impaired healing	Monitor for and prevent pressure sores.
Hypercalcemia	Electrolyte imbalance	See nursing considerations for skeletal system.
Decreased production of stress hormones	Decreased physical and emotional coping capacity	Identify causes of stress. Implement appropriate interventions to lower physical and psychosocial stresses.
Cardiovascular System		
Decreased efficiency of orthostatic neurovascular reflexes	Inability to adapt readily to upright position (**orthostatic intolerance**) Pooling of blood in extremities in upright posture	Monitor peripheral pulses and skin temperature changes. Use antiembolism stockings or intermittent compression devices to decrease pooling when upright.
Diminished vasopressor mechanism	Orthostatic hypotension (intolerance) with syncope—Hypotension, decreased cerebral blood flow, tachycardia	Provide abdominal support. In severe cases, use antigravitational pants. Position horizontally.
Altered distribution of blood volume	Increased cardiac workload	Monitor hydration, blood pressure, and urinary output.
	Decreased exercise tolerance	

Continued

TABLE 53.1 Summary of Physical Effects of Immobilization—cont'd

Primary Effects	Secondary Effects	Nursing Considerations
Venous stasis	Systemic embolus or thrombus development, pulmonary emboli	Encourage and assist with frequent position changes. Elevate extremities without knee flexion. Ensure adequate fluid intake. Have patient perform active or passive exercise or movement as needed. Prescribe routine wearing of antiembolism stockings or intermittent compression devices. Monitor for signs of *pulmonary embolism*—sudden dyspnea, chest pain, respiratory arrest. Promptly intervene to maintain adequate oxygenation if signs and symptoms of pulmonary emboli are noted. Measure circumference of extremities periodically. Give anticoagulant medications as prescribed.
Dependent edema	Tissue breakdown and susceptibility to infection	Administer skin care. Turn every 2 hours. Monitor skin colour, temperature, and integrity. Use pressure-reduction surface as necessary to prevent skin breakdown.
Respiratory System		
Decreased need for oxygen	Altered oxygen–carbon dioxide exchange and metabolism	Promote exercise as tolerated. Encourage deep breathing exercises.
Decreased chest expansion and diminished vital capacity	Diminished oxygen intake Dyspnea and inadequate arterial oxygen saturation; acidosis	Position for optimum chest expansion. Semi-Fowler's position may assist in lung expansion if the patient can tolerate it. Use prone positioning without pressure on abdomen to allow gravity to aid in diaphragmatic excursion. Ensure that patient maintains proper alignment when sitting to prevent pressure on respiratory mechanisms.
Poor abdominal tone and distension	Interference with diaphragmatic excursion	Avoid restriction of chest and abdominal musculature. Supply torso support to promote chest expansion.
Mechanical or biochemical secretion retention	Hypostatic pneumonia Bacterial and viral pneumonia Atelectasis	Change position frequently. Carry out percussion, vibration, and drainage (or suctioning) as necessary. Use incentive spirometer. Monitor breath sounds.
Loss of respiratory muscle strength	Poor cough	Encourage deep breathing and coughing. Support chest wall by splinting with pillow when patient coughs. Use incentive spirometer. Observe for signs of respiratory distress with pulse oximetry or blood gas measurement as necessary.
	Upper respiratory tract infection	Prevent contact with an infected person. Provide adequate hydration. Administer immunizations as necessary (pneumococcal, meningococcal).
Gastrointestinal System		
Distension caused by poor abdominal muscle tone	Interference with respiratory movements	Monitor bowel sounds. Encourage small, frequent meals.
No specific primary effect	Difficulty in feeding in prone position Possible constipation caused by gravitational effect on feces through ascending colon and smooth muscle tone	Have patient sit upright in bedside chair, if possible Carry out bowel training program with hydration, stool softeners, increased fibre intake, and mild laxatives if necessary.
	Anorexia	Stimulate appetite with favoured foods.
Urinary System		
Alteration of gravitational force	Difficulty in voiding in prone or supine position	Position as upright as possible to void.

Continued

TABLE 53.1 Summary of Physical Effects of Immobilization—cont'd

Primary Effects	Secondary Effects	Nursing Considerations
Impaired ureteral peristalsis	Urinary retention in calyces and bladder Infection Renal calculi	Hydrate to ensure adequate urinary output for age. Stimulate bladder emptying with warm running water as necessary. Catheterize only for severe urinary retention. Administer antibiotics as indicated.
Integumentary System		
No specific primary effect	Decreased circulation and pressure leading to tissue injury and decreased healing capacity	Turn and reposition at least every 2 hours. Frequently inspect total skin surface. Eliminate mechanical factors causing pressure, friction, moisture, or irritation. Place on pressure-relief mattress.
	Difficulty with personal hygiene	Assess ability to perform self-care and assist with bathing, grooming, and toileting as needed. Encourage self-care to potential ability. Ensure adequate intake of protein, vitamins, and minerals.

*Individualize care according to a child's needs; interventions may vary in different institutions.

of the bones), which may predispose bone to pathological fractures. A joint contracture begins when the arrangement of collagen, the main structural protein of connective tissues, is altered, resulting in a denser tissue that does not glide as easily. Eventually, muscles, tendons, and ligaments can shorten and reduce joint movement, ultimately producing contractures that restrict function. The major musculoskeletal consequences of immobilization are as follows:

- Significant decrease in muscle size, strength, and endurance
- Bone demineralization leading to osteoporosis
- Contractures and decreased joint mobility

Circulatory stasis combined with hypercoagulability of the blood, which results from factors such as damage to the endothelium of blood vessels (Virchow triad), can lead to thrombus and embolus formation. *Deep vein thrombosis (DVT)* involves the formation of a thrombus in a deep vein such as the iliac and femoral veins and can cause significant morbidity if it remains undetected and untreated. The thrombus and emboli may obstruct vessels in organs such as the lungs, kidneys, or brain. Pulmonary embolus is a life-threatening complication of immobilization. The larger the portion of the body immobilized and the longer the immobilization, the greater the hazards of immobility.

Psychological Effects of Immobilization

Throughout childhood, physical activity is an integral part of daily life and is essential for physical growth and development. Physical activity helps children learn and explore the environment around them, helps them regulate a variety of feelings and impulses, and provides a mechanism by which they can exert control over inner tensions. Some children respond to anxiety with increased activity; they process environmental stimuli and their emotions through activity and behaviour. Limiting or restricting physical activity because of illness or injury disrupts their ability to do this.

When children are immobilized by illness or as part of a treatment regimen, they experience diminished environmental stimuli because of the loss of tactile input and an altered perception of themselves and their environment. Sudden or gradual immobilization narrows the amount and variety of environmental stimuli children receive by means of all of their senses: touch, sight, hearing, taste, smell, and *proprioception*, or the feeling of where they are in their environment. This sensory deprivation commonly leads to feelings of isolation and boredom and of being forgotten, especially by peers.

The quest for mastery at every stage of development is influenced by mobility. Even speech and language skills require sensorimotor activity and experience. For the toddler, exploration and imitative behaviours are essential to developing a sense of autonomy. The preschooler's expression of initiative is evidenced by the need for vigorous physical activity. The school-age child's development is strongly influenced by physical achievement and competition. The adolescent relies on mobility to achieve independence.

The monotony of immobilization may lead to sluggish intellectual and psychomotor responses, decreased communication skills, increased fantasizing, and, rarely, hallucinations and disorientation. Children are likely to become depressed over their loss of ability to function or any marked changes in body image. They may seek the attention of others by reverting to earlier developmental behaviours, such as wanting to be fed or bed-wetting and baby talk.

Limbs in casts or traction transmit less than normal sensory data. Children who have limited ability to feel others touching them not only experience less tactile stimuli in a physical sense but also are deprived of warm, loving feelings that arise from being touched. The loss of feeling derived from touch can further add to their sense of being isolated and unwanted.

Children may react to immobility by active protest, anger, and aggressive behaviour; or they may become quiet, passive, and submissive. They may believe the immobilization is a justified punishment for misbehaviour. Children should be allowed to express their feelings, but it should be within the limits of safety to their self-esteem and not damaging to the integrity of others (see Providing Opportunities for Play and Expressive Activities, Chapter 43). For example, providing an inanimate object to attack rather than a person or a valued possession is safe and therapeutic. When children are unable to express anger and frustration, aggression is often displayed inappropriately through regressive behaviour and outbursts of crying or temper tantrums.

Effect on Families

Even brief periods of immobilization may disrupt family function, and sudden catastrophic illness or chronic disability may severely tax their resources and coping abilities. The family's needs often must be met by

the services of an interprofessional team. Nurses play a key role in anticipating the services they will need and in coordinating conferences to plan care.

Nursing Care. Physical assessment of the child who is immobilized as a result of an injury or illness focuses not only on the injured part (e.g., fracture or damaged joint) but also on the functioning of other systems that may be affected secondarily (e.g., the circulatory, renal, respiratory, muscular, and gastrointestinal systems). With long-term immobilization, there may also be neurological impairment and changes in electrolytes (especially calcium), nitrogen balance, and the general metabolic rate. The psychological impact of immobilization should also be assessed.

Children who require prolonged total immobility and are unable to move themselves in bed should be placed on a special surface to prevent skin breakdown. Frequent position changes also help prevent dependent edema and stimulate circulation, respiratory function, gastrointestinal motility, and neurological sensation. Children at greater risk for skin breakdown include those with prolonged immobilization; orthotic and prosthetic devices, including wheelchairs; and casts. Additional risk factors include poor nutrition, friction (from bed linen with traction), and moist skin (from urine or perspiration). In critically ill children, mechanical ventilation may increase the risk for skin breakdown. In newborns and infants, skin breakdown is more likely to occur on the occiput and on the nasal septum when nasal continuous positive airway pressure devices are used (Murray et al., 2013). Nursing care of children at risk includes strategies for preventing skin breakdown when such conditions are present. The Braden Q Scale is a reliable, objective tool that may be used in the assessment for pressure injury development in children who are acutely ill or at risk for skin breakdown from neurological conditions and immobilization (Noonan et al., 2011) (see Additional Resources at the end of the chapter).

The use of antiembolic stockings and intermittent compression devices helps prevent circulatory stasis and dependent edema in the lower extremities and the development of DVT. Some children require anticoagulant therapy with low-molecular-weight heparin, vitamin K antagonists, or unfractionated heparin. Close monitoring of the signs and symptoms for possible DVT and pulmonary emboli is crucial to early detection and intervention for all immobilized children (SickKids, 2017). The child should be allowed as much activity as possible within the limitations of the illness or treatment. Any functional mobility, however minimal, is preferred to total immobility.

High-protein, high-calorie foods are encouraged to prevent negative nitrogen balance, which may be difficult to correct by diet, especially if there is anorexia as a result of immobility and decreased gastrointestinal function (decreased motility and possibly constipation). Stimulating the appetite with small servings of attractively arranged, preferred foods may be sufficient. Sometimes supplementary nasogastric or gastrostomy feedings or intravenous (IV) fluids may be needed, but these are reserved for serious disability in which oral intake is difficult. Adequate hydration and, when possible, an upright position and remobilization promote bowel and kidney function and help prevent complications in these systems.

Children are encouraged to be as active as their condition and restrictive devices allow. This poses few issues for children, whose innate ingenuity and natural inclination toward mobility provide them with the impetus for physical activity. They need the opportunity, the materials, or objects to stimulate activity and the encouragement and participation of others. Those children who are unable to move need passive exercise and movement, often in consultation with a physiotherapist.

Using dolls, stuffed animals, or puppets to illustrate and explain the immobilization method (e.g., traction, cast) is a valuable tool for educating small children. Placing a cast, tubing, or other restraining equipment on the doll offers the child a nonthreatening opportunity to express, through the doll, feelings concerning the restrictions and feelings toward the nurse and other health care providers. The doll or puppet may also be used for teaching the child and family procedures, such as IV therapy, procedural sedation, and general anaesthesia.

Whenever possible, transporting the child outside the confines of the room increases environmental stimuli and allows social contact with others. Specially designed wheelchairs for increased mobility and independence are available. While hospitalized, children benefit from visits by family and friends, use of computers and personal tablets, books, interactive video games, and other items brought from their own room at home. An activity centre or slanting tray can be useful for the child with limited mobility for drawing, colouring, writing, and playing with small toys, such as trucks and cars. Accessibility to clocks, calendars, and a program of diversional therapy are also beneficial. All these interventions help children to function in a more typical way while hospitalized. A child life specialist should be consulted for recreational planning. Children are able to express their frustration, displeasure, and anger through play activities (see Chapter 44), which is helpful in their recovery.

All efforts should be made to minimize family disruption resulting from the hospitalization. Hospitalized children should be allowed to wear their own clothes (street clothes, especially for preadolescent and adolescent children) and resume school and preinjury activities if able. A parent or siblings should be allowed to stay overnight and room in with the hospitalized child to prevent the effects of family disruption. Visits from significant persons, such as family members and friends, offer occasions for emotional support and also provide opportunities for learning how to care for the child. Privacy is necessary, especially for adolescents.

One of the most useful interventions to help children cope with immobility is participation in their own self-care. Self-care to the maximum extent possible is usually well received by children. They can help plan their daily routine, select their diet (when possible), and choose clothes, including innovative adornments such as baseball caps, brightly decorated sunglasses, or brightly coloured stockings, to express their autonomy and individuality. They should be encouraged to do as much as they are able to for themselves to keep muscles active and their interest alive.

Although most of the suggestions discussed here relate to hospital care, the same consultations (physiotherapist, occupational therapist, child life specialist, speech therapist) and environment may also be considered in the home to help the child and family achieve independence and normalization. For a child with greatly restricted movement (e.g., child with a large bilateral hip spica cast), nursing care is often a challenge. These situations require long-term care either in the hospital or at home; but, wherever the care occurs, consistent planning and coordination of activities with other health care workers and significant others are vital nursing functions.

Family Support and Home Care. The needs of a child with complex or chronic conditions that cause immobility can be complex. Although the optimal situation is for family members to have time to assimilate the teachings and demonstrations needed to understand the child's situation and care, this is often shortened considerably by moving the child to a rehabilitation facility or even to the home within a matter of days. Even the child who is confined on a short-term basis can be

a challenge for the family, which is usually unprepared for the adjustments imposed by the child's special needs. Home modification is usually needed for facilitating care, especially when it involves traction, large casts, or extended confinement. Suitable child care may be needed for times when all family members work.

Just as in the hospital, the child at home should be encouraged to be as independent as possible and to follow a schedule that approximates their usual lifestyle as nearly as possible, such as continuing school lessons, regular bedtime, and suitable recreational activities.

TRAUMATIC INJURY

Soft-Tissue Injury

Injuries to the muscles, ligaments, and tendons are common in children; areas of injuries are shown in Figure 53.1. In young children, soft-tissue injury usually results from mishaps during play. In older children and adolescents, participation in sports is the more common cause.

Contusions. A *contusion* (bruise) is damage to the soft tissue, subcutaneous structures, and muscle. The tearing of these tissues and small blood vessels and the inflammatory response lead to hemorrhage, edema, and associated pain when the child attempts to move the injured part. The escape of blood into the tissues is observed as *ecchymosis*, a black and blue discoloration.

Contusions caused by *crush injuries* can occur in children when they slam their fingers (in doors, folding chairs, or equipment) or hit their fingers (as when hammering a nail). A severe crush injury involves the bone, with swelling and bleeding beneath the nail (subungual) and sometimes laceration of the pulp of the distal phalanx. The subungual hematoma can be released by creating a hole at the proximal end of the nail with a battery-operated microcautery device or a heated sterile 18-gauge needle.

Large contusions that are often sustained while the child is participating in sports cause gross swelling, pain, and disability, and usually receive immediate attention from health personnel. Smaller injuries may go unnoticed, allowing continued participation; however, they can become disabling after rest because of pain and muscle spasm. Initial immediate treatment has traditionally consisted of cold application. Return to participation is allowed when the strength and range of motion of the affected extremity are equal to those of the opposite extremity. *Myositis ossificans* may occur from deep contusions to the biceps or quadriceps muscles; this condition may result in a restriction of flexibility of the affected limb.

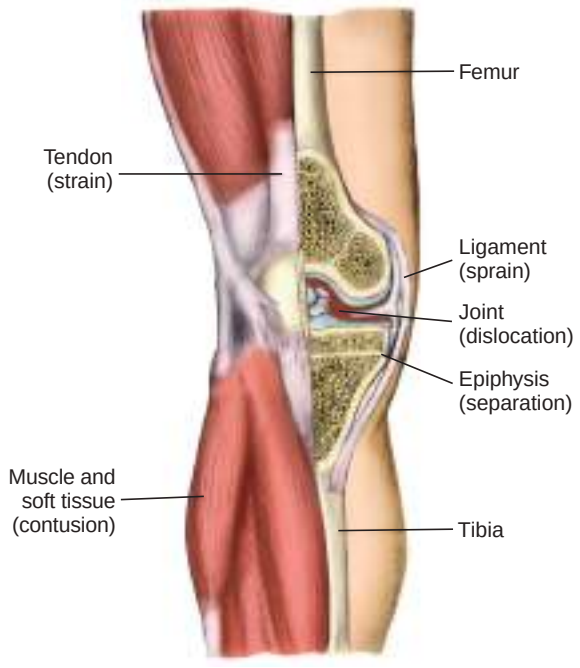

Fig. 53.1 Sites of injuries to bones, joints, and soft tissues.

Dislocations. Long bones are held in approximation to one another at the joint by ligaments. A dislocation occurs when the force of stress on the ligament is so great as to displace the normal position of the opposing bone ends or to displace the bone end from its socket. The predominant symptom is pain that increases with attempted passive or active movement of the extremity. In dislocations there may be an obvious deformity and inability to move the joint. Children with naturally lax joints are more prone to dislocation of joints. Dislocation of the phalanges is the most common type seen in children, followed by elbow dislocation. In the adolescent population, shoulder dislocations are more common, and dislocation unaccompanied by fracture is rare.

A common injury in young children is subluxation or partial dislocation of the radial head, also called *pulled elbow* or *nursemaid elbow*. In most cases, the injury occurs in a child less than 5 years old who receives a sudden longitudinal pull or traction at the wrist while the arm is fully extended and the forearm pronated (Carrigan, 2020). It usually occurs when an adult or older sibling who is holding the child by the hand or wrist gives a sudden pull or jerk to prevent a fall or attempts to lift the child by pulling the wrist, or when the child pulls away by dropping to the floor or ground. The child often cries, appears anxious, and refuses to use the affected limb. To treat this, the health care provider manipulates the arm by applying firm finger pressure to the head of the radius, then supinates and flexes the forearm to return the ligament to its place. A click or clunk may be heard or felt, and functional use of the arm returns within minutes. However, the longer the subluxation is present, the longer it takes for the child to recover mobility after treatment. Usually no anaesthetic is required; a mild pain reliever such as acetaminophen or ibuprofen may be given. In an older child, severe elbow injury or dislocation should be carefully evaluated by a health care provider immediately. If a traumatic elbow injury in a younger child is not a subluxation or if attempts at reduction are unsuccessful, the child should be carefully evaluated, with the consideration of X-rays.

In children younger than 5 years of age, the hip can be dislocated by a fall. The greatest risk after this injury is the potential loss of blood supply to the head of the femur. Relocation of the hip within 60 minutes after the injury provides the best chance for prevention of damage to the femoral head.

Shoulder dislocations occur most often in older adolescents and are often sports related. In a shoulder dislocation, temporary restriction of the joint, with a sling or bandage that secures the arm to the chest, can provide sufficient comfort and immobilization until medical attention is received.

Simple dislocations should be reduced as soon as possible with the child under mild (procedural) sedation and local anaesthesia as required. An unreduced dislocation will be complicated by increased swelling, making reduction difficult and increasing the risk of neurovascular complications. Treatment depends on the severity of the injury.

Sprains. A *sprain* occurs when trauma to a joint is so severe that a ligament is partially or completely torn or stretched by the force created as a joint is twisted or wrenched, often accompanied by damage to associated blood vessels, muscles, tendons, and nerves. Common sprain

sites include ankles and knees. Sprains can be graded as follows: *grade 1 sprain* has mild damage to a ligament or ligaments without instability of the affected joint; *grade 2 sprain* is a partial tear to the ligament, stretched to the point that it exhibits excessive laxity; and *grade 3* has a complete tearing of the ligament with a very loose or unstable joint (Karlin et al., 2020).

The presence of joint laxity is the most valid indicator of the severity of a sprain. In a severe injury the child may describe the joint as "feeling loose" or as if "something is coming apart" and may describe hearing a "snap," "pop," or "tearing." Pain is seldom the principal subjective symptom. There is a rapid onset with swelling (often diffuse), accompanied by immediate disability and appreciable reluctance to use the injured joint.

Strains. A *strain* is a microscopic tear to the musculotendinous unit and has features in common with sprains. The area is painful to touch and swollen. Most strains are incurred over time rather than suddenly, and the rapidity of the appearance provides clues regarding severity. In general, the more rapidly the strain occurs, the more severe the injury. When the strain involves the muscular portion, there is more bleeding, often palpable soon after injury and before edema obscures the hematoma.

Therapeutic Management. The first minutes to 12 hours are the most critical period for virtually all soft-tissue injuries. The goal is to limit further injury, control swelling and pain, and minimize strength and flexibility losses (Karlin et al., 2020). Basic principles of managing sprains and other soft-tissue injuries are summarized in the acronym *PRICE*:

P—Protection
R—Rest
I—Ice
C—Compression
E—Elevation

Crutches, air stirrups for ankle sprains, slings for arm injuries, and elastic wraps are used for compression. Compression limits further bleeding and swelling but should not be so tight that it limits perfusion (Karlin et al., 2020). Ice applied to the injury shunts blood flow from the injury, decreasing inflammation and swelling. This is best accomplished with crushed ice wrapped in a towel, a screw-top ice bag, or a resealable plastic storage bag. Chemical-activated ice packs are also effective for immediate treatment. A cloth barrier should be used between the ice container and the skin to prevent trauma to the tissues. Ice should be applied for 20 minutes three to four times per day until the swelling resolves. The application of heat is best suited for more chronic injuries, muscle soreness or pre-emptively before activity to improve blood flow to the site. The literature of the application of heat in acute soft tissue injuries is still variable and more research on its use is required.

Elevating the extremity uses gravity to facilitate venous return and to reduce edema formation in the damaged area. The point of injury should be kept several inches above the level of the heart for therapy to be effective. Several pillows can be used for elevation. Allowing the extremity to be dependent causes excessive fluid accumulation in the area of injury, delaying healing and causing painful swelling.

A nonsteroidal anti-inflammatory medication can be used to manage pain and decrease the edema. For minor ankle sprains, the child can start pain-free isometric strengthening and range-of-motion exercises as soon as possible (Karlin et al., 2020). Full weight-bearing is recommended in uncomplicated ankle sprains. The child can return to normal physical activities and sports when there is full range of movement and full strength to the joint.

Torn ligaments, especially those in the knee, are usually treated by immobilization with a knee immobilizer or range-of-motion brace until the child is able to walk without a limp. Crutches are used for mobility to rest the affected extremity. Passive leg exercises, gradually increased to active ones, are begun as soon as sufficient healing has taken place. Parents and children should be cautioned against using any form of liniment or other heat-producing preparation before the injured area is examined. If the injury requires casting or splinting, the heat generated in the enclosed space can cause extreme discomfort and may even cause tissue damage. In some cases torn knee ligaments are managed with arthroscopy and ligament repair or reconstruction as necessary, depending on the extent of the tear, the ligaments involved, and the child's age. Children who experience gait changes and restricted flexibility at 6 weeks after injury should be referred to a physiotherapy for more intensive rehabilitation (Tiemstra, 2012). Surgical reconstruction of the anterior cruciate ligament (ACL) may be warranted for severe ligamentous injuries. Successful surgical outcome correlates with age (Raines et al., 2017).

Fractures

Bone fractures occur when the resistance of bone against the stress being exerted yields to the stress force. Fractures are a common injury at any age but are more likely to occur in children and older persons. Because childhood is a time of rapid bone growth, the pattern of fractures, issues of diagnosis, and methods of treatment in children differ from those for the adult. In children fractures heal much faster than in adults. Consequently, children may not require as long a period of immobilization of the affected extremity as that in an adult with a fracture.

Fracture injuries in children are most often a result of traumatic incidents at home, at school, in a motor vehicle, or in association with recreational activities. Children's everyday activities include vigorous play that predisposes them to injury—climbing, falling down, running into immovable objects, skateboarding, and receiving blows to any part of their bodies by a solid, immovable object.

Aside from automobile accidents or falls from heights, true injuries that cause fractures rarely occur in infancy; thus bone injury in children of that age group warrants further investigation. In any small child, especially under the age of 24 months, radiographic evidence of fractures at various stages of healing is, with few exceptions, a result of nonaccidental injury (child maltreatment). If there is suspicion of child maltreatment, a full skeletal survey is completed to identify multiple fractures and the stage of healing for each fracture. Multiple fractures in varying stages of healing fractures are indicative of child maltreatment (Chauvin-Kimoff et al., 2018). However, any investigation of fractures in infants, particularly multiple fractures, should also include consideration of **osteogenesis imperfecta**.

A distal forearm (radius, ulna, or both) is the most common fracture. The clavicle is also a bone that is commonly broken in childhood, with approximately half of clavicle fractures occurring in children under 10 years of age. Common mechanisms of injury include a fall with an outstretched hand or direct trauma to the bone. In newborns a fractured clavicle may occur with a large newborn and a small maternal pelvis. This may be noted in the first few days after birth by a unilateral Moro reflex or at an early well-child check, when a fracture callus is palpated on the infant's healing clavicle.

Types of Fractures. A fractured bone consists of fragments—the fragment closer to the midline, or the *proximal* fragment; and the fragment farther from the midline, or the *distal* fragment. When fracture

fragments are separated, the fracture is *complete*; when fragments remain attached, the fracture is *incomplete*. The fracture line can be any of the following:

Transverse—Crosswise, at right angles to the long axis of the bone

Oblique—Slanting but straight, between a horizontal and a perpendicular direction

Spiral—Slanting and circular, twisting around the bone shaft

The twisting of an extremity while the bone is breaking results in a spiral break. If the fracture does not produce a break in the skin, it is a *simple*, or *closed*, *fracture*. *Open*, or *compound, fractures* are those with an open wound through which the bone is or has protruded. If the bone fragments cause damage to other organs or tissues (such as the lung or bladder), the injury is said to be a *complicated fracture*. When small fragments of bone are broken from the fractured shaft and lie in the surrounding tissue, the injury is a *comminuted fracture*. This type of fracture is rare in children. The types of fractures seen most often in children are described in Box 53.1 and Figure 53.2.

BOX 53.1 Types of Fractures in Children

Plastic deformation—Occurs when the bone is bent but not broken. A child's flexible bone can be bent 45 degrees or more before breaking. However, if bent, the bone will straighten slowly, but not completely, to produce some deformity but without the angulation seen when the bone breaks. Bends occur most commonly in the ulna and fibula, often in association with fractures of the radius and tibia.

Buckle, or torus, fracture—Produced by compression of the porous bone; appears as a raised or bulging projection at the fracture site. These fractures occur in the most porous portion of the bone near the metaphysis (the portion of the bone shaft adjacent to the epiphysis) and are more common in young children.

Greenstick fracture—Occurs when a bone is angulated beyond the limits of bending. The compressed side bends, and the tension side fails, causing an incomplete fracture similar to the break observed when a green stick is broken.

Complete fracture—Divides the bone fragments. These fragments often remain attached by a periosteal hinge, which can aid or hinder reduction.

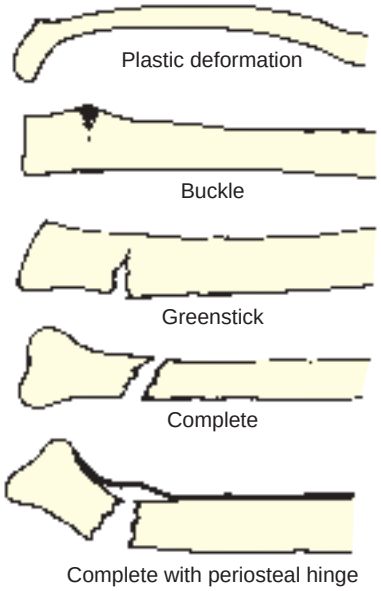

Fig. 53.2 Types of fractures in children.

Immediately after a fracture occurs, the muscles contract and physiologically splint the injured area. This phenomenon accounts for the muscle tightness observed over a fracture site and the deformity that is produced as the muscles pull the bone ends out of alignment. This muscle response must be overcome by traction or complete muscle relaxation (e.g., with anaesthesia) in order to realign the distal bone fragment to the proximal bone fragment.

Growth Plate (Physeal) Injuries. The weakest point of long bones is the cartilage growth plate, or epiphyseal plate. Consequently, this is a common site of damage during trauma. Growth plate fractures are classified with the Salter-Harris classification system (Figure 53.3). Detection of epiphyseal injuries is sometimes difficult, but it is critical. Close monitoring and early treatment, if indicated, are essential to prevent longitudinal or angular growth deformities (or both). Treatment of these fractures may include open reduction and internal fixation to prevent or reduce growth disturbances.

Bone Healing and Remodelling. Bone healing is rapid in growing children because of the thickened periosteum and generous blood supply. When there is a break in the continuity of bone, the osteoblasts are stimulated to maximum activity. New bone cells are formed in immense numbers almost immediately after the injury and, in time, are evidenced by a bulging growth of new bone tissue between the fractured bone fragments. This is followed by deposition of calcium salts to form a callus. Remodelling is a process that occurs in the healing of long bone fractures in growing children. The irregularities produced by the fracture become indistinct as the angles and bone overgrowth are smoothed out, giving the bone a straighter appearance.

Fractures heal in less time in children than in adults. The approximate healing times for a femoral shaft are as follows:

Newborn period—2 to 3 weeks
Early childhood—4 weeks
Later childhood—6 to 8 weeks
Adolescence—8 to 12 weeks

Diagnostic Evaluation. A history may be lacking in some childhood injuries. Infants and toddlers are unable to communicate, and older

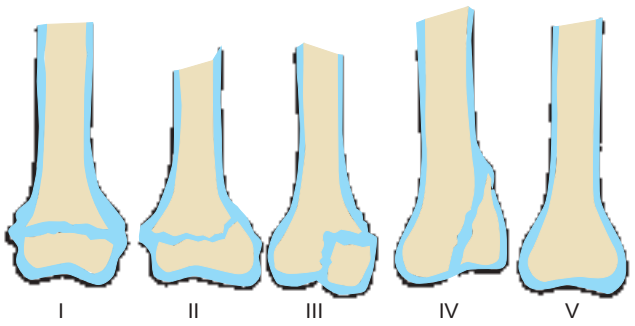

Fig. 53.3 Salter Harris fracture classification. Types of epiphyseal injury in order of increasing risk. The injuries are classified as follows: type I, separation or slip of growth plate without fracture of the bone; type II, separation of growth plate and breaking off of section of metaphysis; type III, fracture of epiphysis extending through joint surface; type IV, fracture of growth plate, epiphysis, and metaphysis; and type V, crushing injury of epiphysis (can be diagnosed only in retrospect). This classification of epiphyseal injuries was developed by orthopedists R. B. Salter and W. R. Harris. (Salter, R. B., & Harris, W. R. [1963]. Injuries involving the physeal plate. *Journal of Bone & Joint Surgery, 45*[3], 587–622. Used with permission. Copyright © 1963 by The Journal of Bone and Joint Surgery, Incorporated.)

children may not volunteer information (even under direct questioning) when the injury occurred during suspicious or forbidden activities. Whenever possible, it is helpful to obtain information from someone who witnessed the injury. In cases of nonaccidental trauma providers may give false information to protect themselves or family members.

The child may exhibit the same manifestations seen in adults (Box 53.2). However, often a fracture is remarkably stable because of an intact periosteum. The child may even be able to use an affected arm or walk on a fractured leg. Because bones have increased vascularity, a soft pliable hematoma may be felt around the fracture site.

Radiographic examination is the most useful diagnostic tool for assessing skeletal trauma. The calcium deposits in bone make the entire structure radiopaque. Radiographic films are taken after fracture reduction and, in some cases, may be taken during the healing process to determine satisfactory progress.

! NURSING ALERT

A fracture should be strongly suspected in a small child who refuses to walk or crawl.

Therapeutic Management. The goals of fracture management are as follows:

- To regain alignment and length of the bony fragments (reduction)
- To retain alignment and length (immobilization)
- To restore function to the injured parts
- To prevent further injury and deformity

The majority of children's fractures heal well, and nonunion is rare. Most fractures are splinted and casted to immobilize and protect the injured extremity. Children with displaced fractures may often require immediate surgical reduction and fixation (internal or external) rather than being immobilized by traction until healing takes place. This practice is more common and holds true for all types of fractures, including femur fractures, although there is variation based on health care provider preference and institutional practice. Some conditions, including open fractures, compartment syndrome, fractures associated with vascular or nerve injury, and joint dislocations that are unresponsive to reduction manoeuvres, require immediate medical attention.

In children the bone fragments are usually realigned and immobilized by traction or by closed manipulation and casting until an adequate callus is formed. The position of the bone fragments in relation to one another influences the rapidity of healing and residual deformity. Weight bearing on lower extremity fractures and active movement for the purpose of regaining function can begin after the fracture site is determined to be stable by the health care provider. The child's natural tendency to be active is usually sufficient to restore normal mobility, and physiotherapy is rarely needed. In most cases children's fractures can be managed by closed reduction and cast immobilization, which is most often provided on an outpatient basis with re-evaluation in 7 to 10 days.

Children are most frequently hospitalized for fractures of the femur and the supracondylar area of the distal humerus, which may require internal fixation and pinning. If simple reduction cannot be achieved or a neurovascular condition is detected after the injury, observation in a hospital setting may be indicated. The trend is to avoid hospitalization. The major methods for immobilizing a fracture (i.e., casting and traction) are described later in the chapter.

Wrist buckle fractures are common in children who fall and extend their arm forward to break the fall. Radius or ulna buckle fractures in children can be treated with a cast or a removable splint for 3 to 4 weeks.

Nursing Care. Nurses are frequently the persons who make the initial assessment of a child with a suspected fracture (see Emergency box: Fracture). The child and parents may be frightened and upset, and the child is often in pain. Therefore, if the child is alert and there is no evidence of hemorrhage, the initial nursing interventions are directed toward calming and reassuring the child and parents so that a more extensive assessment can be more easily accomplished. While remaining calm and speaking in a quiet voice, the nurse can ask the parents and an older child to describe how the injury occurred.

EMERGENCY

Fracture

Determine the mechanism of injury.
Assess the 6 P's (Box 53.3).
Move the injured part as little as possible.
Cover open wounds with a sterile or clean dressing.
Immobilize the limb, including joints above and below the fracture site; do not attempt to reduce the fracture or push protruding bone under the skin.
Use a soft splint (pillow or folded towel) or rigid splint (rolled newspaper or magazine).
The uninjured leg can serve as a splint for a leg fracture if no splint is available.
Reassess neurovascular status.
Apply traction if circulatory compromise is present.
Elevate the injured limb if possible.
Apply cold to the injured area.
Call emergency medical services, or transport child to a medical facility.

The child may arrive with the limb supported in some manner; if not, careful support or immobilization may be provided to the affected site. In the event that the limb is already supported or immobilized, it may be best not to touch the child but to ask them to point to the painful area and to wiggle their fingers or toes. By this time the child may feel relatively safe and will allow someone to gently touch the area just enough to feel the pulse and test for sensation. A child's anxiety is greatly influenced by previous experiences with injury and with health care personnel; they need to be told what will happen and what to do to help. The affected limb need not be palpated, and it should not be moved unless properly splinted. Parental anxiety may be heightened by the child's pain reaction and fear, and possibly other events surrounding the accident; thus it is important to communicate to the parents that the child will receive the necessary care, including pain management.

The Child Requiring a Cast

The completeness of the fracture, the type of bone involved, and the amount of weight bearing influence how much of the extremity must be included in the cast to immobilize the fracture site completely. In most cases the joints above and below the fracture are immobilized

BOX 53.2 Clinical Manifestations of a Fracture

Signs of injury:
- Generalized swelling
- Pain or tenderness
- Diminished functional use of affected part

May be:
- Bruising
- Severe muscular rigidity
- **Crepitus** (grating sensation at fracture site)

Fig. 53.4 Types of casts.

to eliminate the possibility of movement that might cause further displacement at the fracture site. Four major categories of casts are used for fractures: *upper extremity* to immobilize the wrist or elbow, *lower extremity* to immobilize the ankle or knee, *spinal* and *cervical* for immobilization of the spine, and *spica* casts to immobilize the hip and knee (Figure 53.4).

Casts are constructed from gauze strips and bandages impregnated with plaster of paris or, more commonly, from synthetic lighter weight and water-resistant materials (e.g., waterproof liners, fibreglass, and polyurethane resin). Both types of casting produce heat from the chemical reaction activated by water immediately after application. Plaster casts mould closely to the body part, take 10 to 72 hours to dry, have a smooth exterior, and are inexpensive. The newer synthetic casting material is lighter, dries in 30 minutes, and permits earlier weight bearing. The disadvantage of synthetic casting is its inability to mould closely to body parts; its rough exterior, which may scratch surfaces; and increased cost.

Synthetic casts have special advantages for children. They come in different colours and with designs (e.g., cartoons, stripes), and they are lightweight, durable, easy to clean, and relatively water resistant, depending on the type of inner lining used; only those with a Gore-Tex inner lining may be immersed in water without affecting the cast integrity. Bathing with a synthetic cast may be accomplished by covering the cast with a plastic bag; if the synthetic cast gets wet, it should be dried thoroughly. One drawback to immersion is the time necessary to completely dry the cast. The availability of casting materials varies at each clinical setting. The synthetic casts are more difficult to write on.

Cast Application. The child's developmental age should be considered before the cast is applied. For preschoolers who fear bodily harm and fantasize about the loss of an extremity, it may be helpful to use a plastic doll or stuffed animal to explain the procedure beforehand. Toddlers and preschoolers do not have easily defined body boundaries; if an extremity is wrapped in a bandage, cast, or splint, to the young child the extremity often ceases to exist. It is also helpful to explain that some synthetic cast material will become warm but will not burn. During the application of the cast various distraction methods can be used, such as blowing bubbles. In this age group explanations such as "This will help your arm get better" are futile because the child has no concept of causality. To assist with child coping and their overall understanding of the cast application procedure, child life specialists can be consulted.

Before the cast is applied, the extremities are checked for any abrasions, cuts, or other alterations in the skin surface, and rings or other items that might cause constriction from swelling are removed. The skin is protected by a cloth stockinette and cotton batting, which is applied liberally to the area to be casted. Particular attention is given to bony prominences, where areas of pressure, friction, and shearing could be noted. The stockinette is pulled over the ends of the cast to protect the skin from rough edges. Waterproof tape can also be used over the cast edges to create a smoother surface; this is commonly referred to as "petalling" the cast.

Nursing care. The complete evaporation of the water from a hip spica cast can take 24 to 72 hours when older types of plaster materials are used. Fibreglass cast material dries within 30 minutes and is preferred. The cast must remain uncovered to allow it to dry from the inside out. Children in hip spica casts should be turned every 2 hours to minimize prolonged pressure. A regular fan (set on cool) can be helpful in drying wet casts, if needed.

! NURSING ALERT

Heated fans or dryers are not used because they cause the cast to dry on the outside and remain wet beneath or cause burns from heat conduction by way of the cast to the underlying tissue.

A wet plaster cast should be supported by a pillow that is covered with plastic and should be handled by the palms of the hands to avoid indenting the cast, which can create pressure areas. A dry plaster of paris cast produces a hollow sound when it is tapped with the finger. After it has dried, "hot spots" felt on the cast surface or a foul-smelling odour may indicate an infection. This should be reported for further evaluation. The health care provider may decide to make an opening, or a "window," to expose the area in question for evaluation.

During the first few hours after a cast is applied, the chief concern is that the extremity may continue to swell to the extent that the cast becomes a tourniquet, shutting off circulation and producing neurovascular complications (**compartment syndrome**) (Box 53.3). To prevent swelling, elevation of the body part increases venous return. If edema is excessive, casts are bivalved (i.e., cut to make anterior and posterior halves that are held together with an elastic bandage, Velcro, or straps). The cast and the involved extremity need to be observed frequently for neurovascular integrity and any signs of compromise. Permanent muscle and tissue damage can occur within 6 to 8 hours.

BOX 53.3 Compartment Syndrome Evaluation

Assess the extent of injury—"the 6 P's":

1. **Pain:** Severe pain that is not relieved by analgesics or elevation of the limb, movement that increases pain
2. **Pulselessness:** Inability to palpate a pulse distal to the fracture or compartment
3. **Pallor:** Pale appearing skin, poor perfusion, capillary refill greater than 3 seconds
4. **Paresthesia:** Tingling or burning sensations
5. **Paralysis:** Inability to move extremity or digits
6. **Pressure:** Involved limb or digits may feel tense and warm; skin is tight, shiny; pressure within the compartment is elevated

See Nursing Skills on Evolve: Monitoring Neurovascular Status for the Child in Traction or a Cast.

! NURSING ALERT

Compartment syndrome is a serious complication that results from compression of nerves, blood vessels, and muscle inside a closed space. This injury may be devastating, resulting in tissue death, and thus requires emergency treatment (fasciotomy). The six P's of ischemia from a vascular, soft tissue, nerve, or bone injury should be included in an assessment of any injury (see Box 53.3).

! NURSING ALERT

Observations such as pain (unrelieved by pain medication 1 hour after administration), changes in sensation, swelling, discoloration (pallor or cyanosis) of the exposed skin, decreased pulses, decreased temperature, or the inability to move the distal exposed part(s) should be reported to the health care provider immediately.

When an extremity that has sustained an open fracture is casted, a window is often left over the wound area to allow for observation and for dressing of the wound or a splint is used temporarily to allow for observation before casting. For the first few hours after surgery, there may be substantial bleeding that will soak through the cast. Periodically, the circumscribed blood-stained area should be outlined with a ballpoint pen or pencil and the time indicated to provide a guide for assessing the amount of bleeding.

Appropriate cast care guidelines for the child's caregiver are necessary before discharge. Parents need instructions on appropriate cast care and on monitoring for signs and symptoms that indicate the cast is too tight or is too loose (see Family-Centred Care box: Cast Care).

Nurses can help families adapt the child's home environment to meet the temporary encumbrance of a large cast or one that restricts the child's mobility (e.g., a long-leg or spica cast) (Figure 53.5). Commonplace situations can become problematic (e.g., transporting a child safely and comfortably in a car). Standard seat belts and car seats may not be readily adapted for use by children in some casts and may require special seating or a specialized seatbelt adaptive device called an "EZ on vest." The adaptations must meet specific Canadian safety regulations (see Additional Resources at the end of this chapter). Alterations to standard car seats to accommodate the cast are not recommended because the structure may be adversely altered and fail to properly restrain the child.

Parents need to be taught the proper care of the cast (or immobilization device) and helped to devise means for maintaining cleanliness. With a hip spica cast, a superabsorbent disposable diaper may be tucked beneath the entire perineal opening of the cast. A larger diaper can be applied and fastened over the small diaper and cast to hold the smaller diaper in place.

For tightly fitting casts, transparent film dressings can be cut into strips with one edge applied to the cast edge and the other directly to the perineum; this forms a continuous waterproof bridge between the perineum and the cast to prevent leakage. An additional advantage to the use of this transparent dressing is that it keeps both the skin and the cast dry while allowing for observation of skin beneath the dressing.

Older infants and small children may stuff bits of food, small toys, or other items under the cast; parents should be alerted to this possibility so that suitable preventive measures can be initiated.

FAMILY-CENTRED CARE

Cast Care

Keep the casted extremity elevated on pillows or similar support for the first day, or as directed by the health care provider.

Avoid denting the plaster cast with fingertips (use palms of hand to handle) while it is still wet to avoid creating pressure points (if wet plaster is used).

Explore the plaster cast to air until dry.

Observe the extremities (fingers or toes) for any evidence of swelling or discoloration (darker or lighter than a comparable extremity), and contact the health care provider if noted.

Check movement and sensation of the visible extremities frequently.

Follow the health care provider's orders regarding any restriction of activities.

Restrict strenuous activities for the first few days.

- Engage in quiet activities but encourage use of muscles.
- Move the joints above and below the cast on the affected extremity.

Encourage frequent rest and breaks for a few days, keeping the injured extremity elevated while resting.

Avoid allowing the affected limb to hang in a dependent position for any length of time.

- Keep an injured upper extremity elevated (e.g., in a sling) while upright.
- Elevate a lower limb when sitting and avoid standing for too long.

Do not allow the child to put anything inside the cast. Keep small items that might be placed inside the cast away from small children.

Keep a clear path for ambulation. Remove toys, hazardous floor rugs, pets, or other items the child might stumble over.

Use crutches appropriately if lower limb fracture requires non–weight bearing on affected extremity.

The crutches should fit properly, have a soft rubber tip to prevent slipping, and be well padded at the axilla.

With crutch walking, the child's body weight is supported on the hand grips, not the axilla.

Feeding the infant in a hip spica cast presents challenges in positioning. Very young newborns can be fed in the supine position with the head elevated. With the newborn's hips and legs supported on a pillow at the side, the parent can cuddle the newborn in their arms during feeding. A somewhat similar position can be used for breastfeeding (i.e., with the newborn supported on pillows or held in a "football" hold

Fig. 53.5 Spica cast with hip abductor. Note casts on doll as well.

facing the breastfeeding parent with the legs behind them). An alternative position is to hold the newborn upright on the caregiver's lap with the legs of the child astride the adult's leg.

Children in spica casts may find the prone position easier for self-feeding from a small table placed next to the dining table; alternatively they may manage a semi-sitting position in a bed or wheelchair. The use of a conventional toilet is almost impossible. A bedside toilet can be adapted for use. Small bedpans or other containers offer alternatives to a toilet for elimination. The nurse may suggest waterproofing methods, using plastic wraps that can help with elimination and showers. Baths are possible only if the plaster cast is kept out of the water and covered to prevent it from becoming wet.

Cast Removal. Cutting the cast to remove it or to relieve tightness is frequently a frightening experience for children. They fear the sound of the cast cutter and are terrified that their flesh, as well as the cast, will be cut. The oscillating blade vibrates rapidly back and forth and will not cut when placed *lightly* on the skin. Children have described it as producing a "tickly" sensation. The vibration also generates heat that may be felt by the child. Both of these feelings should be explained.

Preparation for the procedure will help reduce anxiety. Child life specialists should be utilized when possible. Many young children come to regard the cast as part of themselves, which intensifies their fear of removal (Figure 53.6). They need continual reassurance that all is going well and that they are helping things go well. After the cast is removed, the parents and child should be given the option of keeping it. If the cast has been in place for a lengthy period, decreased muscle mass will be noted. The child should be reassured that resuming exercise and routine activities will return function and appearance (provided there was no significant trauma beforehand).

After the cast is removed, the skin surface will be caked with desquamated skin and sebaceous secretions. Simple soaking in a bathtub is usually sufficient for their removal, but several days may be required to eliminate the accumulation completely. Application of oil or skin lotion may provide comfort. The parents and child should be instructed not to pull or forcibly remove this material with vigorous scrubbing because it may cause excoriation and bleeding.

Fig. 53.6 Young children usually adapt well to a cast but often fear the removal.

The Child in Traction

The ever-changing health care arena has witnessed the demise of many long-term treatments involving lengthy hospitalization; one such change is in the area of traction. Most balanced skeletal traction is applied in children after a severe or complex injury to allow physiological stability, align bone fragments, and permit closer evaluation of the injured site. Newer technology has produced orthopedic fixation devices that allow partial or full mobility, thus preventing long-term immobilization and its consequences. In many situations, surgical intervention may be carried out within a matter of days; thus skeletal traction devices described here may be used infrequently in pediatrics.

Purposes of Traction. The six primary purposes of traction are as follows:

1. To fatigue the involved muscles and reduce muscle spasm so that bones can be realigned
2. To position the distal and proximal bone ends in desired realignment to promote satisfactory bone healing
3. To immobilize the fracture site until realignment has been achieved and sufficient healing has taken place to permit casting or splinting
4. To help prevent or improve contracture deformity
5. To provide immobilization of specific areas of the body
6. To reduce muscle spasms (rare in children)

The three essential components of traction management are traction, countertraction, and friction (Figure 53.7). To reduce or realign

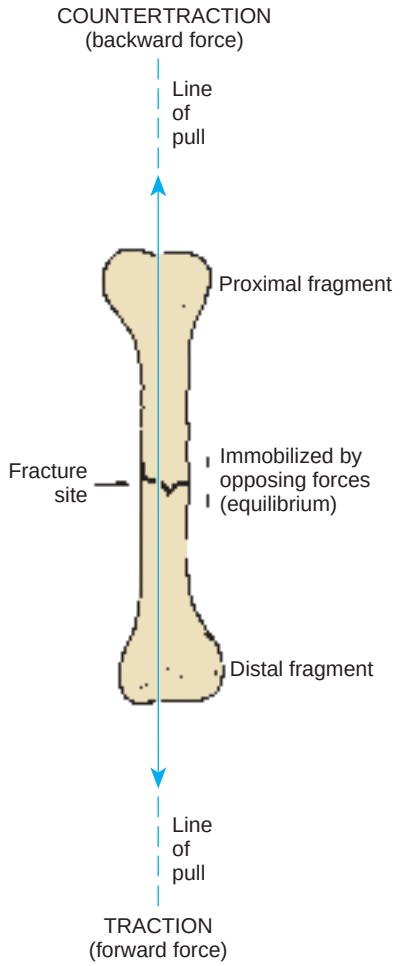

Fig. 53.7 Application of traction for maintaining equilibrium.

a fracture site, *traction* (forward force) is produced by attaching weight to the distal bone fragment. Body weight provides *countertraction* (backward force), and the patient's contact with the bed constitutes the *frictional* force. These forces are used to align the distal and proximal bone fragments by adjusting the line of pull upward or downward and adducting or abducting the extremity.

To attain equilibrium, the amount of forward force is adjusted by adding weight to or subtracting weight from the traction, and countertraction can be increased by elevating the foot of the bed to create a greater gravitational pull to the backward force.

The *all-or-none law*, characteristic of muscle contractibility, influences the complete relaxation. When muscle is stretched, muscle spasm ceases and permits the realignment of the bone ends. The continuous maintenance of traction is important during this phase because releasing the traction allows the normal contracting ability of the muscle to again cause a malpositioning of the bone ends.

The traction pull to some degree immobilizes the fracture site; however, adjunctive immobilizing devices such as splints or casts may also be used with skeletal traction. In injuries in which there is severe soft-tissue swelling or vascular and nerve damage, traction may be used until these complications have been resolved and it is safe to apply a cast or to perform surgical fixation.

Types of Traction. The pull needed for traction can be applied to the distal bone fragment in several ways (Box 53.4). The type of traction applied is determined primarily by the child's age, the condition of the soft tissues, and the type and degree of displacement of the fracture. Fractures most commonly treated by the application of traction are those involving the femur and vertebrae. The major types of traction for specific fractures are discussed in the following sections.

Fractures of the femur can often be reduced with immediate application of a hip spica cast in young children. When traction is required, several types may be used, based on the initial assessment.

Bryant traction; also known as *Gallows traction*, is a type of running traction in which the pull is in only one direction. Skin traction is applied to the legs, which are flexed at a 90-degree angle at the hips. The child's trunk (with the buttocks raised slightly off the bed) provides countertraction. Bryant traction is often used to treat femoral shaft fractures in young children. Constant traction reduces muscle spasms while maintaining proper alignment of the affected limb.

Buck extension traction (Figure 53.8) is a type of skin traction with the legs in an extended position. Except for fracture cases, turning from side to side with care is permitted to maintain the involved leg alignment. Buck extension is used primarily for short-term immobilization, providing a light traction force preoperatively for conditions involving dislocated hips or contractures or for bone deformities such as Legg-Calvé-Perthes disease. Buck traction may be accomplished with either skin straps or a special foam boot designed for traction.

BOX 53.4 Types of Traction

Manual traction—Applied to the body part by the hands placed distal to the fracture site. Manual traction may be provided during application of a cast but more commonly when a closed reduction is performed.

Skin traction—Applied directly to the skin surface and indirectly to the skeletal structures. The pulling mechanism is attached to the skin with adhesive material or an elastic bandage. Both types are applied over soft, foam-backed traction straps to distribute the traction pull.

Skeletal traction—Applied directly to the skeletal structure by a pin, wire, or tongs inserted into or through the diameter of the bone distal to the fracture.

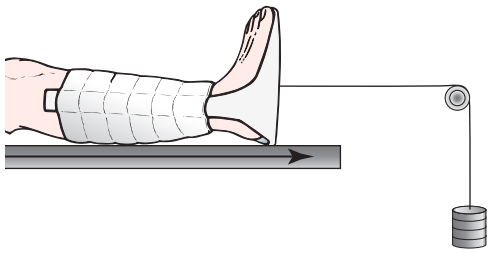

Fig. 53.8 Buck extension traction.

Russell traction uses skin traction on the lower leg and a padded sling under the knee. Two lines of pull, one along the longitudinal line of the lower leg and one perpendicular to the leg, are produced. This combination of pulls allows realignment of the lower extremity and immobilizes the hip and knee in a flexed position. The hip flexion must be kept at the prescribed angle to prevent fracture malalignment, since there is no direct support under the fracture and the skin traction may slip. Special nursing measures include carefully checking the position of the traction so that the amount of desired hip flexion is maintained and damage to the common peroneal nerve under the knee does not produce footdrop.

A common type of skeletal traction used for unstable fractures is *90-degree–90-degree traction* (90-90 traction) (Figure 53.9). The lower leg is supported by a boot cast or a calf sling, and a skeletal Steinmann pin or Kirschner's wire is placed in the distal fragment of the femur, resulting in a 90-degree angle at both the hip and the knee, creating a strong and constant pull. From a nursing standpoint, this traction facilitates position changes, toileting, and prevention of complications related to traction.

Balanced suspension traction may be used with or without skin or skeletal traction. Unless used with another traction, the balanced suspension merely suspends the leg in a desired flexed position to relax the hip and hamstring muscles and does not exert any traction directly on a body part. A *Thomas splint* extends from the groin to midair above the foot, and a *Pearson attachment* supports the lower leg. When the child is lifted off the bed, the traction lifts with the child without loss of alignment. This traction requires very careful checking of splints and ropes to make certain that no slippage or fraying has occurred. The traction is of great value in an older and heavier child when it is essential to lift the patient for care.

The cervical area is a vulnerable site for flexion or extension injuries to muscle, vertebrae, or the spinal cord. Pediatric cervical spine trauma is often related to motor vehicle accidents, falls and sports injuries

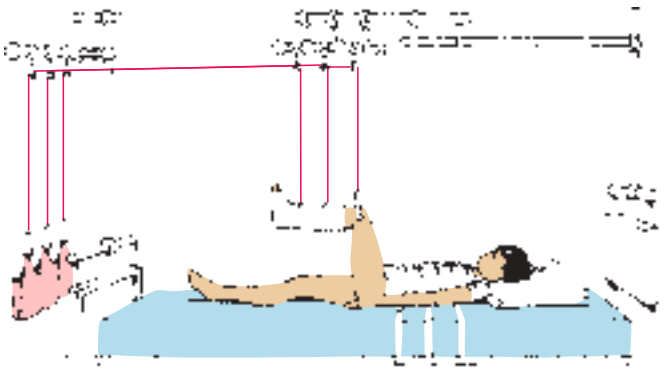

Fig. 53.9 "90-90" traction.

(Aiyer & Moore, 2019). Cervical muscle trauma without other complications is treated with a cervical hard or soft collar to offload the pressure at the site of injury while stabilizing the cervical spine to prevent further trauma and allow for healing. The use of a soft versus hard collar is controversial, but generally is dependent on the severity of injury and potential for further injury (Aiyer & Moore, 2019). When a child displaces or fractures a cervical vertebra, it may be necessary to reduce and immobilize the site with cervical skeletal traction. The spinal cord runs through the intravertebral canal, and dislocation or fracture of the vertebrae can also cause spinal cord injury. Nursing assessment of neurological function is essential to prevent further injury during the application and use of cervical skeletal traction.

Most cervical traction is accomplished with the use of a *halo brace* or *halo vest* (Figure 53.10). This device consists of a steel halo attached to the head by 6 to 8 screws inserted into the outer skull; several rigid bars connect the halo to a vest that is worn around the chest, thus allowing for greater mobility of the rest of the body while avoiding cervical spinal motion altogether. If the injury has been limited to a vertebral fracture without neurological deficit, a halo brace can be applied to permit earlier ambulation.

Complications of cervical traction include cranial nerve deficits, pain (pin site or generalized headache), pin site displacement, pin site infection, and pin loosening. Incidents of complications are higher in children than in adults, in those with an underlying medical complexity, and in those receiving active correction with pin site fixation (Kazmers et al., 2016).

As the neck muscles fatigue with constant traction pull, the vertebral bodies gradually separate so that the cord is no longer pinched between the vertebrae. Immobilization until fracture healing or surgical fixation can occur is an essential goal of cervical traction. If immobilization is required in an infant or young child, the Minerva cast is preferred.

Nursing Care. To assess the child in traction, it is essential to know the purpose for which the traction is applied and to understand the basic principles of traction. Regular assessment of both the child and the traction apparatus is required (see Guidelines box: Traction Care). Many of the nursing issues associated with a child in traction are related to immobility or improper maintenance and care of the traction device, which may lead to complications. Modifying the child's diet, encouraging fluids, increasing fibre, and offering a mild stool softener may be necessary to prevent constipation.

Fig. 53.10 Halo vest.

GUIDELINES

Traction Care

Understand Therapy

Understand the purposes of traction.
Understand the function of traction in each specific situation.

Maintain Traction

Check desired line of pull and relationship of distal fragment to proximal fragment. Check whether the fragment is being directed upward, adducted, or abducted.
Check function of each component.
- Position of bandages, frames, splints, specialized boot
- Ropes—In centre track of pulley, taut, no fraying, knots tied securely
- Pulleys—In original position on attachment bar; have not been displaced from original site
- Wheels freely moveable
- Weights—Correct amount of weight, hanging freely, in safe location

Check bed position; the head or foot should be elevated as directed for desired amount of pull and countertraction.
Do not remove skeletal traction or adhesive traction straps on skin traction.

Maintain Alignment

Observe for correct body alignment with emphasis on alignment of shoulder, hip, and leg.
Check after the child has moved.
Maintain correct angles at joints.

Skin Traction

Replace nonadhesive straps or elastic bandage on skin traction when permitted or absolutely necessary, but make certain that traction on limb is maintained by someone during procedure.
Assess straps or bandages to ascertain whether they are correctly applied (diagonal or spiral), not too loose or too tight, which could cause slippage and malalignment of traction.
Assess the traction boot to ensure it has not slipped and is not causing compression of the foot, thus impairing the circulation.

Skeletal Traction

Check pin sites frequently for signs of migration, loosening, bleeding, inflammation, or infection.
Cleanse and dress pin sites per institution protocol or as ordered.
Apply topical antiseptic or antibiotic to pin sites daily as ordered.
Cover ends of pins with protective rubber or padding to prevent the child's being scratched by the pin.
Note pull of traction on the pin; pull should be even.
Check pin screws to be certain that screws are tight in metal clamp that attaches the traction apparatus to the pin.

Prevent Skin Breakdown

Provide alternating-pressure mattress underneath hips and back.
Make total-body skin checks for redness or breakdown, especially over areas that receive the greatest pressure.
Wash and dry skin at least daily.
Inspect pressure points daily or more often if risk of breakdown is observed.
Use a skin breakdown assessment scale such as the Modified Braden Q.
Stimulate circulation with gentle massage over pressure areas.
Change position at least every 2 hours to relieve pressure.
Encourage increased intake of oral fluids.
Provide and encourage the patient to eat a balanced diet, including vegetables and fruits.

Prevent Complications

Check pulses in the affected area and compare with pulses in the contralateral site.

Assess circular dressings for excessive tightness.

Assess restrictive bandages or devices used to maintain traction on the affected limb.

- Make certain that they are not too loose or too tight.
- Remove periodically and check for pressure areas.

Encourage deep breathing or use of incentive spirometry.

Note any neurovascular changes by monitoring the 6 P's (see Box 53.3).

Take immediate action to correct a complication or report to the primary health care provider if neurovascular changes are found.

Record findings of neurovascular changes.

Carry out passive, active, or active-with-resistance exercises of uninvolved joints.

Note if any tightness, weakness, edema, or contractures are developing in uninvolved joints and muscles.

Take measures to correct or prevent further development of weakness, such as applying footboard or foot orthoses to prevent footdrop.

For cervical traction, regular cranial nerve assessments and spinal cord/dermatome testing (sharp/dull) are required. Any and all changes from baseline should be reported to the health care provider immediately.

When indicated by the attending health care provider, the nurse may remove nonadhesive skin traction. In these cases intermittent traction is released periodically and reapplied as ordered. A child may have several types of traction at one time; each one must be assessed separately to avoid complications.

! NURSING ALERT

Skeletal traction is never released by the nurse (except under direct supervision by the health care provider). This precaution includes not lifting the weights that are applying traction (e.g., for moving the child in bed, for repositioning).

In addition to routine skin observation and care, the child in skeletal traction will need special skin care at the pin site according to hospital policy or health care provider preference. Pin sites should be frequently assessed and cleaned to prevent infection. Pin site infection is a common and significant complication after external fixation insertion. Health care organizations have their own pin care protocol with cleaning using an antiseptic cleaner or just normal saline. As well, some protocols have the nurse removing adherent pin scabs and others not. The frequency of cleaning varies.

When the child is first placed in traction, an increase in discomfort is common as a result of the traction pull fatiguing the muscle. Orthopedic conditions are associated with a higher-than-average number of painful events and a higher percentage of bodily symptoms than other common conditions. IV opioids, including analgesics and muscle relaxants, help during this phase of care and should be administered liberally.

! NURSING ALERT

For skeletal traction to be effective, ensure that the weights are hanging freely at all times. The specific nursing responsibilities for the patient in traction are outlined in the Guidelines box: Traction Care.

Distraction

Unlike *traction*, which helps bones realign and fuse properly, *distraction* is the process of separating opposing bone to encourage regeneration of new bone in the created space to correct leg length discrepancies, which can be either due to congenital disease (achondroplasia, arthrogryposis, Blount disease) or acquired conditions (posttraumatic growth arrest, rickets, osteogenesis imperfecta) (Young, 2017).

External Fixation. Monolateral, Taylor Spatial Frame, and Ilizarov external fixator (IEF) are common external fixation devices. The IEF uses a system of wires, rings, and telescoping rods that permits limb lengthening to occur by manual distraction (Figure 53.11). In addition to lengthening bones, the device can be used to correct angular or rotational defects or to immobilize fractures. The device is attached surgically by securing a series of external full or half rings to the bone with wires. External telescoping rods connect the rings to each other. Manual distraction is accomplished by manipulating the rods to increase the distance between the rings. A percutaneous **osteotomy** is performed when the device is applied to create a "false" growth plate. A special osteotomy or corticotomy involves cutting only the cortex of the bone while preserving its blood supply, bone marrow, endosteum, and periosteum. Capillary blood flow to the transected area is essential for proper bone growth. Cut bone ends typically grow at a rate of 1 cm/month. The IEF can result in up to a 15-cm gain in length. A new technology yielding comparable outcomes to the IEF is the intramedullary leg lengthening PRECICE nail system. This system facilitates distraction using magnetically driven nails to correct leg length discrepancy (Young, 2017).

Nursing Care. Success of external fixation devices depends on the child's and family's ability to collaborate with the health care team. Before surgery they must be fully informed of the appearance of the device, how it accomplishes bone growth and limits mobility, and of home and follow-up care. Children need to be involved in learning to adjust the device to accomplish distraction. Children, as well as parents, should be instructed in thorough hand hygiene and pin care, including observation for infection and loosening of the pins. Cleaning routines for the pin sites vary among health care providers but should not traumatize the skin. For example, the pins in IEF are thin and the

Fig. 53.11 Child with Ilizarov external fixator (right leg) during physiotherapy on parallel bars.

child can go directly into a shower to clean the device and pins, if approved by the health care provider.

Children who participate actively in their care report less discomfort. Because the device is external, the child and family need to be prepared for the reactions of others and helped to camouflage it with appropriate apparel, such as wide-legged pants that close with self-adhering fasteners around it. A loose sock or stockinette may also be used over the device to help camouflage it. Partial weight bearing is allowed (see Figure 53.11), and the child learns to walk with crutches. Alterations in activity include modifications at school and in physical education. Full weight bearing is not allowed until the distraction is completed and bone consolidation has occurred. Follow-up care is essential to maintaining appropriate distraction until the desired leg length is achieved. The device is removed surgically after the bone has consolidated, and the child may need to use crutches for 4 to 6 weeks after removal until involved muscles have reconditioned.

Amputation

A child may be born with the congenital absence of a body part, have a traumatic loss of an extremity, or need a surgical amputation for a pathological condition such as osteosarcoma (see discussion later in chapter). With today's surgical technology and the quick thinking of bystanders who save a traumatically amputated body part, children have had fingers and arms reattached with variable degrees of functional use regained.

! NURSING ALERT

For an amputated limb or body part that may be reattached, do the following:

1. Rinse limb gently with normal saline.
2. Loosely wrap limb in sterile gauze.
3. Place wrapped limb in a watertight bag.
4. Cool (without freezing) bag in ice water (do not pack in ice because this may harm tissue).
5. Label with child's name, date, and time, and transport with the child to the hospital.

Surgical amputation or the surgical repair of a permanently severed limb focuses on constructing an adequately nourished residual limb. A smooth, healthy, padded stump, free of nerve endings, is important in prosthesis fitting and subsequent ambulation. Once the stump skin has healed and when there is no vascular or neurological deficit, preparation for donning a prosthesis may begin through stump shaping.

Nursing Care. *Stump shaping* is performed postoperatively with special elastic bandaging using a figure-8 bandage, which applies pressure in a cone-shaped fashion. This technique decreases stump edema, controls hemorrhage, and aids in developing the desired contours so that the child will bear weight on the posterior aspect of the skin flap rather than on the end of the stump. Stump elevation may be used during the first 24 hours, but after this time the extremity should not be left in this position because contractures will develop in the proximal joint and seriously hamper ambulation. Monitoring proper body alignment will further decrease the risk of flexion contractures. Exercises such as stretching are helpful for prevention of flexion contractures for all children.

For older children and adolescents, arm exercises (as well as parallel bars, which are used in prosthesis-training programs) help build up the arm muscles necessary for walking with crutches. Full range-of-motion exercises of joints above the amputation must be performed several times daily using active and isotonic exercises. Younger children are often spontaneously active and require little encouragement.

Depending on the child's age, children or their parents will need to learn stump hygiene, including careful soap-and-water washing every day and checking for skin irritation, breakdown, or infection. A tube of stockinette or powder is used to slide the prosthesis on more easily. Skin must be checked carefully every time the prosthesis is removed, and prosthesis tolerance time is slowly titrated up to prevent skin breakdown.

For children who have had an amputation, *phantom limb sensation* is an expected experience because the nerve–brain connections are still present. Gradually these sensations fade, although in many amputees they persist for years. Preoperative discussion of this phenomenon will aid a child in understanding these "unusual feelings" and in not hiding the experiences from others. Limb pain, especially pain that increases with ambulation, should be evaluated for the possibility of a neuroma at the free nerve endings in the stump, or other issues such as a poorly fitting prosthesis or joint instability. To assist with coping, a child life specialist or social worker should be consulted by the health care team.

HEALTH CONCERNS RELATED TO SPORTS PARTICIPATION

Every sport has the potential for injury to the participant—whether the youngster engages in serious competition or participates for enjoyment. Serious injury occurs most often during rough contact sports or to persons who are not physically prepared for the activity. Injuries also occur to children or adolescents when their body is not suited to the sport, when their muscles and body systems (respiratory and cardiovascular) are not conditioned to endure physical stress, or when they lack the insight and judgement to recognize that an activity exceeds their physical abilities. More injuries occur during recreational sports participation than during organized athletic competition.

Acute overload injuries are those that occur suddenly during an activity and produce immediate symptoms. A blow or overstretching, twisting, or sudden stress to tissues can cause these injuries. For descriptions and management of traumatic injuries, see Chapter 54.

Overuse Syndromes

To excel in sports, the young athlete is forced to train longer, harder, and earlier in life than previously. The rewards are an increased level of fitness, better performances, faster times, and the satisfaction of attaining a personal goal. However, the risk of overuse injury is always present and is related to several factors: training errors, muscle–tendon imbalance, anatomical malalignment, incorrect footwear or playing surface, an associated disease state, and growth. Growing numbers of young people participate in organized sports, resulting in an increase in overuse injuries.

The risk for overuse injury is always present and can be related to several factors, including training errors, muscle/tendon imbalance, anatomical malalignment (e.g., femoral anteversion, excessive lumbar lordosis, tibial torsion), incorrect footwear or playing surface, an associated disease state, and growth (growth cartilage is less resistant to microtrauma). Persistent pain in athletes is often associated with overuse injury, which can occur at any level of athletic participation. The common feature in overuse injuries is the repetitive microtrauma that occurs to a particular anatomical structure. Performing the same movements repeatedly can cause several types of injury:

1. **Frictional**, or rubbing of one structure against another
2. **Tractional**, or repeated pull on a ligament or tendon
3. **Cyclic**, or repetitive loading of impact forces (stress fractures)

The end result is inflammation of the involved structure with symptoms of pain, tenderness, swelling, and disability.

Stress Fractures. Stress fractures occur as a result of repeated muscle contraction and are seen most often in repetitive weight-bearing sports such as running, gymnastics, and basketball. They occur less often in swimmers. The most common symptoms are a sharp, persistent, progressive pain or a deep, persistent, dull ache located over the bone. Sometimes there is pain on impact (heel strike), but the most important clinical sign is pain over the involved bony surface. Diagnosis is established on the basis of clinical observation, but occasionally a bone scan is performed.

Therapeutic management. Inflammation is common in all overuse syndromes, and management is directed toward rest or alteration of activities, physiotherapy, and medication. Rest is the primary therapy and is usually interpreted as reduced activity and the use of alternative exercise—not bed rest or immobilization with casting. The primary purpose is to alleviate the repetitive stress that initiated the symptoms. It is important to keep the youngster mobile, and training can be continued. Alternative exercise that maintains conditioning without aggravating the injury is selected. For example, pool running (treading water in the deep end of a pool) is an excellent alternative to running. Pool running involves the same movements as running without weight bearing.

Other therapies include **cryotherapy**, cold whirlpools, and sometimes taping, bracing, splinting, or other orthoses. Treatment is specific to the injury. Nonsteroidal anti-inflammatory drugs (NSAIDs) are prescribed to reduce pain and inflammation. Topical medications are of questionable value.

Nursing care. Nurses' involvement in children's sports activities often entails preparation and evaluation for activities, prevention of injury, treatment of injuries, and rehabilitation after injury. Selecting an appropriate sport for both recreation and competition is a joint effort of the youngster, parents, and health care providers. The best approach to counselling children and parents regarding sports participation is to encourage activities that are most likely to provide pleasure and physical benefits throughout childhood and into adulthood. Exposure to a variety of activities is better for young children than limiting them to one sport. Parents should be cautioned against overcommitting children to sports activities so that they have time for other activities.

When children sustain athletic injuries, nurses are often responsible for instructions in care. The instructions (e.g., schedule for appointments, application of ice, and any restrictions in activity) should be clear and accompanied by written directions. The importance of taking medications as prescribed should also be emphasized, especially if medications are needed for an extended period and if adherence is an issue. Medications given an hour before practice or competition may be advantageous to children who are continuing their activities.

Prevention of sports injuries is the most important aspect of athletic programs. Children should be suited to the activity, and the environment and equipment must be safe. Children should be prepared for the sport, especially if it requires strenuous or continuous physical exertion. Nurses, coaches, and athletic trainers must collaborate to ensure that safety measures are implemented. Stretching exercises, warm-up and cool-down activities, and appropriate training are requirements for safe participation. Protective measures such as pads, taping, and wrapping are also important to prevent injury.

CONGENITAL DEFECTS

Some skeletal defects may be diagnosed at birth or within days, weeks, or months after birth. In other cases the deviation may be difficult to detect without careful inspection. It is imperative that nurses become acquainted with signs of these defects and understand the principles of therapy in order to direct others in the care and management of these children.

Arthrogryposis

Arthrogryposis is a term used to describe a number of rare, congenital conditions that are characterized by stiff joints and abnormally developed muscles. It is also called *arthrogryposis multiplex congenital*, or *amyloplasia*. The incidence is likely 1 in every 5 000 to 10 000 live births (Horstmann & Davidson, 2020). Arthrogryposis is not considered to be an inherited condition. While the exact etiology is unknown, there are several proposed theories: obstruction to uterine movement during pregnancy, an early viral infection during fetal development, and the result of the central nervous system or muscular system not developing appropriately.

Children experience clinical manifestations differently. *Amyoplasia*, also known as *classic arthrogryposis*, is a sporadic symmetrical disorder that includes the following symptoms: internally rotated and adducted shoulders, extended elbows, pronated forearms, flexed fingers and wrists, dislocated hips, feet with severe equinovarus contractures, and extended knees. The involved muscles are hypoplastic and fibrotic and patients often have midfacial hemangioma. Intelligence is usually normal (Horstmann & Davidson, 2020).

Diagnostic Evaluation. To diagnose the condition, the health care provider takes a comprehensive medical history and performs a careful physical examination. Radiography and other diagnostic imaging, blood work, and muscle biopsy may also be used.

Therapeutic Management. Treatment consists of physiotherapy and occupational therapy to increase flexibility and strengthen joints. Orthopedic surgery might be needed to increase joint function, and the child will likely have some persistent muscle and joint limitations caused by the underlying condition that may improve substantially with treatment. This condition is not progressive and will not get worse as the child gets older (Horstmann & Davidson, 2020).

Achondroplasia

Achondroplasia is a bone disorder that is genetic; it is the most common type of dwarfism. The incidence is 1 in 20 000 infants. The arms and legs are short in proportion to the body length, and the head is often large and the trunk of normal size. The genetic mutation causes abnormal cartilage formation (Ireland et al., 2014).

The average height of adult males with achondroplasia is 118 to 145 cm, and the average height of adult females with achondroplasia is 112 to 136 cm.

The most common clinical manifestations are as follows:

- Shortened arms and legs, with the upper arms and thighs more shortened than the forearms and lower legs
- Large head size with prominent forehead and a flattened nasal bridge; crowded or misaligned teeth
- Curved lower spine (*lordosis*), which may lead to *kyphosis*, or the development of a small hump near the shoulders, that usually goes away after the child begins walking; small vertebral canals bones, which may lead to spinal cord compression in adolescence. Occasionally children with achondroplasia die suddenly in infancy or early childhood in their sleep because of compression of the upper end of the spinal cord, which interferes with breathing.
- Bowed lower legs
- Flat feet that are short and broad
- Extra space between the middle and ring fingers (also called a *trident hand*)
- Poor muscle tone and loose joints
- Frequent middle ear infections, which may lead to hearing impairment
- Normal intelligence

- Delayed developmental milestones, such as walking (which may occur between 18 and 24 months instead of around 1 year of age) (Hoover-Fong et al., 2020; Ireland et al., 2014)

In some cases, the child inherits the achondroplasia from a parent with the condition, but most cases are caused by a new genetic mutation. This means the parents are of average height and do not have the abnormal gene. However, people with achondroplasia have a 50% chance of passing the gene to their child, resulting in the condition. Achondroplasia can be diagnosed before birth by fetal ultrasound or after birth by complete medical history and physical examination. DNA testing is available before birth to confirm fetal ultrasound findings for parents who are at increased risk for having a child with achondroplasia (Hoover-Fong et al., 2020).

Therapeutic Management. Some children may be treated with a growth hormone, although this has little effect on the height of the child. In some very specific cases, surgeries to lengthen legs may be considered (see Distraction above). It is important to check for bone abnormalities, especially in the back region, as these can cause respiratory difficulties and leg pain. Kyphosis may need to be corrected through surgery if it does not correct itself when the child starts to walk. Surgery may also be done to help prevent bowing of the legs.

Developmental Dysplasia of the Hip

The broad term *developmental dysplasia of the hip (DDH)* describes a spectrum of disorders related to abnormal development of the hip that may develop at any time during fetal life, infancy, or childhood, in which there is a shallow acetabulum, subluxation, or dislocation. The incidence of hip instability of some kind is approximately 10 per 1 000 live births. The incidence of frank dislocation or a dislocatable hip is 1 to 1.5 per 1 000 live births (Sankar et al., 2020). Girls are more commonly affected (80%), and there is a positive family history in approximately 12 to 33% of affected children (Sankar et al., 2020).

Pathophysiology. Predisposing factors associated with DDH may be divided into three broad categories:

1. Physiological factors, which include maternal hormone secretion and intrauterine positioning
2. Mechanical factors, which involve breech presentation, multiple fetuses, oligohydramnios, and large infant size (other mechanical factors may include continued maintenance of the hips in adduction and extension, which will in time cause a dislocation)
3. Genetic factors, which entail a higher incidence of DDH in siblings of affected infants, and an even greater incidence of recurrence if a sibling and one parent were affected

Some experts categorize DDH into two major groups: (1) *idiopathic*, in which the infant is neurologically intact; and (2) *teratological*, which involves a neuromuscular defect such as arthrogryposis or myelodysplasia. The teratological forms usually occur in utero and are much less common.

Three degrees of DDH are illustrated in Figure 53.12.

1. **Acetabular dysplasia**—The mildest form of DDH, in which there is neither subluxation nor dislocation. There is a delay in acetabular development evidenced by osseous hypoplasia of the acetabular roof that is oblique and shallow, with cartilaginous roof that is comparatively intact. The femoral heal remains in the acetabulum.
2. **Subluxation**—The largest percentage of DDH, subluxation, implies incomplete dislocation of the hip and is sometimes regarded as an intermediate state in the development from primary dysplasia to complete dislocation. The femoral head remains in contact with the acetabulum, but a stretched capsule and ligamentum teres cause the head of the femur to be partially displaced. Pressure on the cartilaginous roof inhibits ossification and produces a flattening of the socket.
3. **Dislocation**—The femoral head loses contact with acetabulum and is displaced posteriorly and superiorly over the fibrocartilaginous rim. The ligamentum teres is elongated and taut.

There appears to be a relationship between tight swaddling of a newborn and hip dysplasia. It is recommended that infants' hips be placed in slight flexion and abduction during swaddling and that the knees be maintained in slight flexion. Forced or sustained passive hip extension in the first few months should be avoided in order to decrease the incidence of hip dysplasia in infants. See Cultural Awareness box: Developmental Dysplasia of the Hip.

CULTURAL AWARENESS

Developmental Dysplasia of the Hip

Among the cultures with the highest incidence of dislocation (Indigenous People in North America), newly born infants may be tightly wrapped with the hips adducted and extended in blankets or other swaddling material or are strapped to cradle boards. In cultures such as those in Central and South America, Asia, and Africa, where mothers traditionally carry infants on their backs with the infants' hips in the abducted and flexed hip position, hip dysplasia is much less common.

Diagnostic Evaluation. DDH is often not detected at the initial examination after birth; thus all infants should be carefully monitored for hip dysplasia at follow-up visits throughout the first year of life. In

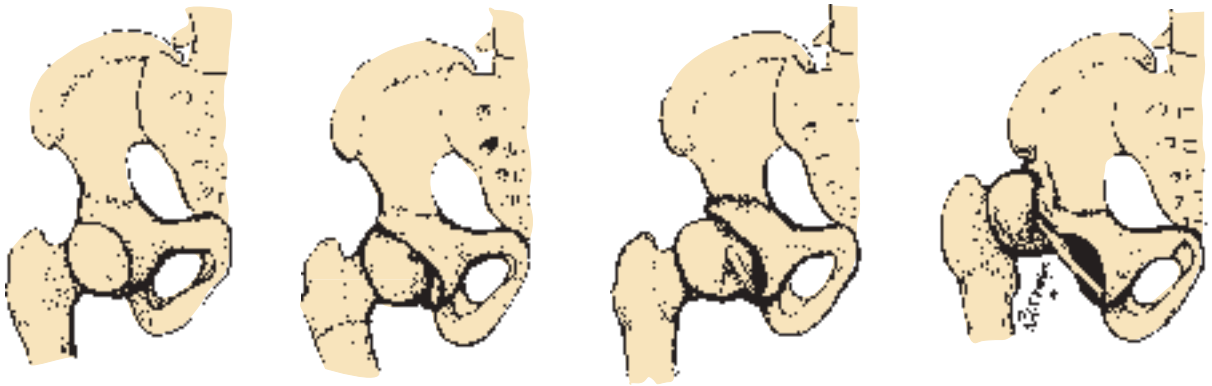

Fig. 53.12 Configuration and relationship of structures in developmental dysplasia of the hip.

BOX 53.5 Clinical Manifestations of Developmental Dysplasia of the Hip

Infant

Shortening of limb on affected side (Galeazzi sign)
Restricted abduction of hip on affected side
Unequal gluteal folds (best visualized with infant prone)
Positive Ortolani test (hip reduced by abduction)
Positive Barlow test (hip dislocated by adduction)

Older Infant and Child

Affected leg shorter than the other
Telescoping or piston mobility of joint—Head of femur felt to move up and down in buttock when extended thigh is pushed first toward child's head and then pulled distally
Trendelenburg sign—When child stands first on one foot and then on the other (holding onto a chair, rail, or someone's hands) bearing weight on the affected hip, the pelvis tilts downward on the normal side instead of upward, as it would with normal stability
Greater trochanter prominent and appearing above a line from anterosuperior iliac spine to tuberosity of ischium
Marked lordosis and waddling gait (bilateral dislocations)

the newborn period dysplasia usually appears as hip joint laxity rather than as outright dislocation. The clinical manifestations of DDH are outlined in Box 53.5.

The Ortolani and Barlow tests are the most reliable tests for newborns from birth to 4 weeks of age (see Figure 25.13). The *Barlow test* identifies a hip that can be passively displaced. The test involves the newborn laying in a supine position and the knees (flexed to 90 degrees) and being adducted while being pushed posteriorly. A "clunk" is palpated when the femoral head exits the acetabulum. The *Ortolani test* identifies the dislocated hip that can be reduced. The test involves the newborn again laying supine, and abducting the knees while anteriorly lifting the femoral trochanter to reduce the hip. A "clunk" is palpated when the hip is reduced into proper position. Other signs of DDH are shortening of the leg on the affected side, asymmetrical thigh and gluteal folds, and broadening of the perineum (in bilateral dislocation) (see Box 53.5).

Radiographic examination in early infancy is not reliable, since ossification of the femoral head does not normally take place until the fourth to sixth month of life. However, the cartilaginous head can be visualized directly by **ultrasonography**, and it is recommended as an adjunct to other diagnostic procedures (Sankar et al., 2020). In children between 4 and 6 months, radiographic examination is useful in confirming the diagnosis. An upward slope in the roof of the acetabulum (the acetabular angle) greater than 40 degrees with upward and outward displacement of the femoral head is a frequent finding in older children. A magnetic resonance imaging (MRI) scan is most commonly used to assess the position of the femoral head relative to the acetabulum after closed reduction and casting. An MRI is now generally preferred to a computed tomography (CT) scan as it equates to less radiation exposure (Studer et al., 2017).

Therapeutic Management. Treatment is begun as soon as the condition is recognized, because early intervention is more favourable to the restoration of normal bony architecture and function. The longer treatment is delayed and the more severe the deformity, the more difficult the treatment and the less favourable the prognosis. The treatment varies with the child's age and the extent of the dysplasia. The goal of treatment is to obtain and maintain a safe, congruent position of the hip joint to promote normal hip joint development.

Newborn to age 6 months. The hip joint is maintained by splinting with the proximal femur centred in the acetabulum in an attitude of flexion. Of the numerous devices available, the *Pavlik harness* is the most widely used, and with time, motion, and gravity, the hip works into a more abducted, reduced position (Figure 53.13). The harness is worn continuously until the hip is proved stable clinically and on ultrasound examination, usually in about 6 to 12 weeks. After the age of 6 months the Pavlik harness tends to lose its effectiveness because of the child's increasing mobility and strength (Sankar et al., 2020).

When there is difficulty in maintaining stable reduction of the femoral head, a surgical closed reduction of the hip and application of a hip spica cast is performed. The cast is changed periodically to accommodate the child's growth. Once sufficient stability is acquired, after approximately 3 months, the child is transitioned to a removable hip abduction orthosis. The duration of treatment in the orthosis depends on development of the acetabulum.

Ages 6 to 24 months. In this age group the dislocation may not be recognized until the child begins to stand and walk, when shortening of the limb and contractures of the hip adductor and flexor muscles become apparent. In less severe DDH or acetabular dysplasia, use of a hip abduction orthosis may be initiated. Duration of treatment depends on development of the acetabulum. When adduction contracture is present, devices such as traction may be used to slowly and gently stretch the hip to full abduction, after which wide abduction is maintained until stability is attained. A surgical closed reduction of the hip is performed in cases of hip subluxation or dislocation, and in the event that the hip remains unstable, an open reduction may be necessary. The child is placed in a spica cast for approximately 12 weeks, and a hip abduction orthosis may be used following casting (Sankar et al., 2020).

Older children. Correction of the hip deformity in older children is inherently more difficult than in the preceding age groups, because secondary adaptive changes and other etiological factors (such as juvenile idiopathic arthritis or nonambulatory cerebral palsy) complicate the condition. Operative reduction, which may involve preoperative traction, lengthening of contracted muscles, and pelvic osteotomy procedures designed to construct an acetabular roof, often combined with proximal femoral osteotomy, are usually required. After cast removal and before weight bearing is permitted, range-of-motion exercises help restore movement. Successful reduction and reconstruction become increasingly difficult after the age of 4 years and is more challenging

Fig. 53.13 Child in Pavlik harness. (Courtesy Amanda Politte.)

in children older than 6 years of age because of severe shortening and contracture of muscles and deformity of the femoral and acetabular structures.

Nursing Care. Nurses as part of the interprofessional care team are in a unique position to detect DDH in early infancy. During the infant assessment process and routine nurturing activities, the hips and extremities are inspected for any deviations from normal. These observations should be reported to the attending health care provider, and the ambulatory child who displays a limp or an unusual gait should be referred for evaluation. This may indicate an orthopedic or neurological condition. Nonambulatory children with cerebral palsy should also be assessed for evidence of hip issues.

! NURSING ALERT

The Ortolani and Barlow tests must be performed by an experienced clinician (health care provider) to prevent further damage to the hip. If these tests are performed too vigorously in the first 2 days of life, when the hip subluxates freely, persistent dislocation may occur. An unskilled examiner can cause injury to the newborn.

The major nursing focus is the care of an infant or child in a cast or other device related to maintenance of the device and adaptation of nurturing activities to meet their needs. Generally, treatment and follow-up care of these children are carried out in an outpatient setting. Hospitalization may be necessary for cast application or brace fitting but seldom exceeds 24 to 48 hours. Longer hospitalization is required for open reduction.

! NURSING ALERT

The former practice of double- or triple-diapering for DDH is not recommended because it promotes hip extension, thus impeding proper hip development. There is no evidence to support its efficacy.

The primary nursing goal is teaching parents to apply and maintain the reduction device. The Pavlik harness allows for easy handling of the infant and usually produces less apprehension in the parent than do heavy braces and casts. Because of the infant's rapid growth, the straps should be checked in the beginning of therapy every week for possible adjustments. It is important that parents understand the correct use of the appliance, which may or may not allow for its removal during bathing. Removing the harness is determined individually on the basis of the health care provider's recommendation, the family's level of understanding, and the degree of hip deformity. Parents should be instructed not to adjust the harness. The child should be examined by the health care provider before any adjustment is attempted to make certain the hips are in correct placement.

Skin care is an important aspect of the care of an infant in a harness. The following instructions for preventing skin breakdown are stressed:

- Check frequently (at least two or three times per day) for red areas or skin irritation in skin folds or under the straps.
- Gently massage healthy skin under the straps once per day to stimulate circulation. In general, avoid lotions and powders because they can cake and irritate the skin.
- Always place the diaper under the straps.

Parents should be encouraged to hold the infant with a harness and continue care and nurturing activities. The nurse can assist by being available for parents' questions about the necessary adaptations to daily care to decrease their anxiety and possible feelings about the child being hurt by routine caring.

Casts and orthotics devices (harness) offer more challenges in nursing care because they cannot be removed for routine care, although sometimes a brace may be removed for bathing. Care of an infant or small child with a cast requires nursing innovation to reduce skin pressure or friction and to maintain cleanliness of both the child and the cast, particularly in the diaper area.

It is important for nurses, parents, and other caregivers to understand that children in corrective devices need to be involved in all the activities of any child in the same age group. Confinement in a cast or appliance should not exclude children from family (or unit) activities. They can be held astride the lap for comfort and transported to areas of activity. The child may be allowed to walk in a cast or orthotic device. An adapted wheelchair, stroller, or scooter can offer mobility to an older infant or child. An EZ-on vest (adaptive seat belt) is required for safe for transportation in a car, as the device or cast typically does not fit in a typical car seat.

Clubfoot

Clubfoot or congenital talipes equinovarus (CTEV) is a complex deformity of the ankle and foot that includes forefoot adduction, midfoot supination, hindfoot varus, and ankle equinus. The foot is pointed downward (plantarflexed) and inward in varying degrees of severity (Figure 53.14). Clubfoot may occur as an isolated deformity or in association with other disorders or syndromes, such as chromosomal abnormalities, arthrogryposis, or spina bifida.

The incidence of clubfoot in the general population is 1 in 1 000 births worldwide and is one of the most common congenital deformities, with boys affected twice as often as girls. Bilateral clubfeet occur in 50% of the cases (Winell & Davidson, 2020). The precise cause of clubfoot is unknown. However, there is a strong familial tendency: 1 in 4 when both a parent and one sibling have clubfeet. Other possible theories as to the cause of clubfoot include arrested or abnormal fetal development or abnormal positioning and restricted movement in utero, although the evidence is not conclusive. Whereas arrested development during this early stage tends to result in a rigid deformity, mechanical pressures from intrauterine positioning are likely causes of more flexible deformities (Winell & Davidson, 2020).

Classification. Clubfoot may be further divided into three categories: (1) *positional clubfoot* (also called *transitional, mild,* or *postural clubfoot*), which is believed to occur primarily from intrauterine crowding;

Fig. 53.14 Bilateral congenital talipes equinovarus (congenital clubfoot) in a 2-month-old infant. (From Zitelli, B. J., & Davis, H. W. [2007]. *Atlas of pediatric physical diagnosis* [5th ed., p. 8]. Mosby [Fig. 1-12F].)

(2) *syndromic* (or *teratological*) *clubfoot*, which is associated with other congenital anomalies such as myelomeningocele or arthrogryposis and is a more severe form of clubfoot that is often resistant to treatment; and (3) *congenital clubfoot*, also referred to as *idiopathic*, which may occur in an otherwise normal child and has a wide range of rigidity and prognosis.

The mild, or postural, clubfoot may correct spontaneously or may require passive exercise or serial casting. There is no bony abnormality, but there may be tightness and shortening of the soft tissues medially and posteriorly. The teratological clubfoot usually requires surgical correction and has a high incidence of recurrence. The congenital idiopathic clubfoot, or "true clubfoot," almost always requires surgical intervention because there is bony abnormality.

Diagnostic Evaluation. The deformity is often readily apparent and easily detected prenatally through ultrasonography or at birth. However, it must be differentiated from some positional deformities that can be passively corrected or overcorrected. Once it is detected, a careful yet comprehensive physical assessment of the affected foot (or feet) should be completed to allow for appropriate decision making regarding treatment plans and prognosis. The affected foot (or feet) is usually smaller and shorter with an empty heel pad midfoot medial crease. When the deformity is unilateral, the affected limb may be shorter and calf atrophy is present. Radiographs of the feet are generally not necessary. A thorough hip examination should be performed for all infants with clubfoot; an increased risk for hip dysplasia is associated with clubfoot deformities.

Therapeutic Management. The goal of treatment for clubfoot is to achieve a painless, plantigrade, and stable foot. Treatment of clubfoot involves three stages: (1) correction of the deformity, (2) maintenance of the correction until normal muscle balance is regained, and (3) follow-up observation to avert possible recurrence of the deformity. Some feet respond to treatment readily while others respond only to prolonged, vigorous, and sustained efforts, and the improvement in some remains disappointing despite all the efforts.

Recommended treatment of clubfoot is with the use of the Ponseti method. Serial casting is begun shortly after birth. Weekly gentle manipulation and serial long-leg casts allow for gradual repositioning of the foot (Figure 53.15). The extremity or extremities are casted until maximum correction is achieved, usually within 6 to 10 weeks. Most of the time a percutaneous heel cord tenotomy is performed at the end of the serial casting to correct the equinus. After the tenotomy, a long-leg cast is applied and left in place for 3 weeks. After casting is completed, children are transitioned to utilizing Ponseti sandals with a bar set in abduction to help maintain the correction and prevent a recurrence of the foot deformity. Inability to achieve normal foot alignment after casting and tenotomy indicates the need for surgical intervention.

Fig. 53.15 Feet casted for correction of bilateral congenital talipes equinovarus.

Children with clubfoot need to be followed by a health care provider. Sometimes the original condition will reoccur, particularly at 2 to 3 years of age. There can also be long-term residual symptoms. When an adolescent is having a growth spurt, the pain may reoccur. Orthotics that are customized will be needed to support the foot.

Nursing Care. Nursing care of the child with clubfoot is the same as for any child who has a cast (see discussion earlier in chapter). Because the child will spend considerable time in a corrective device, nursing care plans include both long- and short-term goals. Conscientious observation of the skin and circulation is particularly important in young infants because of their rapid growth rate.

Because treatment and follow-up care are handled in the orthopedist's office, clinic, or outpatient department, parent education and support are important in nursing care of these children. It is important for parents to understand the overall treatment program, the importance of regular cast changes, and the role they play in the long-term effectiveness of the therapy. Reinforcing and clarifying the orthopedist's explanations and instructions, teaching parents about care of the cast or appliance (including vigilant observation for potential complications), and encouraging parents to facilitate normal development within the limitations imposed by the deformity or therapy are all part of nursing responsibilities.

Metatarsus Adductus (Varus)

Metatarsus adductus, or metatarsus varus, is probably the most common congenital foot deformity. In most instances it is a result of abnormal intrauterine positioning, particularly in the firstborn child, and is usually detected at birth. The deformity is characterized by medial adduction of the toes and forefoot, frequently in association with inversion, and by convexity of the lateral border of the foot. Metatarsus adductus may be divided into three categories:

Type I, in which the forefoot is flexible and corrects easily with manipulation

Type II, in which there is only partial flexibility in the forefoot, and it corrects passively past neutral position but only to neutral position with active manipulation

Type III, in which the forefoot is rigid and will not stretch to neutral position with manipulation.

Unlike a clubfoot, with which it is often confused, the angulation occurs at the tarsometatarsal joint, whereas the heel and ankle remain in a neutral position. Ankle range of motion is normal. This deformity often causes a pigeon-toed or in-toeing gait in the child. A thorough hip examination should be performed for all infants with metatarsus adductus, as an increased risk for hip dysplasia is associated with foot deformities.

Therapeutic management depends on the rigidity and type of the deformity. Correction with types I and II can usually be accomplished by gentle manipulation and passive stretching of the foot, which the parent is taught to perform. Repeated and consistent stretching is continued for the first 6 weeks, after which the treatment is based on the flexibility of the foot. With type III, the child will usually require serial manipulation and casting to correct the defect, after which a corrective shoe or orthosis may be used. Surgical correction is rarely required for the condition unless there is residual deformity at 4 to 6 years of age or the child has considerable pain on ambulation or is unable to wear certain kinds of shoes as a result of the defect (Winell & Davidson, 2020).

Nursing Care. The nursing role primarily involves identifying the defect so that early therapy and instruction of the parents can be initiated. The nurse needs to teach the parents how to hold the heel firmly and to stretch only the forefoot; otherwise, undue force on the heel may produce a valgus deformity. If casting or orthosis is required, the nurse should instruct the parents in cast care and observation of the corrective device.

Skeletal Limb Deficiency

Congenital limb deficiencies, or reduction malformations (disruption defects), are manifested by varying degrees of loss of functional capacity. They are characterized by underdevelopment of skeletal elements of the extremities. The range of malformation can extend from minor defects of the digits to serious abnormalities such as *amelia*, absence of an entire extremity, or *meromelia*, partial absence of an extremity that includes *phocomelia* (seal limbs), interposed deficiency of long bones with relatively good development of hands and feet attached at or near the shoulder or the hips. Most reduction defects are primary defects of development of the limb, but prenatal destruction of the limb can occur, such as the amputation of a limb in utero from constriction of an amniotic band (amniotic band disruption sequence). Newborns with congenital limb deficiencies often have associated malformations and should be thoroughly investigated for cardiovascular, central nervous system, renal, and digestive abnormalities (Stoll et al., 2010).

Pathophysiology. Limb deficiencies can be attributed to both heredity and environmental causes and can originate at any stage of limb development. Formation of limbs may be suppressed at the time of limb bud formation, or there may be interference in later stages of differentiation and growth. Heredity appears to play a prominent role, and prenatal environmental insults have been implicated in a number of cases. The latter includes the well-publicized thalidomide tragedy of the 1950s and early 1960s, which demonstrated a clear relationship between the time of exposure of the pregnant person to the antiemetic medication and the presence and type of limb deformity in the newborn. There still are many medications that may have similar teratogenic effects in the first trimester of pregnancy. Therefore, medication administration during this period should be evaluated carefully by the health care provider.

Therapeutic Management. Children with congenital limb deficiencies should be fitted with prosthetic devices whenever possible, and the devices should be applied at the earliest possible stage of development in an attempt to match the infant's motor readiness. This favours natural progression of prosthetic use. For example, a young infant with an upper extremity deficiency is fitted with a simple passive device, such as a mitten prosthesis, to encourage limb exploration, sitting (with the extremities needed for support), and bilateral hand activities. Lower limb prostheses are applied when the infant begins sitting up and can maintain balance, typically recommended at 6 months of age.

In preparation for prosthetic devices, surgical modification may be necessary to ensure the most favourable use of the device, since severe deformity can interfere with its effective use. Phocomelic digits are preserved for controlling switches of externally powered appliances in upper extremities. Digits (in both upper and lower extremities) provide the child with surfaces for tactile exploration and stimulation. Prostheses are replaced to accommodate the child's growth and increasing capabilities.

Nursing Care. Prosthetic application training and habilitation are most successfully carried out in a rehabilitation centre that specializes in meeting the special needs of these children, especially very young children and those with amputations or missing limbs. Therapeutic management involves a prosthetist, who as a member of the interprofessional care team specializes in the development, fitting, and maintenance of prosthetic limbs, and other health care workers such as physiotherapists and occupational therapists. Parents need special attention and support and should be encouraged to assist the child in making age-commensurate adjustments to the environment. Although these children need assistance, overprotection may produce overdependence, with later maladjustment to school and other situations.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is a rare genetic disorder characterized by bones that fracture easily. Although inheritance follows an autosomal dominant pattern in most cases, rare autosomal recessive inheritance exists. Most types of OI have defects in the *COL1A1* or *COL1A2* genes, which code for polypeptide chains in type 1 procollagen, a precursor of type 1 collagen, which is a major structural component of bone. The error results in faulty bone mineralization, abnormal bone architecture, and increased susceptibility to fracture. There are at least eight described types of OI, which accounts for significant disease variability. Clinical features may include varying degrees of bone fragility, deformity, and fracture; blue sclerae; hearing impairment; and *dentinogenesis imperfecta* (hypoplastic discolored teeth). Cardiac function can be affected in children with OI, warranting routine screening (Tidy, 2016).

Classifications for OI are based on clinical features and patterns of inheritance (Box 53.6). Clinically, type I is the most common,

BOX 53.6 Classification of Osteogenesis Imperfecta

Type I*

A—Mild bone fragility, blue sclerae, normal teeth, hearing loss (occurs between ages 20 and 30 years), autosomal dominant inheritance

B—Same as A except dentinogenesis imperfecta instead of normal teeth

C—Same as B but no bone fragility

Type II

Lethal; stillborn or die in early infancy; severe bone fragility, multiple fractures at birth; 10% of cases of osteogenesis imperfecta (OI); autosomal recessive inheritance

Type III

Severe bone fragility leading to severe progressive deformities, normal sclerae, marked growth failure, most autosomal recessive inheritance, with a few autosomal dominant inheritance

Type IV

A—Mild to moderate bone fragility; normal sclerae; normal teeth; short stature; variable deformity; autosomal dominant inheritance

B—Same as A except dentinogenesis imperfecta instead of normal teeth; approximately 6% of cases of OI

Type V

Clinically similar to type IV; hyperplastic callus; collagen mutation is negative

Type VI

Sclerae and dentition normal; moderate to severe bone fragility; diagnosis by bone biopsy because of similarities to other types (Land et al., 2007)

Type VII and VIII (Recessive Form)

Clinically overlap types II and III but affected individuals have white sclerae, rhizomelia (shortening of proximal limb segments), and small-to-normal head circumference; severe osteochondroplasia and short stature in survivors (Marini, 2020).

*Two thirds of cases are type I.

with wide variability of bone fragility; some affected family members have significant deformity and disability, whereas others lead agile, active lives. Type II variants are the most severe and are considered lethal in infancy. Type III OI is characterized by multiple fractures often present at birth, short stature, severe bone deformity, and disability with a shortened life expectancy. Type IV is similar to type I although slightly more severe, with short stature and mild to moderate bone deformities. Types V and VI do not have a type 1 collagen defect and are clinically similar to type IV. Both types demonstrate a unique pattern to their bone. Affected individuals have hypertrophic callus formation at fracture sites, a radiodense metaphyseal band, and calcification of the interosseous membrane of the forearm. In type VI, bone has a characteristic mineralization defect or microscopic "fish scale" appearance with elevated alkaline phosphatase activity. Types VII through XII are rare, recessive forms of OI with different genetic defects being found. Clinical severity is variable and overlaps types II and III in relation to clinical features. Those who survive have white sclerae, short stature, and rhizomelia (Marini, 2020). Type VII follows the autosomal recessive inheritance that has been described in a consanguineous Indigenous community from Northern Québec.

Therapeutic Management. The treatment for OI is primarily supportive. The use of bisphosphonate therapy is widely used in therapeutic management of OI. Bisphosphonates commonly used are IV pamidronate or zolendronate; their mechanism of action is to promote increased bone density and prevent fractures by binding to stabilize bone by inhibiting osteoclast activity while stimulating osteoblast activity (Tidy, 2016). One of the advantages of bisphosphonate therapy is the decrease in vertebral compression and scoliosis (Marini, 2020). Bisphosphonate therapy is often given as adjunct therapy to dietary supplementation of vitamin D and calcium and weight bearing to strengthen bones.

An interprofessional care team approach offers the optimal support for children with OI, key team members being endocrinologists, orthopedic surgeons, and rehabilitation specialists. The goals of a rehabilitative approach to management are directed toward preventing (1) positional contractures and deformities, (2) muscle weakness and osteoporosis, and (3) malalignment of lower extremity joints prohibiting weight bearing. Lightweight braces and splints help support limbs, prevent fractures, and aid in ambulation. Physiotherapy helps prevent disuse osteoporosis and strengthens muscles, which in turn improves bone density.

Surgery is sometimes used to help treat the manifestations of the disease. Surgical techniques are used to correct deformities that interfere with bracing, standing, or walking. The placement of intramedullary rod into the long bones can provides stability to bone, as well as prevent or correct deformities.

Nursing Care. Infants and children with this disorder require careful handling to prevent fractures. They must be supported when they are being turned, positioned, moved, and held. Even changing a diaper may cause a fracture in severely affected infants. These children should never be held by the ankles when being diapered but should be gently lifted by the buttocks or supported with pillows. However, nurses should not be afraid to touch or handle the infant or child with OI. Such children need compassionate handling and care as much as any other patient. Care plans should always identify these infants and children as high risk for fractures.

! NURSING ALERT

Children with current fractures or healing fractures should be screened for osteogenesis imperfecta—the assumption that maltreatment or neglect is the cause of fractures in children must be carefully evaluated by an interprofessional team.

Both parents and the affected child need education regarding the child's limitations and guidelines in planning suitable activities that promote optimum development and protect the child from harm. Realistic occupational planning is part of the long-term goals of care. Because there is a 50% risk of an affected individual passing the gene to an offspring, genetic counselling is recommended.

OI is a differential diagnosis that must be ruled out in the event of multiple fractures that may be attributed to nonaccidental injury. A detailed history, no evidence of associated soft-tissue injury, and the presence of other symptoms related to OI help determine the diagnosis.

ACQUIRED DEFECTS

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease, sometimes called *coxa plana*, is a self-limited disorder in which there is aseptic necrosis of the proximal femoral epiphysis (femoral head). The disease occurs in approximately 1 in 1 200 children with boys 4 to 5 times more likely to be affected than girls. The peak incidence of the disease is between the ages of 4 and 8 years. It is typically unilateral, approximately 10% are bilateral and these cases require further investigation for other skeletal dysplasias. Most of the affected children have a skeletal age significantly below their chronological age (Sankar et al., 2020).

Pathophysiology. The cause of the disease is unknown, but there is a disturbance of circulation to the femoral capital epiphysis that produces an ischemic avascular necrosis of the femoral head. During middle childhood, circulation to the femoral epiphysis is more tenuous than at other ages and can become obstructed by disrupted blood supply, repeated microtrauma, inflammation, coagulation defects, and a variety of other causes. The pathological events seem to take place in four stages (Box 53.7). The disease process may last as little as 18 months or up to 4 years. The reformed femoral head may be severely altered or appear entirely normal.

BOX 53.7 Radiographic Stages of Legg-Calvé-Perthes Disease

- **Stage I: initial or avascular stage**—Aseptic necrosis or infarction of the capital femoral epiphysis with degenerative changes producing flattening of the upper surface of the femoral head
- **Stage II: fragmentation or revascularization stage**—Capital bone resorption and revascularization with fragmentation (vascular resorption of the epiphysis) that gives a mottled appearance on radiographs
- **Stage III: reossification or reparative stage**—New bone formation, which is represented on radiographs as calcification and ossification or increased density in the areas of radiolucency. This filling-in process appears to take place from the periphery of the head centrally.
- **Stage IV: residual or regenerative stage**—Gradual reformation of the head of the femur without radiolucency and, it is hoped, to a spherical form

Clinical Manifestations and Diagnostic Evaluation. The onset of Legg-Calvé-Perthes disease is usually insidious, and the history may reveal only the intermittent appearance of a painless limp on the affected side or symptoms including hip soreness, ache, or stiffness (constant or intermittent). The parents may report seeing the child limping, and the limp becomes more pronounced with increased activity. The pain may be experienced in the hip, along the entire thigh, or in the vicinity of the knee joint. The pain and limp are usually most evident on arising and at the end of a long day of activities. The pain is usually accompanied by joint dysfunction and limited range of motion. There may be a vague history of trauma but not necessarily. The diagnosis is established by characteristic radiographic findings including medial joint space widening, flattening of the femoral head with irregular ossification, and possible subchondral fracture. A perfusion MRI of the hip may be obtained to assess the blood flow to the femoral head.

Therapeutic Management. Because deformity occurs early in the disease process, the aims of treatment are to eliminate hip irritability; restore and maintain adequate range of hip motion; prevent capital femoral epiphyseal collapse, extrusion, or subluxation; and ensure a well-rounded femoral head at the time of healing. Treatment varies according to the child's age at the time of diagnosis, the appearance of the femoral head vasculature, and position within the acetabulum. Nonsurgical management consists of observation alone, rest or activity restriction (non–weight bearing), range-of-motion exercises, nonsteroidal anti-inflammatory medication, and potentially an abduction cast for 4 to 6 weeks to gain containment of the femoral head in the acetabulum (Sankar et al., 2020). This approach is most beneficial for management of early-onset Legg-Calvé-Perthes disease (less than 8 years old). Conservative therapy must be continued for 2 to 4 years. Surgical management consists of femoral and/or pelvic osteotomy to attain femoral head containment. The extent of surgical manipulation is related to extent of femoral head noncontainment (surgery indicated if greater than 50%), the extent of hip range of motion, and pain. Surgical containment is often reserved for more progressive disease or in children older than 8 years of age. In some cases traction is also applied to stretch tight adductor muscles.

The surgical correction recovery is typically 3 to 4 months. The child may require crutches or a walker after surgery to offload pressure from the affected leg. The child also will require physiotherapy to improve range of motion and recondition muscle.

Prognosis. The disease is self-limited, but the ultimate outcome of therapy depends on early and efficient treatment and the child's age at the onset of the disorder. A younger age of onset (bone age of less than 6 years) equates to a better prognosis for complete recovery becasue the epiphyses are more cartilaginous. Children 10 years and older have a significant risk for degenerative arthritis, especially with femoral head deformity at the time of diagnosis. The later the diagnosis is made, the more femoral damage will have occurred before treatment is implemented. In many cases, with adherence to the prescribed regimen, the prognosis is excellent. Females seem to have a poorer prognosis (Souder, 2020).

Nursing Care. Nurses may be the first health care providers to identify affected children and to refer them for medical evaluation. They are also persons on whom the child and the family can rely to help them understand and adjust to the therapeutic measures. Most of the child's care is conducted on an outpatient basis; thus the major emphasis of nursing care is teaching the family the care and management of pain, cast care, and activity management. Activity management is one of the most difficult aspects associated with the disorder as parents must cope with a normally active child who feels well but must remain relatively inactive. Suitable activities must be devised to meet the needs of the child in the process of developing a sense of initiative or industry.

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) refers to the spontaneous displacement of the proximal femoral epiphysis in a posterior and inferior direction. It develops most frequently before or during accelerated growth and the onset of puberty (children between the ages of 10 and 16 years) and is most frequently observed in boys and in children with obesity. The incidence is 2 cases per 100 000 children. Bilateral involvement occurs in up to 60% of cases (Sankar et al., 2020). The left hip is most common side effected.

Classification and Pathophysiology. SCFEs are classified as stable (able to weight bear) or unstable (unable to weight bear) and on level of chronicity (acute; symptomatic less than 3 weeks, chronic; symptomatic greater than 3 weeks). Most cases of SCFE are idiopathic, although it can be associated with endocrine disorders, renal osteodystrophy, and radiotherapy. The cause of idiopathic SCFE is multifactorial and includes obesity, physeal architecture and orientation, and pubertal hormone changes that affect physeal strength. Although obesity stresses the physeal plate, SCFE can also occur in children without obesity. Radiographs show medial displacement of the epiphysis and an uncovered upper portion of the femoral neck adjacent to the physis. There is a widened growth plate and irregular metaphysis. The capital femoral epiphysis remains in the acetabulum, but the femoral neck slips, deforming the femoral head and stretching blood vessels to the epiphysis.

Diagnostic Evaluation. The disorder is suspected when an adolescent or preadolescent displays clinical signs or complains of hip, groin, thigh, or knee pain. Hip pain may be referred to the knee as a result of the distribution of sensory nerves (Box 53.8). The diagnosis is confirmed by radiographic examination that reflects a change in position of the proximal femoral epiphysis.

Therapeutic Management. The treatment goals of SCFE are to (1) prevent further slipping until physeal closure, (2) avoid further complications such as avascular necrosis, and (3) maintain adequate hip function (Sankar et al., 2020). After the diagnosis has been established, the child should be non–weight bearing to prevent further slippage. Some surgeons prefer to perform surgery within 24 hours of the onset of acute symptoms to avoid further risk for avascular necrosis. The extent of surgical treatment varies with the degree of displacement. Surgical management options may include the following:

- Surgical pinning in situ, which involves the placement of a single pin or multiple pins and screws through the femoral neck into the proximal femoral epiphysis to prevent further slippage
- Surgical hip dislocation and realignment, to correct the deformity, re-establish blood supply, and stabilize the epiphysis
- Osteochondroplasty and femoral osteotomies when pain and hip impingement is a concern

Postsurgical care includes non–weight bearing with crutch ambulation for 6 weeks. Physiotherapy is also required for restrengthening of hip and leg muscles. SCFE is an emergency and requires early diagnosis and treatment to increase the likelihood of an acceptable outcome.

Nursing Care. Nursing care is the same as that for a child in a cast or a child in traction, as discussed earlier in this chapter. Postoperative care involves hemodynamic stabilization and assessment for complications. The adolescent needs to be taught the proper use of crutches and the

importance of avoiding any weight bearing on the affected hip (if unilateral). The adolescent may be involved in building upper body strength during the convalescent period to increase mobility from bed to wheelchair, as appropriate. Self-care and performance of activities of daily living to the person's capability are encouraged to promote confidence and decrease a sense of helplessness.

! NURSING ALERT

Children with hip issues such as Legg-Calvé-Perthes or SCFE often present with groin, thigh, or knee pain. This is often because of referred pain and is anatomically related to the obturator nerve. Any time a child presents with groin, thigh, or knee pain, a complete hip examination is paramount to rule out underlying hip pathology.

Kyphosis and Lordosis

The spine, consisting of numerous segments, can acquire deformity curves of three types: **kyphosis**, **lordosis**, and **scoliosis** (Figure 53.16).

Kyphosis is an abnormally increased convex angulation in the curvature of the thoracic spine (see Figure 53.16, *B*). In children and adolescents, it is most commonly benign, but it can occur secondary to trauma such as compression fractures, congenital bony malformations such as hemivertebrae, Scheuermann's kyphosis, and infectious disease processes such as tuberculosis.

The most common form of kyphosis is idiopathic in nature, is related to poor body alignment, and is known to be "postural." Children are prone to exaggeration of a normal kyphosis, especially when skeletal growth outpaces growth of muscle. They assume abnormal sitting and standing positions. This is particularly common in self-conscious adolescent girls who assume a round-shouldered slouching posture in an attempt to hide their developing breasts and increasing height. Postural (flexible) kyphosis is almost always accompanied by a compensatory postural lordosis, an abnormally exaggerated concave lumbar curvature. Treatment of kyphosis consists of exercises to strengthen shoulder and abdominal muscles and bracing for more marked deformity. With adolescents who are significantly self-conscious about their appearance, the best approach is to emphasize the cosmetic value of corrective therapy and to place the responsibility on the adolescent for carrying out an exercise program at home, with regular visits to and assessments by a physiotherapist for adjacent muscle strengthening. Treatment with a brace may be indicated until skeletal maturity; surgical spinal fusion may be considered for severe, painful, or progressive deforming thoracic curves.

A common congenital cause for kyphosis in children, which is structural in nature, is called *Scheuermann's kyphosis*. Scheuermann's kyphosis is a thoracic curve greater than 45 degrees with wedging greater than 5 degrees of at least three adjacent vertebral bodies and vertebral irregularity. This deformity is typically painful and can restrict physical activity tolerance. Treatment options are nonsurgical, including observation and physiotherapy, or surgical correction for curves greater than 75 degrees or if persistent pain is present (Haddadi et al., 2018).

Lordosis is an accentuation of the cervical or lumbar curvature (most common) beyond 60 degrees (see Figure 53.16, *C*). It may be a secondary complication of a disease process, a result of trauma, or idiopathic. It is often seen in association with flexion contractures of the hip, scoliosis, spondyliothesis, obesity, DDH, and slipped capital femoral epiphysis. During the pubertal growth spurt, lordosis of varying degrees is observed in teenagers, especially girls. In children with obesity the weight of the abdominal fat alters the centre of gravity, causing a compensatory lordosis. Unlike kyphosis, severe lordosis is usually accompanied by pain. The most common clinical feature is a prominent buttocks.

Treatment involves management of the predisposing cause when possible, such as weight loss and correction of the deformity. Postural exercises or support garments may be helpful in relieving symptoms in some cases; however, these do not usually result in a permanent cure.

(Redrawn from Hilt, N. E., & Schmitt, E. W. [1975]. *Pediatric orthopedic nursing.* Mosby.)

Scoliosis

Scoliosis is a structural spinal deformity in three planes, usually involving lateral curvature, spinal rotation causing rib asymmetry, and when in the thoracic spine, often thoracic hypokyphosis (see Figure 53.16). It is the most common spinal deformity and is typically classified according to the following categories: *congenital*, during fetal development; *neuromuscular*, curvature caused by disorders of the brain or spinal cord; and *idiopathic*, which is further categorized into *infantile*, at birth or up to 3 years of age; *juvenile*, in children 4 to 10 years of age; or, the most common, *adolescent* (diagnosed at age 10 to 18 years), which develops during the growth spurt of early adolescence. There appears to be a genetic component to the etiology of idiopathic scoliosis; however, the exact relationship has yet to be established. The following discussion involves the adolescent type, which is often called *adolescent idiopathic scoliosis*.

Idiopathic scoliosis is most noticeable during the preadolescent growth spurt. School screening is somewhat controversial, since there are no controlled studies to demonstrate improved outcomes and a reported number of false positives leading to referrals. Screenings may cause potential harm in terms of unnecessary medical evaluations and an adverse psychological impact. As a result, the Canadian Paediatric Society does not recommend routine screening (Greig et al., 2016; Sheehan & Grayhack, 2017).

Diagnostic Evaluation. Observation is performed behind an undressed (in undergarments) standing child, noting any asymmetry of shoulder height, scapular or flank shape, or hip height and alignment. When the child bends forward at the waist so that the trunk is parallel with the floor and the arms hang free (the Adams forward bend test), asymmetry of the ribs and flanks may be noted (see Figure 53.16, *G*). A scoliometer is also used in the initial screening to measure truncal rotation. Often a primary and a compensatory curve will place the head in alignment with the gluteal cleft. On radiographic evaluation, this gives the S-shaped curve commonly seen with idiopathic scoliosis. However, in the uncompensated curves the head and hips are not aligned (see Figure 53.16, *E* and *F*).

Definitive diagnosis is made by radiographs of the child in the standing position and use of the Cobb technique that establishes the degree of curvature. The Risser scale is used to evaluate skeletal maturity on the radiographs; the scale assists in making a determination of the likely progression of the spinal curvature based on growth potential. Radiographic curves need to measure at least 10 degrees for diagnosis. Curves of less than 25 degrees are mild and require observation during growth. It is important to note that there is an allowable 10 degree margin of error when interpreting radiographs.

! NURSING ALERT

Congenital or neuromuscular conditions or other disease processes that can associated with scoliosis must be ruled out. The presence of pain, sacral dimpling or hairy patches, café au lait spots (greater than five), cutaneous vascular changes, absent or abnormal reflexes, bowel or bladder incontinence, or left thoracic curves may indicate an underlying congenital or neuromuscular cause or spinal cord abnormality, such as syringomyelia, diastematomyelia, or tethered cord syndrome. An MRI scan should be obtained for evaluation before any surgical intervention is considered.

Therapeutic Management. Current management options include observation with regular clinical and radiographic evaluation, orthotic intervention (bracing), and surgical spinal fusion. Treatment decisions are based on the magnitude, location, and type of curve; the age and skeletal maturity of the child or adolescent; and any underlying or contributing disease process.

Bracing and exercise. For many curves in the growing child and adolescent, bracing may be the treatment of choice. It is important to realize that *bracing is not curative*, but it may slow the progression of the curvature to allow skeletal growth and maturity. The goals of conservative management of scoliosis by brace treatment are to accomplish three-dimensional correction of the curvature, slow curve progression, decrease pain, improve quality of life and self-perceived body image, and prevent surgical intervention (Karavidas, 2019). Various brace types are used to treat scoliosis; braces are selected on the basis of multiple factors: location of the curve, flexibility of the curve, extent of curve rotation, and the number of curves a patient has. The principle behind bracing is to manage the progression of the curve by utilizing corrective force against the apex to facilitate spinal alignment. Some common brace types used for conservative scoliosis management are (1) the *Boston*, (2) Milwaukee, (3) Charleston (night-time brace), and (4) *TLSO (thoracolumbosacral orthotic,* which is custom moulded to correct the curve) (Figure 53.17). Adherence to wearing the brace can be difficult because of the adolescent's age and preoccupation with body

Fig. 53.17 **A:** Standard thoracolumbosacral (TLSO) brace for idiopathic scoliosis. Note the colour and design incorporated into the brace to make it more acceptable to children and adolescents. **B:** Variation of a standard TLSO that fastens in the back **(C)** to provide needed support for the spine curvature.

image and appearance. Bracing is also ineffective in managing curves greater than 50 degrees. However, brace treatment in some children with significant scoliosis may help delay surgical intervention by slowing curve progression (Schlenzka & Yrjonen, 2013).

Growth guidance devices: Growing rods. Growth guidance devices are implantation systems for early-onset scoliosis (less than 9 years old). The aim of surgical intervention is to maximize skeletal growth and development and guide truncal growth (Muharrem & Deniz-Olgun, 2012). This surgery involves incremental hardware distraction to assist in the guiding the spine as it grows. Every 3 to 6 months, the surgeon distracts the implanted spinal hardware to guide straight spinal alignment. Various growing rod instrumentation systems are available and are chosen based on patient need and surgeon preference. Magnetic driven (MAGEC) growing rods are now also commonly used. These implants minimize repeated general anaesthesia, infection, and pain (Thompson et al., 2016).

Surgical management. Surgical intervention may be required for correction of severe curves, which are typically greater than 50 degrees. It is required for progressive curves that do not respond to bracing and for progressive congenital and neuromuscular curves. The degree of curvature and the cause guide the decision to perform surgery.

Spinal instrumentation and fusion surgery consists of attaining spinal alignment with internal instrumentation and fixation combined with bony fusion (*arthrodesis*). The patient's own bone is harvested for fusion; common harvest sites include the iliac crest, spinous processes, or tibia. Sometimes donor bone is used. The goals of spinal fusion are to correct the curvatures on the sagittal and coronal planes and to have a solid, pain-free fusion in a well-balanced torso, with maximum mobility of the remaining spinal segments. Surgical approaches may be posterior, anterior, or both.

There are many spinal instrumentation systems used for spinal fusion surgery. Selection of the instrumentation system is individualized according to the patient's needs and surgeon's preference. Surgical correction of adolescent idiopathic scoliosis is rarely medically required and is typically done for cosmetic purposes.

Nursing Care. Treatment for scoliosis extends over a significant portion of the affected child's period of growth. In adolescents this period is the one in which their identity—physical and psychological—is formed. The identification of scoliosis as a "deformity," in combination with unattractive appliances and a significant surgical procedure, can have a negative impact on the already vulnerable adolescent body image. The adolescent and family require nursing care that meets both physical and psychological needs associated with the diagnosis, surgery, and postoperative recovery. Formal rehabilitation is not required after surgery.

Although adolescents with scoliosis are encouraged to participate in most peer activities, necessary therapeutic modifications are likely to make them feel different. Nursing care of the adolescent who is facing scoliosis surgery should address potential social isolation, pain, uncertainty, and emotions related to body image issues. Social work referrals should be considered when the child discloses experiencing bullying or self-harm behaviours.

When a child or adolescent first faces the prospect of a prolonged period in an orthotic, the therapy program and the nature of the device must be explained thoroughly to both the child and the parents so that they will understand the anticipated results, how the appliance corrects the defect, the freedoms and constraints imposed by the device, and what they can do to help achieve the desired goal. Management involves the skills and services of a team of specialists, including an orthopedist, nurses, orthotist (a specialist in fitting orthopedic braces), social worker, and sometimes a thoracic or pulmonary specialist.

It is difficult for a child to be restricted at any phase of development, but for adolescents in particular continual positive reinforcement and encouragement are needed, along with as much independence as can be safely assumed during this time. Adolescents appreciate guidance and assistance by the interprofessional care team regarding anticipated issues, such as selection of clothing and participation in social activities. Socialization with peers is strongly encouraged, and every effort should be made to help the adolescent feel attractive and of value.

Preoperative care. The preoperative workup usually involves a radiographic series, including anterior/posterior, lateral and side-bending films, at times pulmonary function studies, and a number of routine laboratory studies (including prothrombin, partial thromboplastin, and bleeding times; blood count; iron studies, electrolyte levels; urinalysis and urine culture; and blood levels of any medications). Spinal surgery usually involves considerable blood loss, thus several options are considered preoperatively to increase hemoglobin, such as high-dose iron supplementation or use of erythropoietin. Intraoperative interventions to maintain or replace blood volume may include blood transfusion, intraoperative blood salvage (cell-saver), intraoperative hemodilution, tranexemic acid, and controlled induced hypotension, all of which must be carefully monitored at all times to prevent physiological instability.

Surgery for spinal fusion is complex, and often adolescents who require the procedure are not familiar with the medical terms, procedures, or experiences. Preoperative teaching is critical for the adolescent to be able to participate in their treatment and recovery. The corrective surgery is extensive so the patient must be told what to expect immediately after surgery in terms of pain management, remobilization requirements, common postoperative equipment, and devices such as a chest tube (for anterior repair) and Foley catheter. It is recommended that the child or adolescent bring personal items such as a favourite stuffed animal, laptop computer or personal tablet (with Internet access), or cell phone for postoperative use. Meeting with a peer who has undergone a similar surgery is also valuable.

Postoperative care. After surgery, patients are closely monitored, with respect to vital signs, spinal cord function, routine body systems, pain, and incision site. In some cases an immobilization brace or cast is used postoperatively depending on the type of surgical intervention. Skin care is important; if mobilization after surgery is delayed, pressure-relieving mattresses or beds may be needed to prevent pressure wounds (see Maintaining Healthy Skin, Chapter 44). Antithrombolytic stockings to prevent DVT may also be necessary if mobilization if delayed (see DVT risk in the immobilized child, earlier in this chapter).

In addition, the neurological status of the patient's extremities requires special attention. Common postoperative complications after spinal fusion include neurological injury or spinal cord injury, hypotension from acute blood loss, wound infection, syndrome of inappropriate secretion of antidiuretic hormone, atelectasis, pneumothorax, ileus, delayed neurological injury, and implanted hardware complications (Freeman, 2013). Thus postoperative assessment and monitoring are of utmost importance. Another rare but serious complication after spinal fusion is *superior mesenteric artery (SMA) syndrome,* which may occur several days after spinal surgery. This involves duodenal compression by the aorta and SMA and may result in acute partial or complete duodenal obstruction. Clinical manifestations include epigastric pain, nausea, copious vomiting, and eructation. Symptoms are aggravated in the supine position and often relieved with decompression (using a nasogastric tube) and having the patient in a left lateral decubitus or prone position.

The adolescent usually has considerable pain for the first few days after surgery and requires frequent administration of pain medication,

preferably IV opioids administered on a regular schedule. For children able to understand the concept, patient-controlled analgesia (PCA) is recommended. In addition to pain management, the patient is evaluated for skin integrity, adequate urinary output, fluid and electrolyte balance, and ileus.

In most cases the patient begins ambulation as soon as possible; depending on the instrumentation used and the surgical approach, most patients are walking by the first postoperative day and are discharged by 5 to 7 days after surgery. Discharge planning should include a timetable for follow-up with the orthopedic care provider and resumption of regular activities.

Physiotherapy is typically only required for those children who experience weakness due to a spinal cord breach intraoperatively. Throughout the hospitalization, age-appropriate activities and contact with family and friends are important parts of nursing care and planning (see The Immobilized Child, at the beginning of the chapter). The family should be encouraged to become involved in the patient's care in order to facilitate the transition from hospital to home management.

INFECTIONS OF BONES AND JOINTS

Osteomyelitis

Osteomyelitis, an infectious process in the bone, can occur at any age but most frequently is seen in children 10 years of age or younger, although the incidence is highest for children younger than 2 years of age (Le Saux & Canadian Paediatric Society [CPS], Infectious Diseases and Immunization Committee, 2018). The current incidence of osteomyelitis in developing countries is 1 to 13 per 100 000 children (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2018). The limbs most commonly affected include the foot, femur, tibia, and pelvis. Methicillin-sensitive *Staphylococcus aureus* (MSSA), methicillin-resistant *Staphylococcus aureus* (MRSA), and group A Streptococcus (GAS) are the most common causative organisms. Newborns are also likely to have osteomyelitis caused by group B streptococci or Enterobacter. Children with sickle cell disease may develop osteomyelitis from *Salmonella* organisms and *S. aureus*. *Neisseria gonorrhoeae* is a potential causative organism in sexually active adolescents. *Kingella kingae* has been reported as one of the most causative organisms in children younger than 5 years of age (Robinette & Shah, 2020a).

Acute hematogenous osteomyelitis (lasting less than 2 weeks) results when a bloodborne bacterium causes an infection in the bone. Common foci include infected lesions, upper respiratory tract infections, otitis media, tonsillitis, abscessed teeth, pyelonephritis, and infected burns. Exogenous osteomyelitis is acquired from direct inoculation of the bone from a puncture wound, open fracture, surgical contamination, or adjacent tissue infection. Subacute osteomyelitis has a longer course (lasting less than 3 months) and may be caused by less virulent microbes with a walled-off abscess or Brodie's abscess, typically in the proximal or distal tibia. Chronic osteomyelitis (lasting greater than 3 months) is a progression of acute osteomyelitis and is characterized by dead bone, bone loss, drainage, and sinus tracts.

Generally, healthy bone is not likely to become infected. Factors that contribute to infection include inoculation with a large number of organisms, presence of a foreign body, bone injury, high virulence of an organism, immunosuppression, and malnutrition. Certain types and locations of bone are also more vulnerable to infection.

Typically, children with acute hematogenous osteomyelitis are seen with a 2- to 7-day history of pain, warmth, tenderness, and decreased range of motion in the affected limb, along with systemic symptoms of fever, irritability, and lethargy (Box 53.9). Infants may have an adjacent joint effusion as well. Symptoms often resemble those observed in other diseases involving bones, such as arthritis, leukemia, or sarcoma.

BOX 53.9 Clinical Manifestations of Acute Osteomyelitis

General Manifestations
- History of trauma to affected bone (frequent)
- Child appears very ill
- Irritability
- Elevated temperature
- Restlessness
- Rapid pulse
- Dehydration

Local Manifestations
- Tenderness
- Increased warmth
- Diffuse swelling over involved bone
- Involved extremity painful, especially on movement
- Involved extremity held in semiflexion
- Surrounding muscles tense and resistant to passive movement

Pathophysiology. In acute osteomyelitis bacteria adhere to bone, causing a suppurative infection with inflammatory cells, edema, vascular congestion, and small-vessel thrombosis; the result is bone destruction, abscess formation, and dead bone (sequestra). Infection within the bone can rupture through the cortex into the subperiosteal space, stripping loose periosteum and forming an abscess. As dead bone is resorbed, new bone is formed along the live bone and infection borders. This surrounding sheath of live bone is called an *involucrum*. Sinus tracts from perforations in the involucrum may drain pus through soft tissue to the skin.

The pathology of osteomyelitis is different in infants, children older than 1 year of age, and adults. In infants blood vessels cross the growth plate into the epiphysis and joint space, which allows infection to spread into the joint. In children the infection is contained by the growth plate, and joint infection is less likely (unless the infection is intracapsular). In older adolescents (with a closed growth plate) the infection is poorly contained, and the joint is compromised. Adult periosteum is attached to bone; consequently, rupture through the periosteum and sinus drainage are more common in adults.

Diagnostic Evaluation. Organism identification and antibiotic susceptibility testing are essential for effective therapy. Cultures of aspirated subperiosteal pus along with cultures of blood, joint fluid, and infected skin samples should be obtained. Bone biopsy is indicated if blood culture results and radiographic findings are not consistent with osteomyelitis. Supporting evidence for osteomyelitis includes peripheral blood cultures, leukocytosis, and elevated C-reactive protein (CRP) and erythrocyte sedimentation (ESR) rates. Radiographic signs, except for soft-tissue swelling, are evident only after 2 to 3 weeks. An ultrasound may be used as an initial diagnostic test as it is noninvasive and readily accessible to view for potential collections. An MRI is the most sensitive and specific, and is the gold standard diagnostic test to confirm a diagnosis. A three-phase technetium bone scan can show areas of increased blood flow, such as occurs in early stages in infected bone, and is useful in locating multiple sites or in chronic infections; however, it is not a diagnostic test. CT can be used to detect bone destruction but is not typically used as a diagnostic test (Le Saux & CPS, Infectious Diseases and Immunization Committee, 2018).

Therapeutic Management. After culture specimens are obtained, empiric therapy is started with IV antibiotics covering the mostly likely organisms. For *S. aureus*, nafcillin or clindamycin is generally used. Consideration should be given to the increased rates of community-acquired MRSA in the selection of first-line antibiotic therapy, which may require vancomycin. When the infective agent is identified, antibiotics can be adjusted to target culture sensitivities. Length of therapy is typically prolonged and is determined by the duration of the symptoms, the response to treatment, and the organism's sensitivity; 6 weeks to 4 months may be required in some cases (Robinette & Shah, 2020a). In select stable and responsive cases, IV antibiotics may be changed to oral antibiotic therapy. Given the prolonged duration of high-dose antibiotic therapy, it is important to monitor for hematological, renal, hepatic, ototoxic, and other potential adverse effects. To prevent antibiotic-associated diarrhea in some children, administration of a probiotic may be considered.

Surgery may be indicated if there is no response to specific antibiotic therapy, persistent soft-tissue abscess is seen, or the infection spreads to the joint or if localized to the site of a recent surgical site where hardware is in situ. While opinions differ regarding surgical intervention, many advocate sequestrectomy and surgical drainage to decompress the metaphyseal space before pus erupts and spreads to the subperiosteal space, forming abscesses that strip the periosteum from bone or form draining sinuses. When these complications occur, a chronic infection usually persists, which may require antibiotic therapy for several months.

Nursing Care. During the acute phase of illness any movement of the affected limb will cause discomfort, thus the child needs to be positioned comfortably with the affected limb supported. A temporary splint or cast may be applied. Weight bearing is avoided in the acute phase, and moving and turning are carried out carefully to minimize pain. The child may require long-term pain medication to deal with the bone pain. After surgery, pain medication should be considered as with any other surgical procedure. Vital signs should be taken and recorded frequently and measures implemented to reduce a significant temperature elevation.

Antibiotic therapy requires careful observation and monitoring of the IV equipment and site. Because more than one antibiotic is usually administered, the compatibility of the medications needs to be determined and care taken to avoid mixing incompatible medications. A peripherally inserted central catheter (PICC) may be inserted for long-term antibiotic therapy. Antibiotic therapy is often continued at home, thus home care services should be initiated promptly.

Routine precautions are implemented for all children with osteomyelitis. If there is an open wound, it is managed according to standard wound care precautions. If a PICC line or central venous catheter (CVC) is inserted, meticulous care should be taken to prevent catheter-related infection. Administration of an antibiotic solution directly into the wound is most efficiently accomplished using a regular infusion setup that is prepared and regulated in the same manner as for any IV infusion. Intake and output should be measured and recorded, and the character of both the wound and drainage noted. The amount and character of drainage on the wound dressing also should be noted.

The child usually has a poor appetite and may be prone to vomiting. The appetite returns as the acute symptoms recede. During convalescence, adequate nutrition high in protein must be maintained to aid healing and formation of new bone.

When the acute stage subsides, children begin to feel better, appetite improves, and they become interested in their surroundings and relationships. Weight bearing on the affected limb is not permitted until healing is well underway, to avoid pathological fractures. Provision of diversional and constructive activities becomes an important nursing intervention. At this stage, the continuous IV infusion may be replaced by a heparin lock system to allow greater freedom.

As the infection subsides, physiotherapy is instituted to ensure restoration of optimum function. The child is usually discharged on a regimen of oral antibiotics, and progress is followed closely for some time.

Septic Arthritis

Septic arthritis is a bacterial infection in the joint. The most commonly infected joints are hips, knees, and ankles, which make up approximately 80% of all cases (Montgomery & Epps, 2017). It usually results from hematogenous spread or from direct extension of an adjacent cellulitis or osteomyelitis. Direct inoculation from trauma accounts for 15 to 20% of septic arthritis cases. The most common causative organism is *S. aureus*. Community-acquired MRSA is commonly a cause of septic arthritis (Robinette & Shah, 2020b). In addition to *S. aureus*, pathogens seen in newborns include group B streptococci, *Escherichia coli*, and *Candida albicans*. In children 2 months to 5 years of age, *S. aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *Kingella kingae* are the primary organisms causing infection, whereas children older than 5 years are more likely to be infected by *S. aureus* and *S. pyogenes*; sexually active adolescents may be infected by *Neisseria gonorrhoeae* (Robinette & Shah, 2020b).

Clinical manifestations include severe joint pain, swelling, warmth of overlying tissue, and occasionally erythema. However, an infection involving the hip is considered a surgical emergency to prevent compromised blood supply to the head of the femur (Robinette & Shah, 2020b).

The child is resistant to any joint movement. Features of systemic illness, such as fever, malaise, headache, nausea, vomiting, and irritability, may also be present.

Therapeutic Management and Nursing Care. The affected joint is aspirated and the specimen evaluated by Gram stain, culturing (including separate cultures for *Haemophilus influenzae* and *N. gonorrhoeae*), and determination of leukocyte count. In addition, blood culture should be performed, and complete blood count with differential and ESR or C-reactive protein level should be obtained. Early radiographic findings are limited to soft-tissue swelling but may reveal a foreign body, and such films always provide a baseline for comparison. Technetium scans reveal areas of increased blood flow but will not differentiate between sites. MRI and CT scans provide more detailed images of cartilage loss, joint narrowing, erosions, and ankylosis of progressive disease. Ultrasonography is helpful in the detection of joint effusions and fluid in the soft tissue and subperiosteum (Robinette & Shah, 2020b).

Treatment is IV antibiotic therapy based on Gram stain results and the clinical presentation. The benefits of serial aspirations to demonstrate sterility of synovial fluid and reduce pressure or pain are disputed. Pain management is an important aspect of nursing care, particularly with involvement of a large joint such as the hip. Surgical intervention may also be required if there was a penetrating wound or a possible involvement of a foreign object. Physiotherapy may be initiated for the child who is immobilized in a cast or traction to prevent flexion contractures. Additional nursing care is the same as for osteomyelitis.

Skeletal Tuberculosis

In children, tubercular infection of the bones and joints is acquired by lymphohematogenous spread at the time of primary infection. Occasionally it is from chronic pulmonary tuberculosis (TB). Skeletal tubercular infection is not common in North America but should be

considered in communities with high TB case rates. The condition is a late manifestation of TB and is most likely to involve the vertebrae, causing tubercular spondylitis. If the infection is progressive, it causes Pott disease with spread to the paraspinal muscles and destruction of the vertebral bodies, disc erosion, kyphosis caused by vertebral body degradation causing wedging, and cold abscess (collection of causative bacteria) (Ansari et al., 2013). Symptoms are insidious. The child may report persistent or intermittent pain. Other findings include joint swelling and stiffness; fever and weight loss are not common. Skeletal TB typically affects the thoracolumbar spine in children, but it can also affect single joints such as a knee or hip and tends to cause severe destruction of adjacent bone (Ansari et al., 2013).

As with pulmonary TB, the index case should be located. A family and environmental history needs to be obtained and tuberculin skin tests (TSTs) performed. Results of TSTs are positive for the majority of children with skeletal TB; however, the results are not diagnostic, and the clinical and laboratory features do not differentiate skeletal TB from a nontubercular septic arthritis. Diagnosis requires radiographic imaging showing at least 30% bone mineral loss, skeletal deformity, gibbus formation, cold abscess formation plus a positive medical history assist in determining diagnosis (Ansari et al., 2013). Isolation of *Mycobacterium tuberculosis* from the site is typically done by ultrasound and image guided CT for needle aspiration or biopsy (Ansari et al., 2013). Patients with the susceptible organism start treatment with combined antituberculosis chemotherapy (isoniazid, rifampin, and pyrazinamide); directly observed therapy is preferred (see also Chapter 45).

Nursing Care. Nursing care depends on the site and extent of infection. Tuberculous spondylitis and hip infection may require immobilization, casting, and fusion. Nursing care is the same as for osteomyelitis and septic arthritis.

BONE AND SOFT-TISSUE TUMOUR

Approximately 90% of all primary malignant bone tumours in children are either osteogenic sarcoma or Ewing sarcoma; osteosarcoma, the most common type, occurs in 56% of all cases. The peak age for pediatric bone tumours is 15 years, and they occur more often in boys. Between 2012 and 2016, 160 Canadian children were diagnosed with childhood bone cancer (Canadian Cancer Society, 2021a).

Clinical Manifestations

Most malignant bone tumours produce localized pain in the affected site, which may be severe or dull and may be attributed to trauma or the vague complaint of "growing pains." The pain is often relieved by a flexed position, which relaxes the muscles overlying the stretched periosteum. Frequently it draws attention when the child limps, curtails physical activity, or is unable to hold heavy objects (Box 53.10). A palpable mass is also a common manifestation of bone tumours, but systemic symptoms, such as fever, and other clinical symptoms, such as spinal cord compression and respiratory distress, are more frequent in patients with Ewing sarcoma.

BOX 53.10 Clinical Manifestations of Bone Tumour

Pain localized at affected site
- May be severe or dull
- Often relieved by position of flexion

Frequently brought to attention when the child
- Limps
- Curtails own physical activity
- Is unable to hold heavy objects

Diagnostic Evaluation

Diagnosis begins with a thorough history and physical examination. A primary objective is to rule out causes such as trauma or infection. Careful questioning regarding pain is essential in determining the duration and rate of tumour growth. Physical assessment focuses on functional status of the affected area, signs of inflammation, size of the mass, involvement of regional lymph nodes, and any systemic indication of generalized malignancy, such as anemia, weight loss, and frequent infection.

Definitive diagnosis is based on radiological studies, such as plain films and CT and MRI of the primary site, and pathology of the site for tumour staging. CT of chest and radioisotope bone scans are required to evaluate metastasis. Bone marrow examination is done in patients with suspected Ewing sarcoma. Ewing sarcoma most commonly involves the pelvis, long bones of the lower extremities, and chest wall, and radiographically involves the diaphysis with detachment of the periosteum from the bone (Codman triangle). In osteosarcoma lesions are most commonly located in the metaphyseal region of the bone, often involving the long bones. Radial ossification in the soft tissue gives the tumour a "sunburst" appearance on plain radiograph.

Prognosis

A better understanding of the biology of neoplastic growth has resulted in more aggressive treatment and an improved prognosis. The natural history of osteogenic sarcoma and Ewing sarcoma suggests that multiple submicroscopic foci of metastatic disease are present at the time of diagnosis despite clinical evidence of localized involvement. The lungs, distant bones, and bone marrow are the most common sites for metastatic bone tumour disease. With current therapies that include surgery and chemotherapy for osteosarcoma and surgery, radiotherapy, and chemotherapy for Ewing sarcoma, the majority of patients with localized disease can be cured.

Osteosarcoma

Osteosarcoma (osteogenic sarcoma) is the most common bone cancer in children and most commonly affects patients in the second decade of life, during their growth spurt (Arndt, 2020). It presumably arises from bone-forming mesenchyme, which gives rise to malignant osteoid tissue. Most primary tumour sites are in the metaphysis (wider part of the shaft, adjacent to the epiphyseal growth plate) of long bones, especially in the lower extremities. More than half of cases occur in the femur, particularly the distal portion, with the rest involving the humerus, tibia, pelvis, jaw, and phalanges.

Therapeutic Management. Optimum treatment of osteosarcoma includes surgery and chemotherapy. The surgical approach consists of surgical biopsy followed by either limb salvage or amputation. To ensure local control, all gross and microscopic tumours must be resected. There are multiple approaches to surgical management of bone cancer; the type of surgical resection completed is dependent on the tumour site, negative margins (tumour-free border) around the affected site, vascularization of tissues, and joint involvement. The goal is to always preserve the joint when and if possible.

Limb salvage procedures are considered where the tumour can be excised without full resection of the limb. Limb salvage is considered for distal femur or proximal tibial tumours. The surgical procedure is called a *Van Nes rotation* (*rotationplasty*); here the bone that has tumour in it is removed and the ankle joint rotated by 180 degrees

and reattached to mimic knee joint function. Other examples include hemipelvectomy for pelvic bone tumours, in which the pelvic tumour–burdened hip bone is resected and the healthy femoral head is then left to encapsulate around forming scar tissue to maintain function. Forequarter amputations for upper humerus tumours include removal of the arm and scapula and partial removal of the clavicle on the affected side. A prosthetic arm is used for function thereafter.

Frequently children with osteosarcoma will receive preoperative chemotherapy in an attempt to decrease the tumour size and make surgery more manageable (Gorlick et al., 2015).

Chemotherapy plays a vital role in the treatment of osteosarcoma. Antineoplastic medications may be administered singly or in combination and may be used either before or after surgical resection of the tumour. The use of chemotherapy after amputation has comparable results to those in trials using preoperative chemotherapy followed by limb salvage surgery. Preoperative chemotherapy facilitates a decrease in tumour size, which is often predictive of positive clinical outcomes. When pulmonary metastases are found, thoracotomy and chemotherapy have also resulted in prolonged survival and potential cure. These combined-modality approaches have significantly improved the prognosis in osteosarcoma to approximately 78% for patients with nonmetastatic disease (Lanzkowsky, 2015).

Nursing Care. Nursing care depends on the type of surgical approach. The family may have more difficulty adjusting to an amputation than a limb salvage procedure. In either instance, preparation of the child and family is critical. Straightforward honesty is essential in gaining the child's collaboration and trust. The diagnosis of cancer should not be disguised with falsehoods such as "infection." To accept the need for radical surgery, the child must be aware of the lack of alternatives for treatment. Although the responsibility of telling the child is generally left to the primary health care provider, the nurse should be present at the discussion or be aware of exactly what is said. The child should be told a few days before surgery to allow them time to think about the diagnosis and consequent treatment and to ask questions.

Sometimes children have many questions about the prosthesis, limitations on physical ability, and prognosis in terms of cure. At other times they react with silence or with a calm manner that belies their concern and fear. Either response must be accepted, since it is part of the shock and grieving process of a loss. For those who desire information, it may be helpful to introduce them to another amputee before surgery or to show them pictures of the prosthesis. However, the nurse must be careful not to overwhelm children with information. A sound approach is to answer questions without offering additional information. For those who do not pursue additional information, the nurse can express a willingness to talk.

The child is also informed of the need for chemotherapy and its adverse effects before surgery. Caution should be exercised in offering too much information at one time. When discussing hair loss, the nurse can emphasize coping strategies, such as wearing a wig. Because bone tumours affect adolescents and young adults, it is not unusual for them to become angry over all the radical body alterations.

If a limb salvage procedure or full amputation is performed, wound care, initiation of stump care, and counselling on coping and psychological adjustment are required. This is followed by prosthesis fitting and donning (see discussion on amputation management earlier in the chapter). A permanent prosthesis is usually fitted within 6 to 8 weeks. During hospitalization the child begins physiotherapy to become proficient in the use and care of the device. There is a unique "Champ Program" in Canada, developed by War Amps, which matches parents of children who have undergone amputation and junior counsellors who provide support to such children and their families. This organization provides information, support, financial assistance, and public education programs on child safety (see Additional Resources at the end of this chapter).

Phantom limb pain may develop after amputation. This symptom is characterized by sensations such as tingling, itching, and, more frequently, pain felt in the amputated limb. The child and family need to know that the sensations are real, not imagined. Adolescent amputees identify the primary triggers of phantom sensation or pain with exercise, objects approaching the stump, cold weather, and "feeling nervous." Amitriptyline, gabapentin, and pregabalin are successfully used in children to decrease the phantom limb pain. In addition, an epidural is often used before surgery as a nerve block in an effort to decrease or eliminate the occurrence of phantom limb pain. After amputation surgery, if available, the pain team should be consulted to assist in management of postoperative surgical pain and neuropathic pain.

Discharge planning must begin early in the postoperative period. Once the child has begun physiotherapy, the nurse should consult with the therapist and health care provider to evaluate the child's physical and emotional readiness to re-enter school. It is an opportune time to involve a community nurse in the child's home care. Every effort should be made to promote normalcy and gradual resumption of realistic preamputation activities. Role playing can be beneficial in preparing the child for questions and reactions from others. Environmental barriers need to be assessed by an occupational therapist in terms of accessibility in the school and home; the child may need to use crutches or a wheelchair before complete healing and prosthetic competency are achieved.

With respect to coping, the family and child need much support in adjusting not only to a life-threatening diagnosis but also to alteration in the child's body form and function. Loss of a limb entails a grieving process; therefore, those caring for the child need to recognize that the reactions of anger and depression are normal and necessary. Often parents view the anger as a direct affront to them for allowing the amputation to occur, or they see the depression as rejection. These are not personal attacks but the child's attempts to cope with a loss. Social workers and child life specialists are often consulted to assist with coping and overall adjustment.

Ewing Sarcoma (Primitive Neuroectodermal Tumour of the Bone)

Ewing sarcoma, or the Ewing sarcoma family of tumours, which include primitive neuroectodermal tumour of the bone, are the second most common malignant bone tumour in childhood (Lanzkowsky, 2015). Ewing sarcoma arises in the marrow spaces of the bone rather than from osseous tissue. The tumour originates in the shaft of long and trunk bones, most often affecting the femur, tibia, fibula, humerus, ulna, vertebrae, scapula, ribs, pelvic bones, and skull. It occurs almost exclusively in individuals under age 30 and affects White people much more often than those of other ethnicities.

Therapeutic Management. Resection of the tumour is considered in tumours with vertebral and rib involvement (Howell et al., 2019). Limb salvage procedures might also be feasible in extremity lesions, and amputation may be considered if the results of radiotherapy render the extremity useless or deformed (e.g., from restricted growth in young children). The treatment of choice is intensive irradiation of the involved bone, combined with chemotherapy, possibly with surgical resection.

Nursing Care. The psychological adjustment to Ewing sarcoma is typically less traumatic than it is to osteosarcoma because of the preservation of the affected limb. Many families accept the diagnosis with

relief in knowing that this type of bone cancer does not necessitate amputation, and initially they may not be aware of the damaging effects on the irradiated site. They need preparation for the various diagnostic tests, including bone marrow aspiration and surgical biopsy, and adequate explanation of the treatment regimen. High-dose radiotherapy often causes a skin reaction of dry or moist **desquamation** followed by hyperpigmentation. The child should wear loose-fitting clothes over the irradiated area to minimize additional skin irritation. Given the increased sensitivity, the area should be protected from sunlight and sudden changes in temperature, such as from heating pads or ice packs. The child should be encouraged to use the extremity as tolerated. Occasionally the physiotherapist may plan an active exercise program to preserve maximum function.

The child needs the same considerations for adjusting to the effects of chemotherapy as any other patient with cancer. The medication regimen usually results in hair loss, severe nausea and vomiting, peripheral neuropathy, and possibly cardiotoxicity. Every effort should be made to outline a treatment plan that allows the child maximum resumption of their usual lifestyle and activities (see also Nursing Care Plan: The Child With Cancer, from Chapter 48 available on Evolve).

Rhabdomyosarcoma

Rhabdomyosarcoma (*rhabdo*, striated) is the most common soft-tissue sarcoma in children. Striated (skeletal) muscle is found almost anywhere in the body, so these tumours occur in many sites, the most common of which are the head and neck, especially the orbit (eye). In Canada there were 210 new cases of rhabdomyosarcoma from 2012 to 2016 in children aged 0 to 14 years (Canadian Cancer Society, 2021b).

Rhabdomyosarcoma arises from embryonic mesenchyme. Three subtypes are recognized: embryonal, alveolar, and pleomorphic. Soft-tissue sarcomas are the fourth most common type of solid tumour in children. These malignant neoplasms originate from undifferentiated mesenchymal cells in muscles, tendons, bursae, and fascia, or in fibrous, connective, lymphatic, or vascular tissue. They derive their name from the specific tissue(s) of origin, such as myosarcoma (*myo*, muscle).

Clinical Manifestations. The initial signs and symptoms are related to the site of the tumour and compression of adjacent organs (Box 53.11). Some tumour locations, particularly the orbit, produce symptoms early in the course of the illness and contribute to rapid diagnosis and an improved prognosis. Other tumours, such as those of the retroperitoneal area, produce no symptoms until they are large, invasive, and widely metastasized. Unfortunately, many of the signs and symptoms attributable to rhabdomyosarcoma are vague and frequently suggest a common childhood illness, such as "earache" or "runny nose." In some instances a primary tumour site is never identified.

Diagnostic Evaluation. Diagnosis begins with a careful history and physical examination. Radiographic studies to delineate the primary tumour should include CT or MRI. Metastatic evaluation should include a CT of the chest, bone scan, and bilateral bone marrow aspirates and biopsies. For patients with tumours in the parameningeal area, a lumbar puncture should be done to examine the spinal fluid. When possible, an excisional biopsy or surgical resection of the tumour is done to confirm the diagnosis.

Careful staging is extremely important for planning treatment and determining the prognosis. The Intergroup Rhabdomyosarcoma Study Group has developed a surgicopathological staging system, shown in Box 53.12 (Lanzkowsky, 2015; Wexler et al., 2015).

With the use of contemporary multimodal therapy, more than 80% of patients with nonmetastatic disease are expected to survive (Lanzkowsky, 2015; Wexler et al., 2015). If relapse occurs, the prognosis for long-term survival is poor.

Therapeutic Management. All rhabdomyosarcomas are high-grade tumours with the potential for metastases. Therefore, multimodal therapy is recommended for all patients. Complete removal of the primary tumour is advocated whenever possible. However, because the tumour is chemosensitive, radical procedures with high morbidity should be

BOX 53.12 Staging of Rhabdomyosarcoma

Group I—Localized disease; tumour completely resected, and regional nodes not involved
Group II—Localized disease with microscopic residual, or regional disease with no residual or with microscopic residual
Group III—Incomplete resection or biopsy with gross residual disease
Group IV—Metastatic disease present at diagnosis

BOX 53.11 Clinical Manifestations of Rhabdomyosarcoma According to Tumour Site

Orbit
Rapidly developing unilateral proptosis
Ecchymosis of conjunctiva
Loss of extraocular movements (strabismus)

Nasopharynx
Stuffy nose (earliest sign)
Nasal obstruction-dysphagia, nasal voice (obstruction of posterior nasal conchae)
Pain (sore throat and ear)
Epistaxis
Palpable neck nodes
Visible mass in oropharynx (late sign)

Paranasal Sinuses
Nasal obstruction
Local pain, swelling
Discharge (may be unilateral)
Sinusitis
Swelling

Middle Ear
Signs of chronic serous otitis media with effusion (OME)
Pain
Sanguinopurulent drainage
Facial nerve palsy

Retroperitoneal Area
Usually a "silent" tumour
Abdominal mass
Pain
Signs of intestinal or genitourinary obstruction

Perineum
Visible superficial mass (scrotum, vaginal, or cervical areas)
Bowel or bladder dysfunction (from tumour compression)

avoided. In most cases a biopsy is followed by chemotherapy, irradiation, or both. Patients with embryonal tumours and group I disease can be treated with chemotherapy alone, but all others require chemotherapy and radiotherapy.

Nursing Care. The nursing responsibilities are similar to those for other types of cancer, especially the solid tumour when surgery is used. Specific objectives include (1) careful assessment for signs of the tumour, especially during well-child examinations, (2) preparation of the child and family for the multiple diagnostic tests, and (3) supportive care during each stage of multimodal therapy.

DISORDERS OF JOINTS

Juvenile Idiopathic Arthritis (Juvenile Rheumatoid Arthritis)

Juvenile idiopathic arthritis (JIA) refers to chronic childhood arthritis. JIA is a group of heterogeneous autoimmune diseases causing inflammation of the joint synovium and surrounding tissue. The cause of JIA is unknown. JIA starts before age 16 years with peak onset between 1 and 3 years of age. Twice as many girls as boys are affected. In Canada, 3 in 1 000 children are diagnosed with JIA every year (Arthritis Society, 2017). The worldwide incidence of JIA ranges from approximately 1 to 23 per 100 000 children per year (Wu & Rabinovitch, 2020). The cause is unknown, but two factors are hypothesized: immunogenic susceptibility and an environmental or external trigger such as a virus (e.g., rubella, Epstein-Barr virus, parvovirus B19) (Cassidy, 2015). There are a few known genetic risk factors, including HLA class I and class II genes, the *PTPN22* gene, and the *IL2RA/CD 25* gene; however, the genetic contribution is complicated and still not well understood.

Pathophysiology. The disease process is characterized by chronic inflammation of the synovium with joint effusion and eventual erosion, destruction, and fibrosis of the articular cartilage. Adhesions between joint surfaces and ankylosis of joints occur if the inflammatory process persists.

Clinical Manifestations. The outcome of JIA is variable and unpredictable. The disease, even in severe forms, is rarely life-threatening but can cause significant disability. The arthritis tends to wax and wane; however, patterns of clinical remission indicate that approximately 25% of cases will obtain clinical remission off medication for a follow-up duration of at least 4 years. Children with arthritis in four or fewer joints had the greatest likelihood for a sustained remission. Children with extensive arthritis and a positive rheumatoid factor were less likely to have a sustained remission. Their arthritis can cause significant joint deformity and functional disability, requiring medication, physiotherapy, and perhaps future joint replacement. Chronic and acute *uveitis*, inflammation in the anterior chamber of the eye, can cause permanent vision loss if undiagnosed and not aggressively treated.

Classification of Juvenile Idiopathic Arthritis. JIA is not a single disease, but a heterogeneous group of diseases. JIA is categorized into two umbrella categories dependent on age of onset: early onset—symptoms noted before adolescent years, and late onset—symptoms noted in adolescents or later. The International League Associations for Rheumatologists (ILAR) recognizes the following classifications of JIA (Colbert, 2010):

Systemic arthritis (20% incidence) is arthritis in one or more joints associated with at least 2 weeks of fever, rash, lymphadenopathy, hepatosplenomegaly, and serositis.

Oligoarthritis *or pauciarticular arthritis* (50% incidence) is arthritis in one to four joints for the first 6 months of disease. It is subdivided to *persistent oligoarthritis* if it remains in four joints or less, and becomes *extended oligoarthritis* if it involves more than four joints after 6 months.

Polyarthritis (30 % incidence) affects five or more joints in the first 6 months. These children may be either rheumatoid factor negative or positive.

Other subsets of JIA include the following:

Psoriatic arthritis is arthritis with psoriasis or an associated dactylitis, nail pitting, or onycholysis or psoriasis in a first-degree relative.

Enthesitis-related arthritis is arthritis, enthesitis (inflammation at the tendon insertion site), or both associated with at least two of the following: sacroiliac or lumbosacral pain, HLA-B27 antigen, arthritis in boys older than 6 years, acute anterior uveitis, inflammatory bowel disease, Reiter's syndrome, or acute anterior uveitis in a first-degree relative.

Undifferentiated arthritis fits none of the previous categories or fits more than one category.

Diagnostic Evaluation. JIA is a diagnosis of exclusion; there are no definitive tests. Classifications are based on the clinical criteria of age of onset before 16 years, arthritis in one or more joints for 6 weeks or longer, and exclusion of other causes. Laboratory tests may provide supporting evidence of disease. The ESR may or may not be elevated. Leukocytosis is frequently present during exacerbations of systemic JIA. Antinuclear antibodies are common in JIA but are not specific for arthritis; however, they help identify children who are at greater risk for uveitis. Plain radiographs are the best initial imaging studies and may show soft-tissue swelling and joint space widening from increased synovial fluid in the joint. Later films can reveal osteoporosis, narrow joint space, erosions, subluxation, and ankylosis. A slit-lamp eye examination is necessary to diagnose sight-threatening uveitis, which is most common in antinuclear antibody–positive young girls with oligoarthritis. Routine examinations are necessary for early diagnosis and treatment to avoid sight-threatening disease and long-term complications (Ringold et al., 2019). Late diagnosis can result in joint contractures, muscle wasting, growth disturbances, impaired functioning, undetected uveitis, and possible sight loss.

Therapeutic Management. There is no cure for JIA. The major goals of therapy are to control pain; preserve joint range of motion and function; minimize effects of inflammation, such as joint deformity; and promote normal growth and development. Outpatient care is the mainstay of therapy; lengthy hospitalizations are infrequent. The treatment plan can be exhaustive and intrusive for the child and family, including medication administration, physiotherapy and occupational therapy, ophthalmological slit-lamp examinations, splints, comfort measures, dietary management, school modifications, and psychosocial support.

Medications. Many arthritis medications are available, and most are effective in suppressing the inflammatory process and relieving pain. These medications may be given alone or in combination and are prescribed in a stepwise manner dependent on arthritis severity.

Disease-modifying antirheumatic drugs. Disease-modifying antirheumatic drug (DMARD) include nonbiological medications such as methotrexate (MTX), sulphasalazine, and leflunomide. NSAIDS are no longer recommended as first-line interventions due to the success of single-agent DMARD therapy (Ringold et al., 2019). The current recommendations include initial therapy to commence with a single-agent DMARD, the most common being MTX. MTX is effective, with acceptable toxicity, and requires monitoring of complete blood cell counts

and liver function tests. Patient and parent education includes frank discussion about sexual activity and birth defects. Sexually active teenagers need effective birth control. As a precaution, pregnant caregivers or those trying to conceive need to avoid contact with MTX. Instructions about avoiding live immunizations and alcohol are essential during patient education. The typical course of therapy is 3 months. The escalation of therapy is dependent on response to therapy and disease activity. In patients who have a moderate response and show low disease activity, management options may include the addition of intra-auricular glucocorticoid injection, DMARD dose increase, or switch to a different DMARD. Individuals who exhibit moderate to high disease activity and minimal response to DMARD treatment should be evaluated for the addition of a biological agent such as tumour necrosis factor inhibitor (TNFi). Again, escalation of therapeutic management is based on the child's response and disease activity.

Biological disease-modifying antirheumatic medications. Biological agents that work by several mechanisms to interrupt and minimize the inflammatory process are used in children with severe or progressive arthritis. TNFis are alpha-receptor blockers that are effective medications for children with JIA and include etanercept, abatacept, or atlizumab. The administration routes vary, but they typically do not require daily administration. The long-term safety and efficacy of biological agents has been satisfactorily confirmed (Ringold et al., 2019). Possible adverse effects of biologicals include an increased infection risk, rare reports of demyelinating disease and pancytopenia, and allergic reactions. Patient education focuses on the increased risk for infection, holding the scheduled dose if the child has fever or symptoms of infection, and seeking medical attention at early onset of illness. Because of the infection risk, children should be evaluated for TB exposure before starting these medications, and live vaccines should be avoided while taking them. There is a reported potential increased risk of malignancy with anti-TNF agents (etanercept, adalimumab, and infliximab) at high doses (Tarkiainen et al., 2015).

Nonsteroidal anti-inflammatory drugs (NSAIDS). NSAIDs are used as an adjunct to other medications, depending on the amount of disease activity and poor prognostic features. Naproxen, ibuprofen, tolmetin, indomethacin, celecoxib, and meloxicam are approved for use in children. NSAIDs offer an analgesic effect but may require higher dosing for an anti-inflammatory effect. They are effective with few common adverse effects other than gastrointestinal irritation and bruising; with naproxen, skin fragility is a possible adverse effect. NSAIDs must be taken with food. Patient and parent education is important and should include potential adverse effects.

Corticosteroids. Corticosteroids are potent immunosuppressives used for life-threatening complications, incapacitating arthritis, and uveitis. They are administered at the lowest effective dose for the briefest period. Oral preparations, intra-articular joint injections, or eye drops for uveitis are the recommended administration routes. A single intra-articular injection may provide effective relief for children with pauciarticular disease. Corticosteroid education is extensive and includes discussion of potential risk for infection, adrenal insufficiency, growth suppression, cushingoid features, weight gain, mood and sleep changes, hypertension, diabetes, osteoporosis, and avascular necrosis. Simultaneous dietary changes (low calorie and low salt) and, if possible, an active exercise program should be considered when steroids are initiated.

Physiotherapy and occupational therapy. Programs of physical management are individualized for each child and designed to reach the ultimate goal: preserving function or preventing deformity. Physiotherapy is directed toward specific joints, focusing on strengthening muscles, mobilizing restricted joint motion, and preventing or correcting deformities. Occupational therapy assumes responsibility for generalized mobility and performance of activities of daily living.

General treatment or maintenance programs vary; physiotherapists may be involved several times weekly to monthly in the management of a home program, or their visits may be limited to infrequent reviews of the home program for adherence, effectiveness, and need. Normal activities of daily living and the child's natural tendency to be active are usually sufficient to maintain muscle strength and joint mobility.

Exercising in a pool is excellent therapy, since it allows freedom of movement with support and minimal gravitational pull. If there is pain on motion, a hot pack or warm bath before therapy may help.

Health care providers may recommend nighttime splinting to help minimize pain and reduce flexion deformity. Joints most frequently splinted are the knees, wrists, and hands. Loss of extension in the knee, hip, and wrist causes special challenges and requires vigilance to detect the earliest signs of involvement and vigorous attention to prevent deformity with specialized passive stretching, positioning, and resting splints.

Nursing Care. Nursing care of the child with JIA involves assessment of the child's general health, the status of involved joints, and the child's emotional response to all ramifications of the disease—discomfort, physical restrictions, therapies, and self-concept.

The effects of JIA are manifest in every aspect of the child's life, including physical activities, social experiences, and personality development. Nursing interventions to support the parents may foster successful adaptation for the entire family. Parental concerns about the disease prognosis, financial and insurance issues, spouse and sibling relationships, and job and schedule conflicts must all be addressed. Referral to social workers, counsellors, or support groups may be needed.

Relieving pain. The pain of JIA is related to several aspects of the disease: disease severity, functional status, individual pain threshold, family variables, and psychological adjustment. The aim is to provide as much relief as possible with medication and other therapies to help children tolerate the pain and cope as effectively as possible. Nonpharmacological modalities such as behavioural therapy and relaxation techniques have proved effective in modifying pain perception (see Pain Management, Chapter 34) and activities that aggravate pain. Opioid analgesics are typically avoided in treating pain of juvenile arthritis; however, for children immobilized with refractory pain, short-term opioid analgesics can be part of a comprehensive plan that uses multiple pain relief techniques.

Promoting general health. The child's general health must be considered. A well-balanced diet with sufficient calories to maintain growth is essential. If the child is relatively inactive, caloric intake should match energy needs to avoid excessive weight gain, which places additional stress on affected joints. Sleep and rest are essential for children with JIA. Some children require rest during the day; however, daytime napping that interferes with nighttime sleepiness should be avoided. A bedtime routine that involves comfort measures can help induce sleep. A firm mattress, heated water bed, electric blanket, or sleeping bag helps provide warmth, comfort, and rest. Nighttime splints needed to maintain range of motion might initially be a source of bedtime conflict. The family needs to be instructed on how to use the splint appropriately; the splint should not be painful or impede sleep. Behaviour modification programs that reward splint and exercise use may be helpful in reducing barriers to use.

Well-child care to assess growth, development, and immunization requirements needs to be coordinated between the primary health care provider and the rheumatologist. Common childhood illnesses, such as upper respiratory tract infections, may cause arthritis to worsen; consequently, medical attention must be sought quickly for relatively minor illness to prevent arthritis flares. Effective communication

between the family, the primary health care provider, and the rheumatology team is essential for care coordination.

Children should be encouraged to attend school, even on days when there may be some pain or discomfort. Split days or half days may help a child remain involved in school. Permitting the child to come to school late allows time to gain joint movement and reduces the time at school to avoid exhaustion. It is important that the child attend school to learn skills and engage in social interaction, especially if the JIA continues to limit physical skills. Arranging for two sets of textbooks eliminates the need to carry books to and from school, thus reducing discomfort and difficulty walking.

Facilitating adherence. The child and family need to be involved in the therapeutic plan in order to commit to it. They need to know the purpose and correct use of any splints and appliances and the medication regimen. The family should be instructed in the safe administration of medications and the value of a regular schedule of administration to maintain a satisfactory medication level in the body. They should be advised that NSAIDs are not be given on an empty stomach and to be alert for signs of medication toxicity. If evidence of medication toxicity is noted, the family should notify their health care provider and follow that person's instructions.

Comfort measures and exercise. Heat has been shown to be beneficial to children with arthritis. Moist heat is best for relieving pain and stiffness, and the most efficient and practical method is in the bathtub with warm water. In some cases a daily whirlpool bath, paraffin bath, or hot packs may be used as needed for temporary relief of acute swelling and pain. Hot packs are easily applied using a damp towel wrung out after being immersed in hot water or heated in a microwave oven; after testing for heat, hot packs are applied to the area and covered with plastic to retain heat. Commercial pads that warm in only a few minutes in the microwave are also available. Painful hands or feet can be immersed in a pan of warm water or a paraffin unit. Pool therapy is the easiest method for exercising a large number of joints. Swimming activities strengthen muscles and maintain mobility in larger joints. Very small children who are frightened of the water can carry out their exercises in the bathtub; small children love to splash, kick, and throw things in the water. Adult supervision is necessary for all water activities.

Activities of daily living provide satisfactory exercise for older children to maintain maximal mobility with minimal pain. These children should be encouraged in their efforts to be independent and allowed to dress and groom themselves, to assume daily tasks, and to care for their belongings. It is often difficult for children to manipulate buttons, comb or brush hair, and turn faucets, but unless there is an acute flare, parents and other caregivers should not offer assistance. In addition, children should learn and understand why others do not help them. Many helpful devices, such as self-adhering fasteners, tongs for manipulating difficult items, and grab bars installed in bathrooms for safety, can be used to facilitate tasks. A raised (higher) toilet seat often makes the difference between dependent and independent toileting, since weak quadriceps muscles and sore knees inhibit the ability to raise the body from a low sitting position.

A child's natural affinity for play offers many opportunities for incorporating therapeutic exercises. Throwing or kicking a ball and riding a tricycle (with the seat raised to achieve maximum leg extension) are excellent moving and stretching exercises for a very young child whose daily living activities are physically limited.

An effective approach to beginning the day's activities is to awaken children early to give them their medication and then to allow them to sleep for an hour. On arising, children can take a hot bath (or shower) and perform a simple ritual of limbering-up exercises, after which they can start the day's activities, such as going to school. Exercise, heat, and rest are spaced throughout the remainder of the day according to the child's individual needs and schedule. Parents should be instructed in exercises that meet the child's needs.

Supporting the child and family. JIA affects every aspect of life for the child and family. Physical limitations may interfere with self-care, school participation, and recreational activities. The intensive treatment plan, including multiple medications, physiotherapy, comfort measures, and medical appointments, is intrusive and disruptive to the parents' work schedule and the family routine. To prevent isolation and foster independence, the family should be encouraged to pursue their normal activities. At the same time, the adaptations necessary require resourcefulness and commitment from all family members. At diagnosis and throughout the span of JIA, it is essential to recognize signs of stress and counterproductive coping and to provide the necessary support to maximize adaptation. The issues and needs of these families are discussed in Chapter 41, along with guidance in planning care. (See also Nursing Care Plan, The Child With Arthritis on Evolve.)

In Canada, the Arthritis Society provides many services for children with arthritis and their families, including education and support groups (see Additional Resources at the end of this chapter).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, autoimmune diseases that results in inflammation and multiorgan system damage. Its course and symptoms are variable and unpredictable, with mild to life-threatening complications. In addition to SLE, there are other forms of lupus, such as discoid lupus, which is limited to the skin and neonatal lupus, which occurs when maternal autoantibodies cross the placenta and cause transient lupus-like symptoms in the newborn, with the potential serious complication of heart block, but these are rare. The majority of neonatal lupus spontaneously resolves within three to six months of age and does not reoccur (Lupus Canada, 2015). The following discussion focuses on SLE.

SLE can affect anyone, children and adults. In Canada the incidence of SLE is 1 in 1 000 (Lupus Canada, 2015). It is more common in girls, although there is no gender differentiation in those diagnosed younger than 15 years old. Approximately 10 to 20 % of all patients with SLE are diagnosed in childhood (Harry et al., 2018). Age of initial presentation is typically between the ages of 11 and 12 years, and rarely before the age of 5 (Harry et al., 2018; Sadun et al., 2020). There is a familial tendency, although many newly diagnosed patients are unaware of other affected family members. Researchers studying the ethnicity and socioeconomic factors of SLE in Canada discovered that Asian Canadians and those of Afro-Caribbean descent had a higher frequency of renal involvement and more exposure to immunosuppressives. Indigenous people had higher frequencies of antiphospholipid antibodies and **comorbidity**. Canadians of Asian descent had the youngest onset. The results indicated that there are different lupus phenotypes in ethnic groups, but low income was the significant independent predictor for long-term physical damage (Peschken et al., 2009).

The cause of SLE is not known. It appears to result from a complex interaction of genetics with an unidentified trigger that activates the disease. Suspected triggers include exposure to ultraviolet (UV) light, estrogen, pregnancy, infections, and medications. Patients with JIA have been known to develop SLE symptoms as a result of the use of TNF medications such as etanercept. Genetic predisposition to SLE is evidenced in an increased concordance rate in twins (2 to 5% among dizygotic twins and 25 to 60% among monozygotic twins), although multiple genes are probably involved, and epigenetic and nongenetic factors are also important in disease expression (Harry et al., 2018; Sadun et al., 2020).

Clinical Manifestations and Diagnostic Evaluation. The child with SLE may have any number of clinical manifestations with mild to life-threatening severity (Box 53.13). The diagnosis is established when 4 of the 11 diagnostic criteria in Box 53.14 are met; however, children with fewer than four criteria who are suspected of having lupus should receive appropriate medical treatment (Sadun et al., 2020). Kidney involvement heralds progressive disease and the need for rigorous therapeutic management.

Therapeutic Management. The goal of treatment is to ensure the child's health by balancing the medications necessary to avoid exacerbation and complications while preventing or minimizing treatment-associated morbidity. Therapy involves the use of specific medications and general supportive care. The medications used to control inflammation are corticosteroids administered in doses sufficient to control inflammation and then tapered to the lowest suppressive dose. Hydroxychloroquine, an antimalarial, is a useful medication for inflammatory control, rash, and arthritis; NSAIDs are used to relieve muscle and joint inflammation; and immunosuppressive agents, such as cyclophosphamide are used for renal and CNS disease. Mycophenolate, azathioprine, and MTX are effective immunosuppressive medications that may be used to control SLE and allow reduction in steroid use. Antihypertensives, low-dose aspirin (as a blood thinner), and calcium and vitamin D supplements are just a few of the additional remedies that may be necessary to treat or avoid complications.

General supportive care includes sufficient nutrition, sleep and rest, and exercise. Exposure to the sun and ultraviolet B (UVB) light should be limited because of its association with SLE exacerbation.

Nursing Care. The principal nursing goal is to help the child and family positively adjust to the disease and therapy. The child and family must learn to recognize subtle signs of disease exacerbation and potential complications of medication therapy and to communicate these concerns to their health care provider. Patient and family education is an ongoing process initiated at diagnosis and individualized. Referral to a social worker, psychologist, or support group may help the child and family make a successful adjustment. Support groups are available through Lupus Canada and the Arthritis Society (see Additional Resources at the end of this chapter).

Key issues include therapy adherence; body-image concerns associated with rash, hair loss, and steroid therapy; school attendance; vocational activities; social relationships; sexual activity; and pregnancy. (See Chapter 41 for discussion on adjusting to a chronic illness.) Specific instructions for avoiding exposure to the sun and UVB light, such as using sunscreens, wearing sun-resistant clothing, and altering outdoor activities, must be provided with sensitivity to ensure adherence while minimizing the associated feeling of being different from peers (see Sunburn, Chapter 52). Patients need to be instructed to maintain regular medical supervision and seek attention quickly during illness or before elective surgical procedures, such as dental extraction, because of potential needs for increased steroids or prophylactic antibiotics. People with SLE should carry medical alert identification for their disease and steroid dependence.

BOX 53.13 Clinical Manifestations of Systemic Lupus Erythematosus Related to Tissues Involved

Constitutional—Fever, fatigue, weight loss, anorexia
Cutaneous—Erythematous butterfly rash over bridge of nose and across cheeks, discoid rash, photosensitivity, mucocutaneous ulceration, alopecia, periungual telangiectasias
Musculoskeletal—Arthritis, arthralgia, myositis, myalgia, tenosynovitis
Neurological—Headache, seizure, forgetfulness, behaviour change, change in school performance, psychosis, chorea, stroke, cranial and peripheral neuropathy, pseudotumour cerebri
Pulmonary and cardiac—Pleuritis, basilar pneumonitis, atelectasis, pericarditis, myocarditis, endocarditis
Renal—Glomerulonephritis, nephrotic syndrome, hypertension
Gastrointestinal—Abdominal pain, nausea, vomiting, blood in stool, abdominal crisis, esophageal dysfunction, colitis
Hepatic, splenic, and nodal—Hepatomegaly, splenomegaly, lymphadenopathy
Hematological—Anemia, cytopenia
Ophthalmological—Cotton-wool spots, papilledema, retinopathy
Vascular—Raynaud's phenomenon, thrombophlebitis, livedo reticularis

BOX 53.14 Classification Criteria for Systemic Lupus Erythematosus

Four of the following 11 criteria must be met for diagnosis:

1. **Malar rash**—Fixed malar erythema
2. **Discoid rash**—Patchy erythematous lesions
3. **Photosensitivity**—Rash with sun exposure
4. **Oral ulcers**—Painless ulcers in mouth, nose
5. **Arthritis**—Swelling, tenderness, or effusion in two or more peripheral joints (nonerosive)
6. **Serositis**—Pleuritis, pericarditis
7. **Renal disorder**—Proteinuria, casts
8. **Neurological disorder**—Psychosis, seizures
9. **Hematological disorder**—Hemolytic anemia, thrombocytopenia, leukopenia, lymphopenia
10. **Immunological disorder**—Anti-dsDNA, anti-SM, antiphospholipid antibodies, lupus anticoagulant, false-positive syphilis test (RPR)
11. **Antinuclear antibody**

KEY POINTS

- Immobility has a profound effect on all aspects of growth and development.
- The major physical consequences of immobilization are loss of muscle strength, endurance, and muscle mass; bone demineralization; loss of joint mobility; and contractures.
- Features of children's fractures not observed in the adult include presence of growth plate, thicker and stronger periosteum, bone porosity, more rapid healing, and less joint stiffness.
- The goals of fracture management are to regain alignment and length of bony fragments, retain alignment and length, and restore function to injured parts.
- The method of fracture reduction is determined by the child's age, degree of displacement, amount of overriding, amount of edema, condition of the skin and soft tissues, sensation, and circulation distal to the fracture.
- The primary purposes of traction are to fatigue involved muscles and reduce muscle spasm, position bone ends in desired realignment, and immobilize the fracture site until realignment has been achieved to permit casting or splinting.
- The etiology of DDH appears to be related to intrauterine, genetic, and cultural factors.
- Treatment of clubfoot consists of manipulation and casting to correct the deformity, maintenance of the correction, and prevention of possible recurrence of the deformity.

- Acquired hip deformities are managed with non–weight-bearing devices (Legg-Calvé-Perthes disease) or surgical stabilization (SCFE).
- Scoliosis is managed by observation, bracing, or surgical correction.
- Bone infections are managed with vigorous antibiotic therapy, immobilization of the affected part, and (sometimes) surgical drainage.
- Osteosarcoma is a neoplasm of bone-forming tissues; Ewing sarcoma is a neoplasm that arises from bone marrow spaces.
- Rhabdomyosarcoma may occur almost anywhere in the body, but the most common sites are the head and neck.
- Nursing care of the child with juvenile arthritis consists of promoting general health, relieving discomfort, preventing deformity, and preserving function.
- SLE is a chronic autoimmune disorder that affects the collagen tissues of the body.

Neuromuscular or Muscular Conditions

Jennifer Boyd

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

On completion of this chapter the reader will be able to:

1. Discuss the nursing role in helping parents care for a child with cerebral palsy.
2. Formulate a nursing care plan for the preoperative and postoperative care of a child with myelomeningocele.
3. Outline a plan of care for a child with Duchenne muscular dystrophy.
4. List three causes of spinal cord injury in children.
5. Discuss the emergent nursing care of the child or adolescent with a spinal cord injury.

CONGENITAL NEUROMUSCULAR OR MUSCULAR DISORDERS

Cerebral Palsy

Cerebral palsy (CP) is a clinical description of a group of disorders of movement, muscle tone, and posture associated with activity limitations and attributed to nonprogressive, permanent injury or malformation of the developing fetal, infant, or young child's brain (Novak et al., 2017). The etiology, clinical features, and course are variable. Features include abnormal muscle tone, involuntary movements, poor coordination, and exaggerated reflexes that can lead to difficulties with walking, feeding and swallowing, coordinated eye movements, and articulation of speech (Colver et al., 2014). CP may be accompanied by a range of other impairments and conditions either related to the underlying cause of CP or as a secondary consequence of the motor issues such as disturbances of vision, hearing, communication, cognition, and behaviour, as well as musculoskeletal challenges. A significant percentage of children with CP also have epilepsy (Johnston, 2020).

CP is the most common permanent motor disability of childhood (Johnston, 2020). The prevalence of CP is approximately 3.6 per 1 000 live births with a male-to-female ratio of 1.4 to 1 (Johnston, 2020). The risk of developing CP increases with decreased gestational age and birthweight and lower socioeconomic status. Infants born at less than 27 weeks of gestation and weighing less than 1 000 grams are at highest risk (Colver et al., 2014; Johnston, 2020). Approximately one third of newborns born prematurely develop CP. Risk factors for babies born at term include placental abnormalities, birth defects, congenital brain malformations, low birth weight, meconium aspiration, emergency Caesarean birth, newborn asphyxia, newborn seizures, respiratory distress syndrome, hypoglycemia, cerebral infarct or bleed, and newborn infections (Goldsmith et al., 2019; McIntyre et al., 2013). Gestational risk factors include the pregnant parent's inadequate nutrition, their contraction of infection (e.g., rubella, cytomegalovirus), multiple births, death of a twin during pregnancy, and artificial reproductive therapy (possibly attributed to higher risk of multiple and preterm births) (Badawi & Keogh, 2013). Genetics is also increasingly recognized as a potential cause of CP (Morgan et al., 2018). Additional factors that may contribute to the development of CP beyond the newborn period include bacterial meningitis, viral encephalitis, being in a motor vehicle collision, and traumatic brain injury (shaken baby syndrome).

Pathophysiology. It is difficult to establish a precise location of neurological lesions based on etiology or clinical signs because no characteristic pathological pattern exists. Some patients have gross malformations of the brain; others may have evidence of vascular occlusion, atrophy, loss of neurons, and degeneration that produce narrower gyri, wider sulci, and microcephaly. Anoxia appears to play the most significant role in the pathological state of brain damage, which is often secondary to other causative mechanisms.

There are a few exceptions. In some cases, the manifestations or etiology are related to anatomical areas. For example, CP associated with preterm birth is usually spastic diplegia caused by hypoxic infarction or hemorrhage with periventricular leukomalacia in the area adjacent to the lateral ventricles. The athetoid (extrapyramidal) type of CP is most likely to be associated with birth asphyxia but can also be caused by kernicterus and metabolic genetic disorders such as mitochondrial disorders and glutaric aciduria (Johnston, 2020). Hemiplegic (hemiparetic) CP is often associated with a focal cerebral infarction (stroke) secondary to an intrauterine or perinatal thromboembolism, usually a result of

maternal thrombosis or hereditary clotting disorder (Johnston, 2020). Cerebral hypoplasia and sometimes severe newborn hypoglycemia are related to ataxic CP. Generalized cortical and cerebral atrophy often cause severe newborn quadriparesis with cognitive impairments and microcephaly.

Clinical Classifications. Four major dimensions are used to classify CP (Nehring, 2010):

1. Motor abnormalities—Nature and type (muscle tone, movement disorder); functional motor abilities
2. Associated impairments—Seizures; hearing or vision impairment; attentional, behavioural, communicative, or cognitive deficits; oral motor and speed functions
3. Anatomical and neuroimaging findings—Anatomy distribution of parts of the body affected by motor impairments or limitations; neuroimaging findings including location of lesions, ventricular enlargement, white matter loss, and brain anomaly
4. Causation and timing (if known)—Identification of a clearly identified cause or source of the injury, such as postnatal event (e.g., meningitis, traumatic brain injury)

CP has four primary types of movement disorder: spastic, dyskinetic, ataxic, and mixed. The most common clinical type is spastic CP, which represents an upper motor neuron muscle weakness (Box 54.1). The reflex arc is intact, and the characteristic physical signs are increased stretch reflexes, increased muscle tone, and (often) weakness. Early neurological manifestations are usually generalized hypotonia that lasts for a few weeks or may extend for months or even as long as 1 year.

Diagnostic Evaluation. Newborns with associated risk factors for CP warrant careful assessment during infancy to identify the signs of neuromotor dysfunction as early as possible. The neurological examination and history are the primary modalities for diagnosis. Magnetic resonance imaging (MRI) of the brain is recommended for children with suspected brain abnormality and CP. Metabolic and genetic testing is recommended if no structural abnormality is identified by neuroimaging.

Many children do not receive a diagnosis of CP until 2 years of age. However, delays in diagnosis are associated with poorer outcomes (Byrne et al., 2017). Early and accurate diagnosis is important as it allows prompt access to early intervention during the critical periods of brain development (Morgan et al., 2018). Consequently, worldwide efforts are underway to reduce the time to diagnosis through systematic follow-up and assessment of children with identified risk factors. Nurses play a pivotal role in monitoring infants with known etiological risk factors and evaluating them closely in the first 2 years of life.

Early diagnosis is particularly challenging because reliable neurological indicators are lacking in the newborn period. As cortical control of movement does not occur until later in infancy, motor impairment associated with voluntary control is usually not apparent until after 2 to 4 months of age. The most commonly identified early features of CP are early hand preference (before 18 months), delayed or absent achievement of motor development, and persistent primitive reflexes (Garfinkle et al., 2020). Six attributes that should prompt referral for diagnosis of CP include (Boychuk et al., 2020):

- Early handedness in a child under 12 months
- Stiffness or tightness in the legs between 6 and 12 months
- Persistent fisting of the hands in a child over 4 months
- Persistent head-lag in a child over 4 months
- Inability to sit without support in a child over 9 months
- Any asymmetry in posture or movement

Establishing a diagnosis may be easier with the persistence of primitive reflexes: (1) either the asymmetrical tonic neck reflex or persistent Moro reflex (beyond 4 months of age) and (2) the crossed extensor reflex. The tonic neck reflex normally disappears between 4 and 6 months of age. An "obligatory" response is considered abnormal. This reflex is elicited by turning the infant's head to one side and holding it there for 20 seconds. When an infant is unable to move from the asymmetrical posturing of the tonic neck reflex when crying, it is considered

BOX 54.1 Motor Classification of Cerebral Palsy

Spastic (Pyramidal)

Characterized by persistent primitive reflexes, positive Babinski, ankle clonus, exaggerated stretch reflexes, eventual development of contractures

85% of all cases of cerebral palsy (CP)

- **Diplegia**—All extremities affected; lower more than upper (35% of spastic CP)
- **Quadriplegia**—All four extremities involved: legs and trunk, mouth, pharynx, and tongue (20% of spastic CP)
- **Triplegia**—Three limbs involved
- **Monoplegia**—One limb involved
- **Hemiplegia**—Motor dysfunction on one side of the body; upper extremity more affected than lower (25% of spastic CP)

Other features:

- **Hypertonicity** with poor control of posture, balance, and coordinated motion
- **Impairment** of fine and gross motor skills

Dyskinetic (Nonspastic, Extrapyramidal)

Athetoid—Chorea (involuntary, irregular, jerking movements); characterized by slow, wormlike, writhing movements that usually involve the extremities, trunk, neck, facial muscles, and tongue

Dystonic—Slow, twisting movements of the trunk or extremities; abnormal posture

Involvement of the pharyngeal, laryngeal, and oral muscles, causing drooling and dysarthria (imperfect speech articulation)

Ataxic (Nonspastic, Extrapyramidal)

Wide-based gait

Rapid, repetitive movements performed poorly

Disintegration of movements of the upper extremities when the child reaches for objects

Mixed Type

Combination of spastic CP and dyskinetic CP

May be labelled *mixed* when no specific motor pattern is dominant; however, this term is losing favour to more precise descriptions of motor function and affected area of brain involved (Rosenbaum et al., 2007)

Data from Nehring, W. (2010). Cerebral palsy. In Allen, P. J., Vessey, J. A., & Schapiro, N. A. (Eds), *Primary care of the child with a chronic condition* [5th ed.]. Mosby/Elsevier; Jones, M. W., Morgan, E., Shelton, J. E., et al. (2007). Cerebral palsy: Introduction and diagnosis, part 1. *Journal of Pediatric Health Care*, *21*(3), 146–152; National Institute of Neurological Disorders and Stroke. (2020). *Cerebral palsy: Hope through research*. https://www.ninds.nih.gov/Disorders/Patient-Caregiver-Education/Hope-Through-Research/Cerebral-Palsy-Hope-Through-Research.

obligatory and an abnormal response. The crossed extensor reflex, which normally disappears by 4 months, is elicited by applying a noxious stimulus to the sole of one foot with the knee extended. Normally the contralateral foot responds with extensor, abduction, and then adduction movements. The possibility of CP is suggested if these reflexes occur after 4 months.

A number of assessment instruments are now available to evaluate muscle spasticity, including functional independence in self-care, mobility, and cognition; self-initiated movements over time; and capability and performance of functional activities in self-care, mobility, and social function.

Therapeutic Management. The goals of therapy for children with CP are early recognition and optimizing development to enable affected children to attain developmental and activity levels within the limits of their existing health issues. The disorder is permanent, and therapy is primarily preventive and symptomatic.

An interprofessional approach is recommended, focusing on:

1. Optimizing function
2. Maximizing independence
3. Promoting community participation
4. Reducing secondary musculoskeletal issues
5. Managing comorbid conditions

Interventions include the following:

- Rehabilitation: physiotherapy and occupational and speech-language therapy
- Pharmacological: muscle relaxants, botulinum toxin A injections, medication to treat comorbid conditions (e.g., antiepileptic medications)
- Neurosurgical: selective dorsal rhizotomy, insertion of an intrathecal baclofen pump (to treat muscle spasms)
- Orthopedic: monitoring musculoskeletal issues; surgical interventions as appropriate

Each child is evaluated and treated on an individual basis. The scope of the child's needs requires interprofessional planning and care coordination among health care providers and the child's family.

Mobility devices and aids are commonly prescribed for children with CP. Ankle-foot orthoses (AFOs, braces) are worn by many of these children to help prevent or reduce deformity, increase the energy efficiency of gait, and control alignment. Wheeled go-carts that provide sitting balance may serve as early "wheelchair" experience for young children. Manual or powered wheelchairs allow for more independent mobility (Figures 54.1 and 54.2). Strollers and wheelchairs can be equipped with custom, supportive seating for dependent mobilization.

Orthopedic surgery may be required to correct contracture or spastic deformities, to provide stability for an unstable joint, and to provide balanced muscle power. This includes tendon-lengthening procedures (especially heel-cord lengthening), release of spastic wrist flexor muscles, and correction of hip and adductor muscle spasticity or contracture to improve locomotion. Hip dislocation often occurs in children with CP. Spinal fusion may be required for scoliosis. Selective dorsal rhizotomy has provided marked improvement in some children with CP. The procedure involves selectively cutting dorsal column sensory rootlets that have an abnormal response to electrical stimulation. For children to achieve the most benefit from the surgery they must undergo intensive physiotherapy and the family must be committed to it. The procedure results in flaccid muscles, so the child must be retaught to sit, stand, and walk.

Surgical intervention is usually reserved for the child who does not respond to the more conservative measures such as bracing, but it is also indicated for the child whose spasticity causes progressive deformities. Surgery is primarily used to improve function and enable proper sitting, standing, and walking rather than for cosmetic purposes. Surgery may also be performed to improve caloric intake, correct gastroesophageal reflux disease, prevent aspiration, and correct associated dental issues.

Fig. 54.2 Bike walker used to provide mobility and to enhance leg muscle strength. (Courtesy Texas Children's Hospital, Houston, TX)

Pharmacological interventions address issues such as pain, spasticity, and comorbid conditions associated with CP. Intense pain may occur with muscle spasms. Pharmacological agents given orally (dantrolene sodium, baclofen, and diazepam [Valium]) do not improve muscle coordination in children with CP; however, they are effective in decreasing overall spasticity. The most common adverse effects of these medications include hepatotoxicity (dantrolene), drowsiness, fatigue, and muscle weakness; less commonly, diaphoresis and constipation may be seen with baclofen. Botulinum toxin A (Botox) is also used to reduce spasticity in targeted muscles.

Botulinum toxin A is injected into a selected muscle (commonly the quadriceps, gastrocnemius, or medial hamstrings) after a topical anaesthetic or sedation is used. The medication acts to inhibit the release of acetylcholine at the neuromuscular junction of specific muscle groups, causing temporary paralysis. When combined with rehabilitation, it aids motor learning, promotes functional progression, and delays orthopedic complications (Hareb et al., 2020). The goal is to allow stretching of the muscle as it relaxes and enable ambulation with an AFO. The major reported adverse effect of botulinum toxin A injection is pain at the injection site and temporary weakness (Lukban et al., 2009). Prime candidates for botulinum toxin A injections are children with spasticity confined to the lower extremities. The onset of action occurs within 24 to 72 hours, with a peak effect observed at 2 weeks and a duration of action of 3 to 6 months. Botulinum toxin injected into salivary glands may also help reduce the severity of drooling, which is seen in 10 to 30% of patients with CP and has been traditionally treated with anticholinergic agents (Johnston, 2020).

Children with CP may also experience pain as a result of surgical procedures intended to reduce contracture deformities, position, and gastroesophageal reflux. Thus pain management is an important care priority in these children. Pain can be very difficult to assess in children, particularly in children with cognitive or communication impairments. A pediatric questionnaire on pain caused by spasticity (QPS) has been developed to more accurately assess this type of pain. This pain assessment tool was developed with the input of children with CP and their parents. This enhanced pain assessment could also be used to more accurately assess the effectiveness of pain treatments, such as botulinum toxin A (Geister et al., 2014).

The neurosurgical and pharmacological approach to relieving the spasticity associated with CP involves the implantation of a pump to infuse baclofen directly into the intrathecal space surrounding the spinal cord, where it reduces neurotransmission of afferent nerve fibres. Direct delivery to the spinal cord overcomes the concern of central nervous system adverse effects caused by the large oral doses needed to penetrate the blood–brain barrier (Johnston, 2020). Intrathecal baclofen therapy is best suited for children with severe spasticity that interferes with activities of daily living (ADLs) and ambulation.

The implantation procedure is done in the operating room by a neurosurgeon. The pump, which is approximately the size of a hockey puck, is placed in the subcutaneous space of the mid-abdomen. An intrathecal catheter is tunnelled from the lumbar area to the abdomen and connected to the pump. Benefits of intrathecal baclofen include fewer systemic adverse effects than from oral medication, dosage titration for maximizing effects, and reversibility of therapy with removal of the pump if so desired. The patient may remain hospitalized for 3 to 7 days to adjust the dosage and ensure proper healing. Outpatient visits to refill the pump and make dosage adjustments occur about every 3 to 6 months, depending on the patient's response to the treatment. This procedure is most suited for an interprofessional setting where rehabilitation specialists are readily available and consistently involved in the patient's ongoing care. Abrupt withdrawal of intrathecal baclofen, especially at high doses, may result in adverse effects such as rebound spasticity, pruritus, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation, multiorgan failure, and death. In some cases, intrathecal baclofen withdrawal may mimic sepsis. Oral baclofen has also been widely used in children with CP to treat spasticity. However, adverse effects are common and include systemic toxicity, drowsiness, and sedation.

Antiepileptic medications such as carbamazepine (Tegretol), divalproex (valproate sodium and valproic acid; Depakote), levetiracetam (Keppra), and oxcarbazepine (Trileptal) are prescribed routinely for children who have seizures. Other medications include levodopa for treating dystonia, trihexyphenidyl (Artane) for treating dystonia and for increasing the use of upper extremities and vocalizations, and reserpine for hyperkinetic movement disorders, such as chorea or athetosis (Johnston, 2020). All medications used should be assessed for risk/benefit ratio and monitored for maintenance of therapeutic levels and avoidance of subtherapeutic or toxic levels.

Dental hygiene is especially important for children with CP. Regular visits to the dentist along with prophylaxis, including brushing, fluoride, and flossing, should be instituted as soon as the teeth erupt. Additional health issues common among children with CP include constipation, poor bladder control and urinary retention, chronic respiratory tract infections, and aspiration pneumonia. These issues occur as a result of immobility, altered positioning, abnormal muscle tone, gastroesophageal reflux, and impaired swallowing. Skin conditions result from altered positioning, poor nutrition, and immobility.

A wide variety of technical aids are available to improve the functioning of children with CP. These include electromechanical toys that employ the concept of biofeedback and operate from a head unit. The toy is manipulated only when the head and trunk are in correct alignment. Eye–hand coordination can also be enhanced by the use of computerized toys and games. Microcomputers combined with voice synthesizers help children with speech difficulties to "speak." These and other devices print messages onto screen monitors and paper.

Many other electronic devices enable independent functioning. Sensors can be activated and deactivated by using a head-stick or tongue or other voluntary muscle movement over which the child has control. Voice-activated computer technology may also allow increased mobility and ambulation with specially designed devices such as wheelchairs. The application of this technology makes it possible for adults with CP to function independently in their own residences and can be extended into the workplace.

There is some evidence that neuromuscular electrical stimulation (NMES) in addition to dynamic splinting may result in increased muscle strength, range of motion, and function of upper limbs in children with CP. Further studies are needed in children with CP to support the use of botulinum toxin A in conjunction with NMES to decrease muscle spasticity and improve function (Wright et al., 2012).

Behavioural issues may occur and often interfere with the child's development. Attention-deficit/hyperactivity disorder and other learning issues require professional attention. In addition, children with CP may have vision difficulties such as strabismus, nystagmus, and optic atrophy (Johnston, 2020). Speech-language therapy involves the services of a speech-language pathologist who may also assist with feeding difficulties.

Physiotherapy is one of the most frequently used conservative treatment modalities. It requires the specialized skills of a qualified therapist with an extensive repertoire of exercise methods who can design a program to stimulate each child to achieve their functional goals. An active therapy program involves the family, the physiotherapist, and often other members of the health care team, including the nurse. The most common approach employs traditional types of therapeutic exercises that consist of stretching, passive, active, and resistive movements applied to specific muscle groups or joints to maintain or increase range of motion, strength, and endurance.

Prognosis. The prognosis for the child with CP depends largely on the type and severity of the condition. Children with mild to moderate involvement (85%) have the capability of achieving ambulation between the ages of 2 and 7 years (Berker & Yalçin, 2008). If the child does not achieve independent ambulation by this time, chances are poor for ambulation and independence. Approximately 30 to 50% of individuals with CP have intellectual disability, and an even higher

percentage have mild cognitive and learning deficits; however, many children with severe spastic tetraplegic CP have normal intelligence. Growth is affected in children with spastic tetraplegia, and many children remain below the fifth percentile in growth for age and gender.

As children with CP become adults, they may remain in the home and be cared for by a parent or caregiver, although almost half of individuals with spastic tetraplegia live in independent settings and function at appropriate social levels. Vocational rehabilitation and higher education are possible for adults with CP. Children with severe CP, mobility impairment, and feeding difficulties often succumb to respiratory tract infection in childhood. The few studies on survival rates among children and adults with CP show that survival is influenced by existing comorbidities (Nehring, 2010).

Neurorehabilitation involves rehabilitating and stimulating nerves (that control muscle movement) that have been damaged, to improve brain development. Brain plasticity is being examined as a possible route for reorganizing traditionally damaged neural pathways to function optimally for children with CP. Children with CP may benefit from therapies such as constraint-induced movement therapy, in which a stronger extremity is constrained to force the weaker extremity to function; some children with CP who have undergone these treatments have shown improvement in their symptoms (Aisen et al., 2011).

Some progress has been made in the prevention of CP in children. Studies indicate that early neuroprotection in term newborns with the use of therapeutic hypothermia (head cooling or whole-body cooling) within 6 hours of birth has improved survival without CP by approximately 40% (Johnston et al., 2011). Administering magnesium sulphate to pregnant patients before 34 weeks of gestation has been shown to reduce the incidence of CP in their infants (Magee et al., 2019) (see Chapter 20, Evidence-Informed Practice: Magnesium Sulphate for Neuroprotection Against Cerebral Palsy).

Nursing Care. Because CP in children is now being identified and treated at an earlier age, parents are participating earlier in treatment programs for their children with such complex conditions. They are taught proper handling and home care of young children with CP. Close work with other interprofessional team members is essential. Nurses can reinforce the therapeutic plan and assist the family in devising or modifying equipment at home. The nursing care of the child with CP is outlined in the Nursing Care Plan available on Evolve.

Children with CP expend much energy in their efforts to accomplish ADLs, thus more frequent rest periods should be arranged to avoid fatigue. The diet should be tailored to the child's activity and metabolic needs. Gastrostomy feedings may be necessary to supplement regular feedings and ensure adequate weight gain, particularly in the child who is at risk for growth failure or chronic malnutrition and in those with severe CP who have subsequent oral feeding challenges. Oral feedings may be continued in order to maintain oral motor skills. Weight gain is an important measure of adequate oral feeding efficiency.

Difficulties in feeding and swallowing are common among children with CP (Speyer et al., 2019). Consequently, support with feeding may be required, including the need for a gastrostomy tube (see Chapter 44). Parents may need assistance and advice regarding tube care, tube feedings, and medication administration through a gastrostomy tube to prevent blocking of the tube. Jaw control is often compromised in the child with CP. For orally fed children, more normal control can be achieved if the feeder provides stability of the oral mechanism from the side or front of the face. When directed from the front, the middle finger of the nonfeeding hand is placed posterior to the body portion of the chin, the thumb is placed below the bottom lip, and the index finger is placed parallel to the child's mandible (Figure 54.3). Manual jaw control from the side assists with head control, correction of neck and trunk hyperextension, and jaw stabilization. The middle finger of the nonfeeding hand is placed posterior to the bony portion of the chin, the index finger is placed on the chin below the lower lip, and the thumb is placed obliquely across the cheek to provide lateral jaw stability (Figure 54.4).

Fig. 54.3 Manual jaw control provided anteriorly.

Fig. 54.4 Manual jaw control provided from the side.

Safety precautions need to be implemented, such as having children wear protective helmets if they are subject to falls or capable of injuring their head on hard objects. Because the child with CP is at risk for altered proprioception and subsequent falls, the home and play environment should be adapted to the child's needs to prevent bodily harm. Transportation of the child with motor challenges and restricted mobility may be especially challenging for the family and child. Attention must be given to the child's safety when riding in a motor vehicle; a federally approved safety restraint should be used at all times. Dental issues may be more common in children with CP, which creates a need for meticulous attention to all aspects of dental care. In addition, appropriate immunizations should be administered to prevent childhood illnesses and protect against respiratory tract infections such as influenza.

The involvement of physiotherapy, speech therapy, and occupational therapy is particularly important in the establishment and maintenance of muscle function, development of adequate speech and phonation, and identification of modifications necessary for the child's environment so that ADLs can be performed to the child's satisfaction.

As in all aspects of care, educational requirements are determined by the child's needs and potential. Children with mild to moderate involvement are generally able to participate, for varying amounts of time, in regular classes. Resource rooms and support staff are available in most schools to provide more individualized attention. Integration of children with CP into regular classrooms should be promoted as much as possible. For those who are unable to benefit from formal education, a vocational training program may be appropriate. At adolescence, prevocational and vocational counselling and guidance can be arranged. At any phase or in any setting, education is geared toward the child's abilities.

Recreation and after-school activities should be considered for the child who is unable to participate in the regular athletic programs and other peer activities. Some children can compete in adapted athletic and artistic endeavours and take part in many games and pastimes suited to their capabilities. Competitive sports are also becoming increasingly available to children with disabilities and offer an added dimension to physical activities. The Canadian Cerebral Palsy Sports Association (CCPSA) is a national organization that provides sports opportunities for individuals with CP (see Additional Resources at the end of this chapter). Canada is ranked among the top countries for athletes with CP. The CCPSA supports sports for these individuals at the regional, national, and international levels.

Recreational activities serve to stimulate children's interest and curiosity, help them adjust to their disability, improve their functional abilities, and build self-esteem. Any accomplishment that helps children approach a healthy way of life can enhance their self-concept.

Supporting the Family. The nursing interventions that tend to be most valuable to the family are support and help in coping with the emotional aspects of the disorder, many of which are discussed in this book in relation to the child with a disability (see Chapter 41). Initially, the parents need supportive counselling directed toward understanding the implications of the diagnosis and all of the feelings that it engenders. Later they need clarification on what they can expect from the child and from health care providers. Educating families in the principles of family-centred care and parent–professional collaboration is essential. The family may require assistance in modifying the home environment for care of the child (see also Chapter 41), including modifications to facilitate the use of a wheelchair. The child or adolescent should be encouraged to be as independent as possible. Transportation in a car often requires special considerations.

Care coordination for the child with CP and their family is also an important nursing role. In many cases the family assumes complete care of the child and becomes adept at meeting the child's needs. Having a child with CP involves numerous issues of daily management and changes in family life that can require support from the nurse to help with coordinating family activities and care.

The nurse needs to explore and discuss with the parents any frustrations and concerns they may have about parenting a child with CP and support problem solving and approaches to helping their child. Siblings of a child with a disability are also affected and may exhibit behavioural issues in response. The family needs a relationship with nurses who can provide continued contact, support, and encouragement through the long process of habilitation. Parents may also find it helpful to connect with parent groups to share issues, concerns, and experiences and obtain mutual support and practical information. The Family-Centred Teaching box: The Reality of Acceptance of Cerebral Palsy presents a story about a mother with a child with CP and the reality of accepting the diagnosis of CP.

FAMILY-CENTRED CARE

The Reality of Acceptance of Cerebral Palsy

Acceptance is rarely achieved in the length of time implied in the literature.

In the first place, what is it? To me, it is the end of comparing my son with every other child I see. I focus on his gains, not society's expectations.

It is also being able to laugh periodically at his "clumsiness." It is "gallows humour" as he achieves adulthood; jokes about CP can be funny now.

The bitterness is gone; I am now happy for people who have children without CP.

I am no longer sorry for my son, but rather for the people who cannot see him for the great person he is; the CP does not come first.

He is now a young man of 25 years and I am learning to accept his independence.

It is a "never-ending story."

—Elaine A. Dunham, RN, Shriner's Hospitals for Children
Springfield, MA

Supporting the Hospitalized Child. CP is not a disorder that requires hospitalization; thus when children with CP are hospitalized, they are usually admitted for an acute illness or surgery. Nursing care for the child with CP is similar to that for any other child with a disability. Children with CP should be treated in the same manner as for any child in the hospital with adaptions for particular impairments, including mobility and speech. To facilitate the care and management of these children, the therapy program should be continued, insofar as their condition allows, during the time they are hospitalized. Encouraging the parent to room-in and actively participate in the child's care facilitates a continuation of the home therapy program and helps the child adjust to an unfamiliar environment. However, it is equally important to remember that hospitalization may be the first time a parent can defer care to a nurse and not be the primary caregiver. This respite may be crucial to the parent's well-being. It is important to respect the parent's preference in this regard.

Neural Tube Defects

Abnormalities that derive from the embryonic neural tube (**neural tube defects [NTDs]**) constitute the largest group of congenital anomalies (Box 54.2). Normally, the spinal cord and cauda equina are encased

BOX 54.2 Neural Tube Defects

Cranioschisis—A skull defect through which various tissues protrude

Exencephaly—Brain totally exposed or extruded through an associated skull defect; fetus usually aborted

Anencephaly—If fetus with exencephaly survives, there is degeneration of the brain to a spongiform mass with no bony covering; incompatible with life usually beyond a few days

Encephalocele—Herniation of brain and meninges through a defect in the skull producing a fluid-filled sac

Rachischisis or spina bifida—Fissure in the spinal column that leaves the meninges and spinal cord exposed

Meningocele—Hernial protrusion of a saclike cyst of meninges filled with spinal fluid (see Figure 54.5, *C*)

Myelomeningocele (meningomyelocele)—Hernial protrusion of a saclike cyst containing meninges, spinal fluid, and a portion of the spinal cord with its nerves (see Figure 54.5, *D*)

in a protective sheath of bone and meninges (Figure 54.5, *A*). Failure of neural tube closure produces defects of varying degrees. They may involve the entire length of the neural tube or may be restricted to a small area.

Encephalocele and anencephaly are abnormalities resulting from failure of the anterior end of the neural tube to close. An *encephalocele* is a herniation of the brain and meninges through a skull defect, usually at the base of the neck. The defect may be associated with hydrocephalus (see Chapter 50); the resulting sequelae depend on the amount of neural tissue within the protruding sac and associated neurological defects. Treatment consists of surgical repair and shunting to relieve hydrocephalus, unless a major brain malformation is present. *Anencephaly*, the most serious NTD, is a congenital malformation in which both cerebral hemispheres are absent. The condition is incompatible with life, and many affected infants are stillborn. For those who survive, no specific treatment is available. The infants have a portion of the brainstem and are able to maintain vital functions (e.g., temperature regulation and cardiac and respiratory function) for a few hours to several weeks. Comfort measures are provided until the infant eventually dies of temperature instability and respiratory failure.

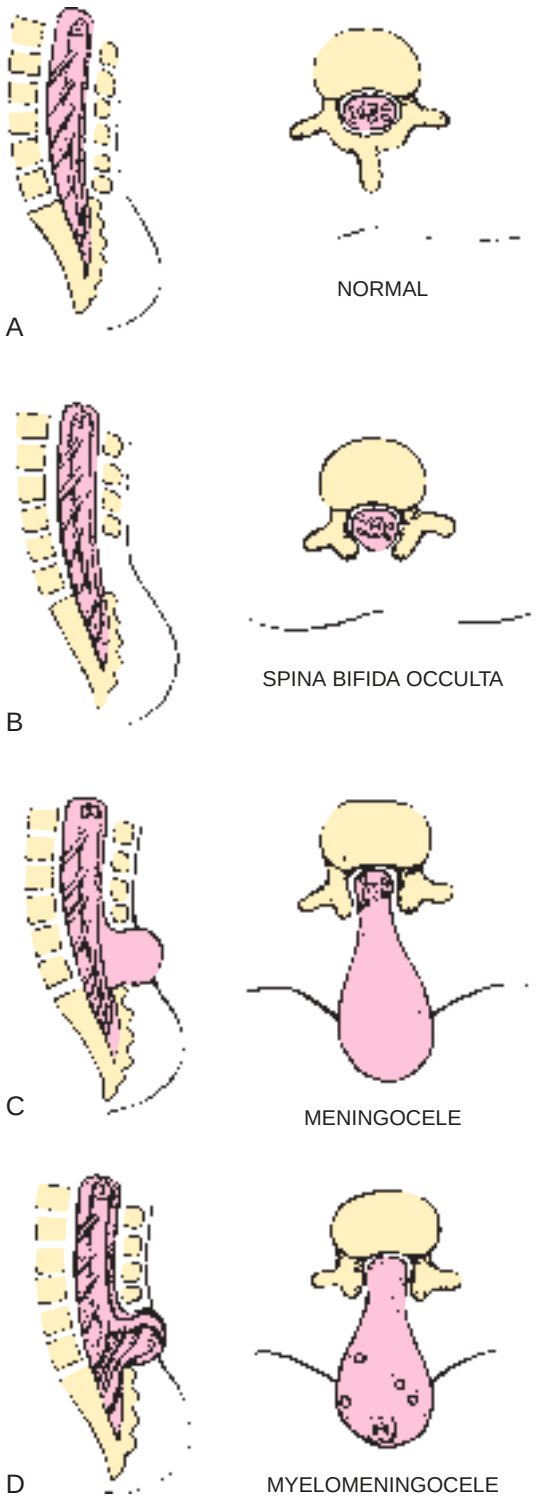

Fig. 54.5 A through **D:** Midline defects of osseous spine with varying degrees of neural herniations.

Myelodysplasia refers broadly to any malformation of the spinal canal and cord. Midline defects involving failure of the osseous (bony) spine to close are called *spina bifida (SB)*, the most common defect of the central nervous system. SB is categorized into two types: spina bifida occulta and spina bifida cystica.

Spina bifida occulta refers to a defect that is not visible externally. It occurs most frequently in the lumbosacral area (L5 and S1) (see Figure 54.5, *B*). SB occulta may not be apparent unless there are associated cutaneous manifestations or neuromuscular disturbances.

Spina bifida cystica refers to a visible defect with an external saclike protrusion. The two major forms of SB cystica are *meningocele*, which encases meninges and spinal fluid but no neural elements (see Figure 54.5, *C*), and *myelomeningocele* (or *meningomyelocele*), which contains meninges, spinal fluid, and nerves (see Figure 54.5, *D*). Meningocele is not associated with neurological deficit, which occurs in varying, often serious, degrees in myelomeningocele.

Pathophysiology. The pathophysiology of NTD is best understood when related to the normal formative stages of the nervous system. At approximately 20 days of gestation, a dedicated depression, the neural groove, appears in the dorsal ectoderm of the embryo. During the fourth week of gestation, the groove deepens rapidly, and its elevated margins develop laterally and fuse dorsally to form the neural tube. Neural tube formation begins in the cervical region near the centre of the embryo and advances in both directions—caudally and cephalically—until by the end of the fourth week of gestation, the ends of the neural tube, the anterior and posterior neuropores, close.

Most experts believe that the primary defect in NTDs is a failure of neural tube closure. However, some evidence indicates that the defects are a result of splitting of the already closed neural tube as a result of an abnormal increase in cerebrospinal fluid (CSF) pressure during the first trimester.

There is evidence of multifactorial etiology, including medications, radiation, malnutrition of the pregnant person, exposure to chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development. There is also evidence of a genetic component in the development of SB; myelomeningocele may occur in association with syndromes such as trisomy 18, PHAVER syndrome (limb pterygia, congenital heart anomalies, vertebral defects, ear anomalies, and radial defects), and Meckel-Gruber syndrome (Shaer et al., 2007). The genetic predisposition is supported by evidence of the risk for recurrence after one affected child (3–8%) and a 10% risk for recurrence with two previously affected children (Ntimbani et al., 2020). Additional factors predisposing children to an increased risk of NTDs include prepregnancy obesity, maternal diabetes mellitus, previous NTD pregnancy, low maternal vitamin B_{12} status, maternal hyperthermia, and the use of antiepileptic medications (e.g., valproic acid) in pregnancy. Folic acid deficiency in the pregnant person is associated with a two- to eight-fold increased risk of a child developing a NTD (Ntimbani et al., 2020).

Fig. 54.6 **A:** Myelomeningocele with intact sac. **B:** Myelomeningocele with ruptured sac. (Courtesy Dr. Robert C. Dauser, Neurosurgery, Baylor College of Medicine.)

The degree of neurological dysfunction depends on where the sac protrudes through the vertebrae, the anatomical level of the defect, and the amount of nerve tissue involved. The majority of myelomeningoceles (75%) involve the lumbar or lumbosacral area (Figure 54.6). Hydrocephalus is a frequently associated anomaly in 80 to 90% of the children. About 80% of patients with myelomeningocele develop a type II Chiari malformation (Kinsman & Johnston, 2020). There is some evidence that prolonged exposure of the myelomeningocele sac to amniotic fluid predisposes an infant to the development of hindbrain herniation and Chiari II malformation (Adzick, 2013).

Diagnostic Evaluation. The diagnosis of SB is made on the basis of clinical manifestations (Box 54.3) and examination of the meningeal sac (see Figure 54.6, *A*). Diagnostic measures used to evaluate the brain and spinal cord include MRI, ultrasound, and CT. A neurological evaluation will determine the extent of involvement of bowel and bladder function as well as lower extremity neuromuscular involvement. Flaccid paralysis of the lower extremities is a common finding with absent deep tendon reflexes.

Prenatal detection. It is possible to determine the presence of some major open NTDs prenatally. A second-trimester anatomical ultrasound with detailed fetal intracranial and spinal imaging and assessment is the primary screening tool for open and closed NTDs. It can detect 80 to 90% of NTDs by identifying irregularities of the bony spine or a bulging of the contour of the fetal back (Ntimbani et al., 2020). Elevated maternal concentrations of alpha-fetoprotein (AFP, or MS-AFP), a fetal-specific γ_1-globulin, in amniotic fluid may indicate anencephaly or myelomeningocele but is only recommended for pregnant patients who do not have geographic or clinical access to good-quality ultrasound screening at 18 to 22 weeks (Audibert et al., 2017). The optimum time for performing these diagnostic tests is between 16 and 18 weeks of gestation.

Therapeutic Management. Management of the child who has a myelomeningocele requires an interprofessional approach involving the specialties of neurology, neurosurgery, pediatrics, urology, orthopedics, rehabilitation, physiotherapy, and social services, along with intensive nursing care in a variety of specialty areas. The collaborative efforts of these specialists are focused on (1) the myelomeningocele and the challenges associated with the defect—hydrocephalus, lower limb paralysis, and orthopedic anomalies (developmental dysplasia of the hip and club foot), and genitourinary abnormalities; (2) possible acquired conditions that may or may not be associated, such as meningitis, hypoxia, and hemorrhage; and (3) other conditions, such as cardiac (Chiari II malformation) or gastrointestinal malformations.

BOX 54.3 Clinical Manifestations of Spina Bifida

Spina Bifida Cystica

Sensory disturbances usually parallel to motor dysfunction

- Below second lumbar vertebra—Flaccid, partial paralysis of lower extremities, varying degrees of sensory deficit, overflow incontinence with constant dribbling of urine, lack of bowel control, rectal prolapse (sometimes)
- Below third sacral vertebra—No motor impairment, may have saddle anaesthesia with bladder and anal sphincter paralysis

Associated deformities (sometimes produced in utero):

- Talipes valgus or varus contractures
- Kyphosis
- Lumbosacral scoliosis
- Hip dislocation or subluxation

Spina Bifida Occulta

Frequently no observable manifestations

May be associated with one or more cutaneous manifestations:

- Skin depression or dimple
- Port-wine angiomatous nevi
- Dark tufts of hair
- Soft, subcutaneous lipomas

May have neuromuscular disturbances:

- Progressive disturbance of gait with foot weakness
- Bowel and bladder sphincter disturbances

A variety of neurosurgical and plastic surgical procedures are used for skin closure without disturbing the neural elements or removing any portion of the sac. The objective is satisfactory skin coverage of the lesion and meticulous closure. Wide excision of the large membranous covering may damage functioning neural tissue.

Associated conditions are assessed and are managed with appropriate surgical and supportive measures. Shunt procedures provide relief from imminent or progressive hydrocephalus (see Chapter 50). When diagnosed, ventriculitis, meningitis, urinary tract infection, and pneumonia are treated with vigorous antibiotic therapy and supportive measures. Surgical intervention for Chiari II malformation is indicated only when the child is symptomatic (i.e., high-pitched crowing cry, stridor, respiratory difficulties, oral-motor difficulties, upper extremity spasticity).

Early surgical closure of the myelomeningocele sac through fetal surgery has been evaluated in relation to prevention of injury to the exposed spinal cord tissue and improvement of neurological and urological outcomes. Research has demonstrated that prenatal surgery has better outcomes (reduced number of shunt placements and less lower limb impairment) than those for children who had postnatal surgery. However, the surgery is not without risks to the fetus and mother, and premature birth is common. Maternal complications included oligohydramnios, chorioamniotic separation, placental abruption, and spontaneous membrane herniation (Adzick et al., 2011; Grivell et al., 2014).

Infancy. Initial care of the newborn involves prevention of infection; performing a neurological assessment, including observing for associated anomalies; and helping the family cope with their child having an NTD. Although meningoceles are repaired early, especially if there is danger of rupture of the sac, the opinion regarding skin closure of myelomeningocele varies. Surgical closure within the first 24 to 72 hours offers the most favourable outcome, preferably in the first 12 to 18 hours. This not only prevents local infection and trauma to the exposed tissues but also avoids stretching of other nerve roots (which may occur as the meningeal sac expands during the first hours after birth), thus preventing further motor impairment. Broad-spectrum antibiotics are initiated, and neurotoxic substances such as povidone-iodine are avoided at the malformation.

As noted earlier, associated issues are assessed and are managed with appropriate surgical and supportive measures. Improved surgical techniques do not alter the major physical disability and deformity, or the chronic urinary tract and pulmonary infections that affect the quality of life for these children. Superimposed on the physical challenges are the effects that the disorder has on family life and finances, including the need for long-term health care services.

Orthopedic management. Early evaluation and treatment of musculoskeletal conditions is recommended. Neurological assessment will determine the neurosegmental level of the lesion and enable recognition of spasticity and progressive paralysis, potential for deformity, and functional expectations. Orthopedic management includes prevention of joint contractures, correction of the existing deformity, prevention or minimization of the effects of motor and sensory deficits, prevention of skin breakdown, and acquisition of the best possible function of affected lower extremities. Common orthopedic conditions requiring attention in SB include abnormalities of the knees, hips (subluxation), feet (clubfeet), and spine. Fractures and insensate skin further complicate orthopedic care. See Chapter 53 for more information on orthopedic management. Other issues that may occur later include kyphosis and scoliosis. Because children with this condition often have decreased sensitivity in their lower extremities, preventive skin care is important. The status of the neurological deficit remains the most important factor in determining the child's ultimate functional abilities.

With technological advances, a variety of lightweight orthoses, including braces, special "walking" devices, and custom-built wheelchairs, are available to provide mobility to children with spinal cord lesions. Early in infancy, intervention with passive range-of-motion exercises, positioning, and stretching exercises may help decrease the incidence of muscle contractures. Corrective surgical procedures, when indicated, are best initiated at an early age. Where there is little hope for lower extremity functioning, surgery is seldom recommended unless it will improve sitting position in a wheelchair and function for ADLs and mobility.

Management of genitourinary function. Myelomeningocele is one of the most common causes of **neurogenic bladder dysfunction** in children. The main goal of treatment is to preserve renal function, but in older children, the secondary goal is to achieve optimal urinary continence. Renal damage can be caused by high bladder pressures associated with neurogenic bladder, recurrent urinary tract infections, and vesicoureteral reflux, among other secondary issues, including poor adherence to intermittent self-catheterization (Saavedra et al., 2018). The characteristics of bladder dysfunction in children vary according to the level of the neurological lesion and the influence of bony growth and development on the spine. Thus ongoing urological monitoring is essential. Evidence is growing that early intervention serves to improve bladder function, reduces the risk of subsequent urinary system distress, and decreases the need for reconstructive surgery of the lower urinary tract (Snodgrass & Gargolla, 2010).

Treatment of renal conditions includes (1) regular urological care with prompt and vigorous treatment of urinary tract infections; (2) a method of regular emptying of the bladder, such as clean intermittent catheterization (CIC) performed by parents or the child; (3) anticholinergic medications to improve bladder storage and continence, such as oxybutynin chloride (Ditropan) and tolterodine (Detrol); and (4) surgical procedures such as bladder augmentation or bladder substitution, including *vesicostomy* (bladder surgically brought out to the abdominal wall, allowing continuous urinary drainage) and *augmentation enterocystoplasty* (using a segment of bowel or stomach to increase bladder capacity, thereby reducing high bladder pressures).

However, despite the combined efforts of CIC, medication, and surgical intervention, some children with myelomeningocele may continue to experience debilitating urinary incontinence. Many of these children are able to attain social continence with a continent urinary diversion commonly referred to as the *Mitrofanoff procedure*. In this procedure, a catheterizable channel is surgically created from the appendix, ureter, or tapered bowel. The proximal end of the channel is connected to the bladder with the distal end brought out as a small stoma on the abdominal wall, usually near the umbilicus. The bladder neck may be sutured to prevent urinary leakage from the urethra. CIC through the easily accessible abdominal route fosters greater independence in children, especially in those unable to transfer from a wheelchair to a toilet to perform CIC. Continence is highly associated with psychosocial outcomes and self-confidence and is a critical aim, particularly in adolescence (Saavedra et al., 2018).

Bowel control. Some degree of fecal continence can be achieved in most children with myelomeningocele. Bowel management programs aim for predictable bowel movements, social continence, and independence and include diet modification, regular toilet habits, and prevention of constipation and impaction (Ambartsumyan & Rodriguez, 2018). Dietary fibre supplements (recommended dosage is age of child in years + 5 = g /day), laxatives, stool softeners, suppositories, or enemas aid in producing regular evacuation. Older children and adolescents seeking more independence may attain bowel continence and higher quality of life after undergoing an antegrade continence enema (ACE) procedure (Masadeh et al., 2013). In a procedure similar to

Mitrofanoff, the appendix or ileum is used to create a catheterizable channel with attachment of the proximal end to the colon. The distal end of the channel exits through a small abdominal stoma. Every 1 or 2 days, a catheter is passed through the stoma, allowing enema solution to be instilled directly into the colon. After administration of the enema solution, the child sits on the toilet for 30 to 60 minutes as stool is flushed out through the rectum. Frequency of enemas and volume of solution used to completely evacuate the bowel vary among individuals.

Prognosis. The early prognosis for the child with myelomeningocele depends on the neurological deficit present at birth, including motor ability, bladder innervation, and associated neurological anomalies. Early surgical repair of the spinal defect, antibiotic therapy to reduce the incidence of meningitis and ventriculitis, prevention of renal damage, and early detection and correction of hydrocephalus have significantly increased the survival rate and quality of life for such children. Children with SB often have learning disabilities and challenges with executive function, particularly if they have associated hydrocephalus (Alimi et al., 2018). Many children with SB achieve partial independent living and gainful employment. Reports of survival rates vary; many include adults who were born before medical advances and surgical techniques seen in the past 25 years.

In children and adolescents with SB, the achievement of urinary continence is associated with improved self-concept and self-esteem, especially among girls. This chronic condition has an array of associated complications, including hydrocephalus and shunt malfunctions, Chiari II development, scoliosis, bowel and bladder management issues, latex allergy, and epilepsy. However, based on current medical knowledge and ethical considerations, aggressive, early management for the child with myelomeningocele improves the prognosis.

Prevention. In Canada, the rate of NTDs decreased from 9.2 per 10 000 total births in 1995 to 5.7 per 10 000 total births in 2014 (Government of Canada, 2019); NTD occurs in about 1 in 1 200 births (Spina Bifida and Hydrocephalus Association of Canada, 2020). Prenatal supplementation of folic acid and the increased use of prenatal diagnostic techniques and termination of pregnancies have affected the overall incidence of NTDs. The Government of Canada and the Society of Obstetrician and Gynecologists of Canada recommend that pregnant patients be advised to maintain a healthy folate-rich diet; however, folic acid supplementation is needed to achieve the red blood cell folate levels associated with maximal protection against NTD (Health Canada, 2019; Wilson & Genetics Committee, 2015). The amount of folic acid required depends on the risk for NTDs in the patient and their partner (see Box 12.2). Nurses and other health care workers have an important task in disseminating information that may decrease the incidence of birth defects in children by promoting pregnant persons' consumption of folic acid (see Chapter 12, Preconception Nutrition).

Nursing Care. At birth an examination should be performed to assess the intactness of the membranous cyst. If a defect is assessed, every effort should be made to prevent trauma to this protective covering. In addition to the routine assessment of the newborn (see Chapter 26), the newborn should be assessed for the level of neurological involvement. Movement of extremities or skin response, especially an anal reflex that might provide clues to the degree of motor or sensory impairment, should be noted. It is important to observe the infant's behaviour in conjunction with the stimulus, since limb movements can be induced in response to spinal cord reflex activity that has no connection with the higher centres. Observation of urine output, especially if a diaper remains dry, may indicate urinary retention. Abdominal assessment revealing bladder distension, even with a wet diaper, may indicate urinary overflow in a retentive bladder. The head circumference should be measured daily and the fontanels examined for signs of tension or bulging.

Care of the myelomeningocele sac. The infant is usually placed in an isolette or warmer so that temperature can be maintained without clothing or covers that might irritate the spinal defect. Before surgical closure, the myelomeningocele is prevented from drying by the application of a sterile, moist, saline gauze dressing over the defect (Boyd et al., 2016). When an overhead warmer is used, the dressings over the defect require more frequent moistening because of the dehydrating effect of the radiant heat.

Dressings are changed frequently (every 2 to 4 hours), and the sac is closely inspected for leaks, abrasions, irritation, or any signs of infection. The sac must be carefully cleansed if it becomes soiled or contaminated. Sometimes the sac ruptures during birth or transport, and any opening in the sac greatly increases the risk of infection to the central nervous system (see Figure 54.6, *B*).

! NURSING ALERT

Avoid measuring rectal temperatures in infants with SB. Because bowel sphincter function is frequently affected, the thermometer can cause irritation and rectal prolapse.

One of the most important and challenging aspects in the early care of the newborn with myelomeningocele is positioning. Before surgery the newborn is kept in the prone position to minimize tension on the sac and the risk of trauma. The prone position allows for optimal positioning of the legs, especially in cases of associated hip subluxation. The newborn is placed prone with the hips slightly flexed and supported to reduce tension on the defect. The legs are maintained in abduction with a pad between the knees to counteract hip subluxation, and a small roll is placed under the ankles to maintain a neutral foot position. A variety of aids, including diaper rolls, pads, small foam pads, or specially designed frames and appliances, can be used to maintain the desired position.

Preventing complications. The prone position affects other aspects of the infant's care. For example, in this position the infant is more difficult to keep clean, pressure areas are a constant threat, and feeding becomes an issue. The infant's head is turned to one side for feeding. Fortunately, most defects are repaired early, and the infant can be held for feeding soon after surgery. Special care must be taken to avoid pressure on the operative site.

Diapering the infant may be contraindicated until the defect has been repaired and healing is well advanced or epithelialization has taken place. The padding beneath the diaper area should be changed as needed to keep the skin dry and free of irritation. When urinary retention is detected, CIC is used. Because the bowel sphincter is frequently affected, there is continual passage of stool, often misinterpreted as diarrhea, which is a constant irritant to the skin and a source of infection to the spinal lesion.

Areas of sensory and motor impairment are subject to skin breakdown and require meticulous care. Placing the newborn on a special mattress or mattress overlay reduces pressure on the knees and ankles. Periodic cleansing and gentle massage aid circulation.

Gentle range-of-motion exercises should be carried out to prevent contractures, and stretching of contractures is performed when indicated. However, these exercises may be restricted to the foot, ankle, and knee joint. When the hip joints are unstable, stretching against tight hip flexors or adductor muscles, which act much like bowstrings, may aggravate a tendency toward subluxation. Consultation with a

physiotherapist is an important aspect of the short- and long-term management of newborns with myelomeningocele.

Newborns with unrepaired myelomeningocele may be unable to be held in the arms and cuddled as unaffected newborns are; their need for tactile stimulation is met by caressing, stroking, and other comfort measures. One method to protect the sac while the parent is holding the newborn is to place a pillow on the parent's lap and lay the newborn on the side on the pillow.

! NURSING ALERT

It is important for nurses to observe for early signs of infection, such as temperature instability (axillary), irritability, and lethargy, and for signs of increased intracranial pressure, which might indicate developing hydrocephalus.

Providing postoperative care. Postoperative care of the newborn with myelomeningocele involves the same basic care as that of any postsurgical newborn: monitoring vital signs, monitoring intake and output, providing nourishment, observing for signs of infection, and managing pain as needed. Care of the operative site is carried out under the direction of the surgeon and includes close observation for signs of leakage of CSF. To prevent stool contamination into the incision, nurses can employ a flap of surgical drape, cut to size, adhered to the lower back below the incision. General care is continued as preoperatively.

The prone position is maintained after surgical closure, although many neurosurgeons allow a side-lying or partial side-lying position unless it aggravates a coexisting hip subluxation or permits undesirable hip flexion. This offers an opportunity for position changes, which reduces the risk of pressure injuries and facilitates feeding. If permitted, the newborn can be held upright against the body, with care taken to avoid pressure on the operative site. After the effects of anaesthesia have subsided and the newborn is alert, feedings may be resumed unless there are other anomalies or associated complications.

Supporting the family. As soon as the parents are able to assist with the newborn's care, they should be encouraged to become involved. They need to learn how to provide the special care their child needs at home, including positioning, feeding, skin care, and range-of-motion exercises when appropriate. In addition, they must learn CIC technique when it is prescribed. Parents also need to know the signs of complications (urinary, neurological, orthopedic) and how to obtain assistance when needed.

The parent who wishes to breastfeed their newborn should be encouraged to do so. Shortly after birth, the parent is started on a program of pumping to initiate and maintain milk supply until the newborn is stable enough to begin breastfeeding. This process may require considerable support from nurses, lactation consultants, health care providers, and family members because of separation from the newborn for surgical care and recovery.

The long-range planning and support of the parents and newborn begin in the hospital and continue throughout childhood and even into young adulthood. The life expectancy of children with SB extends well into adulthood; thus planning should involve long-term goals and plans for optimum function as an adult. As the child with SB matures, preparing for transition to adult care becomes increasingly important. The Spina Bifida Association has developed transition guidelines to assist patients, families, and health care providers with this process (Fremion & Dosa, 2019). Discussion about aspects of adulthood, such as receiving educational or vocational training, living independently, having a mate, having sexual relationships, and bearing and rearing children, is important and should not be overlooked. Betz et al. (2010) interviewed young people with SB making the transition to adulthood. Some common themes that emerged were (1) challenges in preparation for self-management, (2) limited social relationships, (3) awareness of their cognitive challenges, and (4) the cost of independence.

Nurses assume an important role as a central member of the health care team. As a care manager and coordinator, the nurse reviews information with the family, takes responsibility for family teaching, and acts as a liaison between inpatient and outpatient services. The child may need numerous hospitalizations over the years, and each one will be a source of stress to which the younger child is especially vulnerable (see Chapter 41 for a discussion of care of the child with a complex condition).

Habilitation involves solving not only issues of self-help and locomotion but also the challenge of urinary or bowel incontinence, which threatens the child's social acceptance. Assistance in preparing the child and the school for the child's special needs helps provide a better initial adjustment to this broader social experience.

The Spina Bifida and Hydrocephalus Association Canada is a national centre that provides support and various services for families of children with spinal lesions (see Additional Resources at the end of this chapter).

Latex Allergy. Latex allergy or **latex hypersensitivity** was identified as a serious health hazard when a report linked intraoperative anaphylaxis with latex in children with SB. *Latex*, a natural product derived from the rubber tree, is used in combination with other chemicals to give elasticity, strength, and durability to many products. Children with SB are at high risk for developing latex allergy because of repeated exposure to latex products during surgery and procedures. Therefore, such children should not be exposed to latex products from birth onward, to minimize the occurrence of latex hypersensitivity. Allergic reactions range from urticaria, wheezing, watery eyes, and rashes to anaphylactic shock. More severe reactions tend to occur when latex comes in contact with mucous membranes, wet skin, the bloodstream, or an airway. There also can be cross-reactions to a number of foods (e.g., banana, avocado, kiwi, chestnut).

Allergic reactions to latex protein can also occur when the substance is transferred to food by food handlers wearing latex gloves. See Box 54.4 for medical conditions associated with a risk of latex allergy.

The most important goals regarding latex allergy are its prevention and the identification of children with a known hypersensitivity (see Family-Centered Care box: Identifying Latex Allergy). High-risk and latex-allergic individuals must be managed in a *latex-free* environment. Care must be taken so that they do not come in direct or secondary contact with products or equipment containing latex *at any time* during

BOX 54.4 Medical Conditions Associated With Risk of Latex Allergy

- Spina bifida
- Urogenital anomalies
- Imperforate anus
- Esophageal atresia/tracheoesophageal fistula
- VATER association (vertebral defects, imperforate anus, tracheoesophageal fistula, and radial and renal dysplasia)
- Preterm infants
- Ventriculoperitoneal shunt
- Neurocognitive impairment
- Cerebral palsy
- Tetraplegia
- Multiple surgeries
- Atopy

medical treatment. Allergy testing has been used to identify latex allergy with varying success. Skin prick testing and provocation testing carry the risk of allergic reaction or anaphylaxis. Several commercially available assays can be useful in confirming latex sensitivity. To date, none of these tests demonstrates complete diagnostic reliability, and they should not be the sole determinant of the presence or absence of an allergic response to latex.

FAMILY-CENTRED CARE

Identifying Latex Allergy

- Does your child have any symptoms, such as sneezing, coughing, rashes, or wheezing, when handling rubber products (e.g., balloons, tennis or Koosh balls, adhesive bandage strips) or when in contact with rubber hospital products (e.g., gloves, catheters)?
- Has your child ever had an allergic reaction during surgery?
- Does your child have a history of rashes, asthma, or allergic reactions to medication or foods, especially milk, kiwi, bananas, or chestnuts?
- How would you identify or recognize an allergic reaction in your child?
- What would you do if an allergic reaction occurred?
- Has anyone ever discussed latex or rubber allergy or sensitivity with you?
- Has your child had any allergy testing?
- When did your child last come in contact with any type of rubber product? Were you present?

Nonlatex products lists are available to parents and health care workers; these products may be substituted for those containing latex. In the health care arena, it is important to use products with the lowest potential risk for sensitizing patients and staff members. Many health care facilities are establishing latex-safe environments.

! NURSING ALERT

Ask all patients, not only those at risk, about allergic reactions to latex during the health interview with the parent or child. Be certain that this is a routine part of all preoperative and preprocedural histories. Stress the importance of the allergy history to all personnel (e.g., phlebotomists).

The identification of those sensitive to latex is best accomplished through careful screening of *all* patients (see Family-Centered Care box: Identifying Latex Allergy for questions related to latex allergy). Children with latex hypersensitivity should carry or wear some form of medical alert identification; those who have had serious reactions should also carry an injectable epinephrine pen and a pair of latex-free gloves for emergencies. In addition to educating caregivers about the child's exposure to medical products that contain latex, nurses need to inform them of common nonmedical latex objects, such as water toys, pacifiers, and plastic storage bags. Parents should also be given literature explaining signs and symptoms of latex hypersensitivity and appropriate emergency treatment (see Anaphylaxis, Chapter 47).

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a disorder characterized by progressive muscle atrophy, weakness, and paralysis caused by degeneration of the motor neurons (anterior horn cells) of the spinal cord and brainstem (Mercuri et al., 2018). It is an autosomal recessive disorder involving a defect in the survival motor neuron 1 (*SMN1*) gene on chromosome 5q, which causes SMN protein deficiency. It has a varied presentation and is typically classified into three main types based on age of symptom onset and maximum function achieved (Haliloglu, 2020; Kolb & Kissel, 2014) (Box 54.5):

BOX 54.5 Clinical Manifestations of Spinal Muscular Atrophy*

Type 1

Symptoms manifest within the first 6 months of life (may appear normal at birth)
Profound hypotonia and inactivity are most prominent features
Weakness more pronounced in proximal muscles and in the lower limbs
Infants often lie in the frog position with legs externally rotated, abducted, and flexed at knees
Active movement usually limited to hands, fingers and toes
Absent deep tendon reflexes
Paradoxical breathing pattern (diaphragmatic and abdominal) with chest wall collapse and abdominal protrusion, creating a bell-shaped torso
Tongue fasciculations (uncontrolled twitching)
Impaired head control with weak cry and cough (may be absent)
Secretions tending to pool in oropharynx
Alert facies
Normal sensation and intellect
Fatigue quickly during feedings and are prone to aspiration (if breastfed, may lose weight before noticeable)
Affected infants fail to progress to sitting alone, rolling over, or walking
Early death (usually by 2 years of age) from respiratory failure or infection

Type 2

Symptoms manifest between 6 and 18 months of age:
Early—Weakness confined to arms and legs
Later—Becomes generalized
Weakness is slowly progressive with legs affected to greater extent than arms
Initially have head control and able to sit independently, but few can ambulate
Weakness progresses over time leading to swallowing and breathing difficulties, kyphoscoliosis, and joint contractures
Lifespan varies from 3 years to mid-20s, although may have a near normal life expectancy

Type 3

Symptoms manifest after 18 months of age, but may not be seen until adolescence
Normal head control and ability to sit unassisted by 6 to 8 months of age
Thigh and hip muscles are more noticeably affected, but arms and shoulders are also weakened
All learn to walk, but may have difficulty walking long distances, climbing stairs, and getting up from a sitting position
Many present with:
- Waddling gait
- Hyperextension of the knee joints
- Protuberant abdomen with lordosis

Weakness is slowly progressive
Confined to a wheelchair by second decade (may vary)
Loss of ambulation in adolescents or young adulthood
Deep tendon reflexes may be present early but disappear
Scoliosis common
Normal life expectancy unless there is significant respiratory compromise

*Note: These classifications are general and based on the natural history of spinal muscular atrophy. The availability of new treatments is changing the trajectory of the disorder, leading to improved function and prolonged lifespan.

Type 1—symptom onset before 6 months of age, unable to sit unsupported

Type 2—symptom onset between 6 and 18 months of age, able to sit independently, unable to walk

Type 3—symptom onset after 18 months of age, able to walk (though often loses this function over time)

A very rare, severe form of SMA, classified as type 0, is typically not compatible with life. Pregnant persons report decreased fetal movements in utero and infants who survive through pregnancy are born with profound muscle atrophy, joint contractures, and respiratory distress (Haliloglu, 2020. Lastly, there is a SMA type 4, which presents in adulthood (Haliloglu, 2020; Prior, 2010).

SMA type 1 has the most severe presentation with high morbidity and mortality. Without treatment, infants typically die within the first 2 years of life from progressive muscle weakness and respiratory failure. Patients with SMA type 2 also have a shortened lifespan, but will often live into young adulthood. Those with SMA type 3 and 4 typically have a normal lifespan.

Diagnostic Evaluation and Therapeutic Management. The diagnosis is based on the molecular genetic marker for the *SMN* (survival motor neuron) gene, which is located on chromosome 5q13. In families with genetic risk, prenatal diagnosis may be made by genetic analysis of circulating fetal cells in the pregnant person's blood or circulating fetal cells in amniotic fluid. The risk of subsequent affected offspring in carriers of the mutant gene or in families with known cases of SMA may also be evaluated genetically. In patients suspected of having SMA, molecular genetic testing is the gold standard for diagnosis.

While there is no cure for SMA, treatments are available that are changing the course of the disease trajectory. Currently approved in Canada is nusinersen (Spinraza), an antisense oligonucleotide that helps the body make more SMN protein. Greater production of the SMN protein leads to improved function and survival (Finkel et al., 2018). The medication is administered intrathecally, initially as four loading doses (the first three each given 2 weeks apart and the fourth dose given about 1 month after the third dose), then once every 4 months as a maintenance dose. The earlier the treatment is initiated the better the outcome, with presymptomatic treatment offering the best outcomes (De Vivo et al., 2019). Consequently, SMA is now being added to some provinces' newborn screening assessments to offer timely identification and treatment.

In addition to nusinersen, a new therapy called onasemnogene abeparvovec (Zolgensma) is being used to treat SMA in the United States and is being considered for use in Canada. Zolgensma is a gene replacement therapy containing the human *SMN* gene, which increases the functional SMN protein in motor neurons (Al-Zaidy & Mendell, 2019; Mendell et al., 2017). Administered as a one-time intravenous (IV) infusion, this therapy has been found to improve motor function and survival in infants with SMA type 1, with ongoing trials assessing its efficacy in children with other types of SMA. These treatments, along with other agents showing promise in clinical trials, are offering much needed hope for patients with SMA and their families.

Despite the availability of new disease-modifying treatments, patients with SMA continue to need interprofessional symptomatic and preventive care to manage the comorbidities associated with this disorder (Mercuri et al., 2018). For example, preventing joint contractures and surgically treating orthopedic issues, the most serious of which is scoliosis, is an important aspect of care. Hip subluxation and dislocation may also occur. Many children benefit from the use of powered chairs, lifts, special pressure-adjustable mattresses, and accessible environmental controls. Stretching, positioning, bracing, mobility, and exercise all play a role in maximizing function and independence. Nutritional growth failure (failure to thrive) may occur due to impaired swallowing ability, often necessitating supplemental gastrostomy feedings to maintain adequate nutritional status and maintain weight gain. The use of lower extremity orthoses may assist with ambulation in patients with SMA type 3, but eventually the child may require a wheelchair as muscle atrophy progresses.

Restrictive lung disease is the most serious complication of SMA, relating to poor trunk and thoracic muscular support and exacerbated by scoliosis and distortion of the rib cage (Kolb & Kissel, 2014; Mercuri et al., 2018). Upper respiratory tract infections often occur and are treated with antibiotic therapy. Pneumonias with respiratory failure are the cause of death in many children. Sleep-disordered breathing is common in children with SMA types 1 and 2 and can lead to respiratory failure. Pulmonary care has recently shifted from a reactive approach to a more proactive approach of introducing therapies such as noninvasive positive pressure ventilation for those exhibiting signs of nocturnal hypoventilation, and mechanical insufflation-exsufflation (e.g., Cough Assist), manual chest physiotherapy, and suctioning for airway clearance in those exhibiting an ineffective cough (Finkel et al., 2018). **Noninvasive ventilation** methods such as bilevel positive airway pressure (BiPAP) have decreased the morbidity and increased the survival rate of children with SMA types 1 and 2. Children with SMA type 1 who undergo tracheotomy and invasive ventilation often remain ventilator dependent for the rest of their lives, and some families choose to withdraw support when invasive ventilation becomes necessary (Mercuri et al., 2012). Palliative care is an important aspect of care for families of children with SMA type 1 who fail to adequately respond to treatments and experience respiratory failure.

Prognosis. Prognosis varies according to the age of onset or type as described in Box 54.5. Without timely administration of disease-modifying treatment, such as nusinersen or onasemnogene abeparvovec, individuals with SMA type 1 usually succumb to respiratory tract infections or failure between 1 and 24 months of age (Haliloglu, 2020); however, some live longer when supported by enteral feeding and invasive mechanical ventilation with tracheostomy. The newer treatments are changing the trajectory of this disorder, and many patients with SMA type 1 are able to sit and are now reaching school age without the need for invasive mechanical ventilation. The long-term prognosis in these treated patients remains unknown.

Nursing Care. The infant or small child with progressive muscle weakness requires nursing care similar to that of the immobilized patient (see Chapter 53). However, the underlying goal of treatment should be to assist the child and family in coping with the illness while progressing toward a life of normalization within the child's capabilities. Special attention should be directed at preventing muscle and joint contractures, promoting independence in performance of ADLs, and incorporating the child into the mainstream of school when possible. Because children with neuromuscular disease have abnormal breathing patterns that often contribute to early death, it is important to assess adequate oxygenation, especially during the sleep phase when hypoventilation occurs and hypoxemia may develop. Home pulse oximetry may be used to assess the child during sleep, and sleep studies may be required to assess the need for noninvasive ventilation (see discussion below in Duchenne Muscular Dystrophy, for respiratory management). Supportive care also includes management of orthoses and other orthopedic equipment as required. Because children with SMA are intellectually normal with healthy sensation, verbal, tactile, and auditory stimulation are important aspects of developmental care. Supporting children so they can see the activities around them and transporting them in appropriate equipment (e.g., wheelchair, wagon) for a change

of environment are ways to provide stimulation and enhance their development.

Children who are able to sit require proper support and attention to alignment to prevent deformities and promote comfort. Children who survive beyond infancy need attention to educational needs and opportunities for social interaction with other children. The parents of a child who is chronically ill require much support and encouragement (see Chapter 41). Parents who have not sought genetic counselling should be encouraged to do so in order to evaluate further risk potential.

Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD), the most common type of muscular dystrophy, is an X-linked recessive neuromuscular disorder involving mutations in the dystrophin gene (Birnkrant et al., 2018a). These mutations cause the absence of the structural protein dystrophin found in muscle fibre membranes, which leads to progressive muscle degeneration and weakness. Muscle cell fibres (primarily skeletal and cardiac) go through cycles of deterioration and regeneration until repair capacity is no longer sufficient. Ultimately, the muscle fibres undergo irreversible degradation and are replaced by fat and connective tissue (Boyd et al., 2016).

As in all X-linked disorders, males are affected almost exclusively, though in rare instances, a female may be identified with DMD, but with a milder presentation than in boys (Bharucha-Goebel, 2020). The female carrier may have an elevated creatinine kinase, but no muscle weakness; however, about 10% of female carriers develop cardiomyopathy (Bharucha-Goebel, 2020). The incidence is approximately 1 in 3 600 male births (Bharucha-Goebel, 2020). Box 54.6 describes the characteristics of DMD.

Most children with DMD reach the appropriate developmental milestones early in life, although they may have mild, subtle delays. Evidence of muscle weakness usually becomes apparent around 2 to 5 years of age, although there may have been a history of delay in motor development, particularly walking. Difficulties in running, jumping, and climbing stairs as well as frequent falls and toe-walking are usually the first symptoms noted. Typically, affected boys present with a waddling gait and lordosis and develop a characteristic manner of rising from a squatting or sitting position on the floor, called **Gower sign** (Figure 54.7). Lordosis occurs as a result of weakened pelvic muscles, and the waddling gait is a result of weakness in the gluteus medius and maximus muscles. In the early years, rapid developmental gains may mask the progression of the disease.

Muscles, especially in the calves, thighs, and upper arms, become enlarged from fatty infiltration and feel unusually firm, woody, or rubbery on palpation (Box 54.7). The term *pseudohypertrophy* is derived from this muscular enlargement. Profound muscular atrophy occurs in the later stages; contractures and abnormalities involving large and small joints are common complications as the disease progresses. Ambulation is usually lost by late childhood or early adolescence. The loss of mobilization further increases the spectrum of complications, which may include osteoporosis, fractures, constipation, skin breakdown, and psychosocial and behavioural issues. Atrophy of facial, oropharyngeal, and respiratory muscles occurs as the disease progresses. Ultimately, the disease process leads to significant cardiac and

BOX 54.6 Characteristics of Duchenne Muscular Dystrophy

- Early onset, usually between 2 and 5 years of age
- Progressive muscular weakness, wasting, and contractures
- Calf muscle hypertrophy in most patients
- Loss of independent ambulation by 12 years of age
- Slowly progressive, generalized weakness during teenage years
- Relentless progression until death from respiratory or cardiac failure

BOX 54.7 Clinical Manifestations of Duchenne Muscular Dystrophy

Waddling gait
Lordosis
Frequent falls
Gower sign (child turning onto side or abdomen, flexing knees to assume a kneeling position, then with knees extended gradually pushing torso to an upright position by "walking" the hands up the legs)
Enlarged muscles (especially thighs and upper arms); feel unusually firm or woody on palpation
Later stages: profound muscular atrophy
Cognitive impairment
- Mild (about 20 IQ points below normal)
- IQ <70 present in 25 to 30% of patients

Complications:
- Contracture deformities of hips, knees, and ankles
- Scoliosis
- Risk of fractures
- Respiratory and cardiac compromise
- Obesity

Fig. 54.7 A child with Duchenne muscular dystrophy (DMD) attains standing posture by kneeling and then gradually pushing his torso upright (with knees straight) by "walking" his hands up his legs (Gower sign). Note the marked lordosis in an upright position.

respiratory compromise causing premature death (Bharucha-Goebel, 2020; Birnkrant et al., 2018b).

Obesity is a common complication that contributes to premature loss of ambulation. Children with restricted opportunities for physical activity may inadvertently consume calories in excess of their needs. Proper dietary intake and a diversified recreational program can help reduce the likelihood of obesity and enable children to maintain ambulation and functional independence for a longer time.

Mild to moderate cognitive impairment is commonly associated with MD. A deficiency of dystrophin isoforms in brain tissue causes intellectual impairment (Bharucha-Goebel, 2020). The majority of affected children have learning disabilities that still allow them to function in a regular classroom, particularly with remedial help, although more severe cognitive impairment is present in 20 to 30% of these children with an IQ of less than 70 (Bharucha-Goebel, 2020). Verbal IQ is markedly low in boys with DMD, and emotional disturbance is more common than in other children with disabilities.

Diagnostic Evaluation. The diagnosis of DMD is most often confirmed with molecular genetic testing, identifying a deletion, duplication, or point mutation of the dystrophin gene (Bharucha-Goebel, 2020; Birnkrant et al., 2018a). Prenatal diagnosis is also possible as early as 12 weeks of gestation. The clinical symptoms typical of DMD in conjunction with creatine kinase levels 10 times or above normal warrant molecular genetic testing for DMD. If the mutation is not identified through traditional of more advanced methods, then a muscle biopsy to detect absence of dystrophin may be performed to establish the diagnosis.

Therapeutic Management. There is currently no cure for DMD; however, with improved cardiorespiratory management and treatment with corticosteroids, boys with DMD are living several years longer than in the recent past (Ryder et al., 2017). There is evidence that corticosteroids such as prednisone, prednisolone, and deflazacort increase muscle strength; improve physical function, such as time to climb stairs, rise from the floor, or walk 9 metres; delay loss of ambulation; delay cardiomyopathy onset; reduce the need for scoliosis surgery; preserve pulmonary function; enhance quality of life; and increase survival (Gloss et al., 2016; Matthews et al., 2016). The American Academy of Neurology has published a practice parameter for the administration of corticosteroids in the treatment of DMD, which is supported by the Canadian Paediatric Society (Gloss et al., 2016). Major adverse effects of corticosteroids include weight gain, hirsutism, cushingoid facial appearance, and increased risk of cataracts, fractures, and behavioural changes.

Maintaining optimum function in all muscles for as long as possible is the primary goal; secondary is the prevention of contractures. Children with DMD who remain as active as possible are able to avoid the need for a wheelchair for a longer time. Maintenance of function often involves stretching and range-of-motion exercises, strength and muscle training, breathing exercises to increase and maintain vital lung capacity, surgery to release contracture deformities, bracing, and performance of ADLs.

Parents should be supported in making decisions about the child's care; teaching regarding home safety and prevention of falls is important as well. Parents should be encouraged to ensure the child attends follow-up appointments for medical care and physiotherapy and occupational therapy. Because respiratory tract infections are most troublesome in these children, influenza and pneumococcal vaccines are encouraged, and contact with persons with respiratory tract infections should be avoided. Parents should develop action plans for prompt treatment of respiratory illness.

Eventually, respiratory and cardiac complications become the most debilitating aspect of this disorder, leading to significant morbidity and causing early mortality. Children with DMD develop a continuous decline in respiratory function in adolescence, beginning with obstructive events followed by central and hypopneic events associated with hypercapnia (Zielinski et al., 2018). Comprehensive respiratory care improves outcomes, including survival and quality of life, and involves the use of ventilatory support such as nocturnal noninvasive ventilation (e.g., BiPAP) or invasive ventilation with tracheostomy, airway clearance by means of mechanical in-exsufflation devices and suctioning, and medical treatment such as cardioprotective medications and corticosteroids (Zielinski et al., 2018).

Several devices are available for children with neuromuscular disease to assist with cough and airway clearance when the cough reflex is ineffective or diminished. The mechanical cough in-exsufflator (MIE) has been evaluated and found to be safe and effective in the daily management of respiratory function (Katz et al., 2018). The MIE delivers positive inspiratory pressures at a set rate, followed by negative pressure exsufflation coordinated with the patient's own breathing rhythm. The exsufflation is designed to mimic a cough reflex so mucus can be effectively cleared. Airway suctioning after exsufflation is accomplished as necessary to clear the airways. In children, the MIE may be connected directly to a tracheostomy or used with a mouthpiece or face mask. Its use is recommended during times of respiratory infection and postoperatively if hypoventilation is evident.

The use of routine chest physiotherapy (postural drainage) for DMD has not been adequately evaluated for its effectiveness in clearing the airway of mucus except when there is focal atelectasis and mucus plugging the airways (Katz et al., 2018). Survival in individuals with DMD may be prolonged several years with the use of noninvasive ventilation and mechanically assisted coughing as alternatives to tracheotomy and airway suctioning.

Cardiovascular complications including cardiomyopathy and life-threatening rhythm abnormalities are the leading cause of morbidity and mortality in DMD (Birnkrant et al., 2018b). Although symptoms typically manifest later in the disease process, a proactive approach of early diagnosis and treatment is recommended. This includes an annual electrocardiogram and echocardiogram or cardiovascular MRI to assess cardiac function, and initiating treatment with angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) or antiarrhythmic medications as soon as abnormalities are identified (Buddhe et al., 2018). Antithrombotic medications are also considered for individuals with left ventricular dysfunction (Birnkrant et al., 2018b).

Long-term care, advance directives, and palliative care options are issues that must be discussed with the child and family affected by DMD. These discussions should begin early and be revisited periodically as the disorder progresses, during critical illness, or when making major treatment decisions regarding surgery or ventilatory support options (Birnkrant et al., 2018c). Professional counselling may be required to allow frank discussion of these issues, and referrals should be made as appropriate.

Nursing Care. The care and management of a child with DMD involve the combined efforts of an interprofessional health care team. Nurses can help clarify the roles of these health care providers to family and others. The major emphasis of nursing care is to help the child and family cope with a chronic, progressive, incapacitating disease; to help design a program that will afford maximal independence and reduce the predictable and preventable disabilities associated with the disorder; and to help the child and family cope constructively with the limitations the disease imposes on their daily lives. Because of advances in

technology, most children with DMD live into adulthood; thus the goals of care should also involve decisions regarding quality of life, achievement of independence, and transition to adulthood.

Working closely with other team members, nurses assist the family in developing the child's self-help skills to give the child the satisfaction of being as independent as possible for as long as possible. This requires continual evaluation of the child's capabilities and assisting with appropriate adaptations to promote maximal independence. Most children with DMD recognize the need to become as independent as possible and strive to do so.

Practical difficulties faced by families are physical limitations of housing and mobility. Some families live in houses or apartments that cannot accommodate wheelchairs. Transportation may also be a barrier for families of children with DMD. Assisting with these challenges requires team problem-solving. Diet, nutritional needs, and nutrition modification should be discussed according to the needs of the individual child and family.

Children with DMD tend to become socially isolated as their physical condition deteriorates to the point that they can no longer keep up with their friends and classmates. Their physical capabilities diminish, and their dependency increases at the age at which most children are expanding their range of interests and relationships. A concerted effort may be required to support continued connections with social groups and community leisure activities. As well, adolescents with DMD have the same concerns about dating, intimacy, and sexuality as their peers and need opportunities to discuss these topics and how their needs can be met in light of their physical limitations (Birnkrant et al., 2018c).

The parents' social activities may also be restricted, and the family's activities must be continually modified to accommodate the needs of the affected child. When the child becomes increasingly disabled, the family may consider home-based care, an assisted living facility, or respite care. Unless the child has significant cognitive impairments, the child should be involved in the decisions regarding such care. Nurses can assist with decision making by exploring all available options and resources and supporting the child and family in their decisions. Older children with DMD may also need psychiatric or psychological counselling to deal with issues such as depression, anger, anxiety, and quality of life. Parents can be encouraged to become involved in support groups, as adequate social support from family, community, and other parents can be crucial to coping with caring for a child with chronic illness.

Regardless of how successful a treatment or support program is or how well the family adapts to the disorder, superimposed on the physical and emotional issues associated with a child with a long-term disability is the constant knowledge of the ultimate outcome of the disease. Many of the manifestations seen in a child with a chronic life-limiting illness are usually encountered in these families (see Chapter 41).

Nurses are especially valuable to families as they come to know the family and the family's issues and concerns. Nurses can be alert to the family's issues and needs and make necessary referrals when supplementary services are indicated. Muscular Dystrophy Canada has branches in most communities to assist families in caring for a child with DMD (see Additional Resources at the end of this chapter).

ACQUIRED NEUROMUSCULAR DISORDERS

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is a rare, immune-mediated, potentially life-threatening disease that causes acute inflammation and demyelination of the peripheral nerves. Patients typically present with progressive ascending, symmetrical weakness, sensory changes such as numbness and tingling of the hands and feet, and areflexia. The cranial nerves may also be affected, causing facial weakness, difficulty with speech and swallowing, and ophthalmoplegia. Many individuals with GBS develop autonomic dysfunction such as cardiac arrhythmias and hypertension as well as significant neuropathic pain. Weakness can progress to flaccid paralysis and respiratory failure (Ryan, 2020; Willison et al., 2016). The incidence is 1 to 2 per 100 000 persons per year, with children less often affected than adults (Leonhard et al., 2019).

Chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) is a chronic form of GBS that recurs intermittently or does not improve over a period of months to years (Ryan, 2020). The following discussion focuses on GBS.

Pathophysiology. GBS is an autoimmune disease believed to be an aberrant response to an infection or other immune-mediated trigger, including vaccines, surgery, or trauma. It has been associated with a number of viral or bacterial infections, in particular *Campylobacter jejuni* (gastroenteritis), Epstein-Barr virus, and, more recently, the Zika virus (Leonhard et al., 2019). Onset of GBS symptoms usually occurs within 10 days of the primary infection. Pathological changes in spinal and cranial nerves consist of inflammation and edema with rapid, segmented demyelination and compression of nerve roots within the dural sheath. Nerve conduction is impaired, producing ascending partial or complete paralysis of muscles innervated by the involved nerves. GBS has three phases:

1. *Acute*—This phase starts when symptoms begin and continues until new symptoms stop appearing or deterioration ceases; it may last as long as 4 weeks.
2. *Plateau*—Symptoms remain constant without further deterioration; this phase may last from days to weeks.
3. *Recovery*—The patient begins to improve and progress to optimum recovery; this phase usually lasts a few weeks to months depending on the deficits incurred by the illness.

Diagnostic Evaluation. The diagnosis of GBS is based on clinical manifestations (Box 54.8), CSF analysis, and electromyogram (EMG) findings. CSF analysis reveals an abnormally elevated protein

BOX 54.8 Clinical Manifestations of Guillain-Barré Syndrome

Initial Symptoms
Paresthesia of hands and feet
Ascending symmetrical muscle weakness

Paralysis
Ascending bilateral paralysis beginning in arms and legs and progressing to chest and facial muscles
Frequent involvement of muscles supplied by cranial nerves (especially facial)
Flaccid paralysis with loss of reflexes
May involve facial, extraocular, labial, lingual, pharyngeal, and laryngeal muscles
Intercostal and phrenic nerves:
- Breathlessness in vocalizations
- Shallow, irregular respirations

Other Manifestations
Deep tendon reflexes depressed or absent
Variable degrees of sensory impairment
Neuropathic pain
Urinary incontinence or retention and constipation

concentration, normal glucose, and fewer than 10 white blood cells (WBCs)/mm^3 (Ryan, 2020). An EMG shows evidence of acute muscle denervation. An MRI of the spinal cord may show nerve root enhancement but is not required for diagnosis other than to rule out other causes of paralysis. Other laboratory studies are usually noncontributory but may be used to rule out other diagnoses or to identify a triggering infection (Leonhard et al., 2019). The symmetrical nature of the paralysis helps differentiate this disorder from spinal paralytic poliomyelitis, which usually affects sporadic muscles.

Therapeutic Management. Treatment of GBS is primarily supportive. In the acute phase, patients are hospitalized because respiratory and pharyngeal involvement may require assisted ventilation, sometimes with a temporary tracheotomy. Treatment that can halt progression and expedite recovery are intravenous immunoglobulin (IVIG) and plasma exchange (Leonhard et al., 2019). Plasma exchange has been shown to decrease the length of recovery in patients with severe GBS. Adverse effects include hypotension, fatigue, fever, bleeding disorders, chills, urticaria, and bradycardia. There is also evidence of significant improvement in children given high-dose IVIG therapy (versus supportive treatment alone) (Hughes et al., 2014). IVIG is recommended as the primary treatment of GBS when administered within 2 weeks of disease onset (Hughes, 2008).

Medications that may be administered during the acute phase include a low-molecular-weight heparin to prevent deep vein thrombosis in postpubertal children and adolescents, a mild laxative or stool softener to prevent constipation, and pain medication such as acetaminophen or ibuprofen. Persistent **neuropathic pain** may be treated with gabapentin, which is reported to be more effective than carbamazepine (Ryan, 2020).

Rehabilitation after the acute phase may involve physiotherapy, occupational therapy, and speech therapy. Additional consideration should be given to issues of general weakness and retraining for toileting and feeding.

Course and Prognosis. Better outcomes are associated with younger age, no requirement for mechanical respiratory assistance, slower progression of disease, normal peripheral nerve function on EMG, and treatment with either IVIG or plasma exchange. Recovery usually begins within 2 to 3 weeks, and most patients regain full muscle strength. The recovery of muscle strength progresses in the reverse order of onset of paralysis, with lower extremity strength being the last to recover. Poor prognosis with subsequent residual effects in children is associated with cranial nerve involvement, extensive disability at time of presentation, and intubation.

Most deaths associated with GBS are caused by respiratory failure, thus early diagnosis and access to respiratory support are especially important. The rate of recovery is usually related to the degree of involvement and may extend from a few weeks to months. The greater the degree of paralysis and damage to the axons, the longer the recovery phase.

Nursing Care. Nursing care is primarily supportive and is the same as that required for the child with immobilization and respiratory compromise. The emphasis of care is on close observation to assess the extent of paralysis and on prevention of complications, including aspiration, **ventilator-associated pneumonia (VAP)**, atelectasis, DVT, pressure ulcer, fear and anxiety, autonomic dysfunction, and pain.

The child's respiratory function should be closely monitored during the acute phase, and oxygen source, appropriate-sized resuscitation bag and mask, endotracheal intubation, and suctioning equipment need to be kept available. Vital signs, including neurological signs and level of consciousness, should be monitored frequently.

Should intubation be required, respiratory care involves close monitoring of oxygenation status, usually by pulse oximetry and arterial blood gases; maintenance of an open airway with suctioning; and postural changes to prevent pneumonia. Consideration should be given to preventing opportunistic infections such as VAP; meticulous oral care and hypopharynx suctioning, elevation of the head of the bed 30 degrees, and strict asepsis with suctioning equipment (including catheters, a Yankauer device, or both) should be implemented to prevent VAP.

Children with oral and pharyngeal involvement may be fed via a nasogastric tube to ensure adequate feeding. Immobilization, which occurs with GBS, decreases gastrointestinal function; thus conditions such as decreased gastric emptying and constipation require nursing assessment and appropriate collaborative interventions. While urinary retention is uncommon in GBS, appropriate assessment of urinary output is vital. Temporary urinary catheterization may be required.

Sensory impairment and paralysis in the lower extremities make the child susceptible to skin breakdown; therefore attention should be given to meticulous skin care. Deep vein thrombosis is prevented by means of pneumatic compression (antiembolism) devices, administration of a low-molecular-weight heparin, and early mobilization and ambulation. Autonomic dysfunction may be life-threatening; thus close monitoring of vital signs in the acute phase is essential.

A key to recovery for the child with GBS is the prevention of muscle and joint contractures, so passive range-of-motion exercises must be carried out routinely to maintain vital function. As the disease stabilizes and recovery begins, an active physiotherapy program is implemented to prevent contracture deformities and facilitate muscle recovery. This program may include active exercise, gait training, and bracing.

Although the child may have a generalized paralysis, cognitive function remains intact; thus it is important for nursing care to involve communication with the child regarding procedures and treatments that may be frightening, especially if mechanical ventilation is required. Parents should be encouraged to talk to the child and make eye and physical contact as much as possible to reassure the child during the illness. Identifying an alternative means of communication such as a communication board may be helpful for patients unable to speak.

Pain management is essential in the care of children with GBS. Although neuromuscular impairment may make pain perception more difficult to accurately evaluate, objective pain scales should be used. Gabapentin is the most commonly used medication to manage neuropathic pain in patients with GBS.

Throughout the course of the illness, support of the child and parents is paramount. The usual rapidity of the paralysis and the long period of recovery can greatly tax the emotional reserves of all family members. The parents and child benefit from repeated reassurance that recovery is occurring and from realistic information regarding the risk of permanent disability or residual symptoms. In the event of a residual disability, the family needs assistance in accepting and adjusting to the child's loss of function (see Chapter 41). The GBS/CIDP Foundation of Canada is a nonprofit organization devoted to support, education, and research. It provides support to families from recovered persons, publishes informational literature and a newsletter, and maintains a list of health care providers experienced with the disease (see Additional Resources at the end of this chapter).

Spinal Cord Injuries

Spinal cord injuries (SCIs) with major neurological involvement are rare in children, particularly under the age of 15 years. However, children with these injuries are admitted to major medical centres, and because of the increased survival rate with improved management, nurses are often involved in the care and rehabilitation of children with SCI.

In 2010, an estimated 85 556 people in Canada were living with SCI. Of that group, 43 974 people had SCI due to trauma, with 19 232 individuals living with paraplegia and 24 742 with tetraplegia (Noonan et al., 2012). There are very few statistics for rates of children with SCI in Canada. It is estimated that 2 to 5% of SCIs occur in children, and 80% of these injuries occur in the cervical region (Benmelouka et al., 2020; Parent et al., 2011). The incidence of SCI increases rapidly with age, with greater than 30% of injuries occurring between the ages of 17 and 23, and 53% occurring between the ages of 16 and 30 (Parent et al., 2011).

Mechanisms of Injury. Children with traumatic SCI have different mechanisms of injury and have a better neurological outcome potential than that of adults (Parent et al., 2011). The most common cause of serious spinal cord damage in children is trauma involving motor vehicle collisions (MVCs) (including automobile–bicycle, all-terrain vehicles, and snowmobiles), sports injuries (especially from diving, trampolines, gymnastics, skiing, and snowboarding), birth trauma, or nonaccidental trauma. Many SCIs in children relate to being improperly restrained in the car. The increased use of recreational activities involving motorized vehicles such as jet water skis, all-terrain vehicles, and motorcycles has also increased the incidence of SCIs in children (see Chapter 35 for discussion of injury prevention). SCIs can also be the result of a nontraumatic injury to the spinal cord, including injury from inflammation (e.g., transverse myelitis), spinal stroke, infection, or tumours. Children with nontraumatic SCIs require similar care to that for a child with a traumatic injury except they may require additional treatment to manage the underlying cause of the injury.

In MVCs, most SCIs in children are a result of indirect trauma caused by sudden hyperflexion or hyperextension of the neck, often combined with a rotational force. Trauma to the spinal cord without evidence of vertebral fracture or dislocation (spinal cord injury without radiographic abnormality [SCIWORA]) is particularly likely to occur in an MVC when proper safety restraints are not used. An unrestrained child becomes a projectile during sudden deceleration and is subject to injury from contact with a variety of objects inside and outside the vehicle. Individuals who use only a lap seat belt restraint are at greater risk of SCI than those who use a combination lap and shoulder restraint. High cervical spine injuries have been reported in children younger than 2 years of age who are improperly restrained in forward-facing car seats. Infants who are improperly restrained in an infant car seat may experience cervical trauma in a car crash. Small children may also be severely injured by deployment of front-seat air bags.

Another source of SCI, falling from heights, occurs less often among children than adults. Vertebral compression from blows to the head or buttocks can occur in water sports (diving and surfing), falls from horses, or other athletic activities.

There is also increasing concern about the level of injury-inducing contact in sports in organized leagues across Canada that results in concussions and SCI in children and teenagers (see more discussion on concussion in Chapter 50). Parachute (2020), an organization dedicated to injury prevention, has increased awareness of the risks involved in contact sports and has developed evidence-informed guidelines that identify the risks associated with a variety of sports and offer strategies that maximize safe participation (see Chapter 35). The Canadian Paediatric Society recommends that in all levels of organized recreational and nonelite competitive ice hockey bodychecking be eliminated and that it be delayed (in elite competitive leagues) until players are 13 to 14 years of age (bantam level) or older (Houghton et al., 2012).

Birth injuries may occur in breech births from traction force on the spinal cord during the birth of the head and shoulders. Infants, when shaken, commonly sustain cervical cord damage as well as subdural hematoma and retinal hemorrhage; cognitive impairment and death may occur subsequent to the traumatic event. Infants have weak neck muscles, and during vigorous shaking their large and heavy heads rapidly wobble back and forth.

Fracture or subluxation (partial dislocations) is the most common immediate cause of SCI, particularly in the lower cervical region. Although unusual in adults, SCI without fracture is common in children, whose spines are suppler, weaker, and more mobile than those of adults. Therefore, the force is more easily dissipated over a larger number of segments. Infants and small children under the age of 5 years suffer upper cervical spine fractures and spinal compressions more often, whereas adolescents tend to have lower cervical and thoracolumbar fracture dislocations (Proctor, 2020).

The severity of the force, the mechanism of injury, and the degree of the individual's muscular relaxation at the time of the injury greatly influence the extent of the trauma. SCIs are classified as either complete or incomplete. In a *complete injury*, there is no more motor or sensory function more than three segments below the neurological level of the injury. *Incomplete lesions* have several typical characteristics (Mathison et al., 2008):

- Central cord syndrome—Central grey matter destruction and preservation of peripheral tracts: tetraplegia with sacral sparing common; some motor recovery gained
- Anterior cord syndrome—Complete motor and sensory loss with trunk and lower extremity proprioception and sensation of pressure
- Posterior cord syndrome—Loss of sensation, pain, and proprioception with normal cord function, including motor function; able to move extremities but the person has difficulty controlling such movements
- Brown-Séquard syndrome—Unilateral cord lesion with a motor deficit on the opposite side of the body from the primary insult; absence of pain and temperature sensation on the opposite side from the injury
- Spinal cord concussion—Transient loss of neural function below the level of the acute spinal cord lesion, resulting in flaccid paralysis and loss of tendon, autonomic, and cutaneous reflex activity; may last hours to weeks

The injury sustained can affect any of the spinal nerves, and the higher the injury, the more extensive the damage. The child can be left with complete or partial paralysis of the lower extremities (*paraplegia*) or with damage at a higher level and without functional use of any of the four extremities (*tetraplegia*). A high cervical cord injury that affects the phrenic nerve paralyzes the diaphragm and leaves the child dependent on mechanical ventilation.

A mild but equally frightening form of cord trauma is **spinal cord compression**, a temporary neural dysfunction without visible damage to the cord. Complete tetraplegia can result but initially may not be differentiated from serious cord injury.

Clinical Manifestations. It is often difficult to determine the extent and severity of the damage at first. Immediate loss of function is caused by both anatomical and impaired physiology, and improved function may not be evident for weeks or even months. Manifestations of the initial response to acute SCI is flaccid paralysis below the level of the damage. This state is often referred to as **spinal shock syndrome** and is caused by the sudden disruption of central and autonomic pathways. Local effects of cord edema and ischemia produce a physiological transection with or without an anatomic severance. Most children with an SCI experience some spinal shock. Manifestations include the absence of reflexes at or below the cord lesion, with flaccidity or limpness of the involved muscles, loss of sensation, and motor function and

autonomic dysfunction (symptoms of hypotension, low or high body temperature, loss of bladder and bowel control, and autonomic dysreflexia).

Autonomic paralysis also affects thermoregulatory functions. Afferent impulses from temperature receptors in the skin are not integrated; therefore, the child is subject to temperature increases or decreases in response to alterations in environmental temperature. Hyperthermia can result from excessive ambient temperature, such as having too many bed covers.

Except in the situations previously mentioned, flaccid paralysis is replaced by spinal reflex activity and increasing spasticity or, in incomplete lesions, greater or lesser degree of neurological recovery.

The paralytic nature of autonomic function is replaced by autonomic dysreflexia, especially when the lesion is above the midthoracic level T6. This autonomic phenomenon is caused by noxious stimuli below the level of the lesion. It is most commonly precipitated by overdistension of the bowel or bladder, although it can be triggered by any painful or uncomfortable procedure or any circumstance that causes discomfort, including ingrown toenails, tight clothing, wrinkled sheets, and urinary tract infections (Mahanes et al., 2016). Sensory impulses are triggered and travel to the cord lesion, where they are blocked, which causes activation of sympathetic reflex action with disturbed central inhibitory control and vasoconstriction (Solinsky et al., 2016). The hallmark of autonomic dysreflexia is a drastic increase in systemic blood pressure ($\geq$20 mmHg above baseline), frequently accompanied by a constellation of associated symptoms including headache, bradycardia, cardiac dysrhythmias, profuse diaphoresis and flushing above the level of the lesion, piloerection and pallor below the level of the lesion, nasal congestion, anxiety, and visual changes such as blurred vision, photophobia, and visual field cuts. This phenomenon is potentially life-threatening if the noxious stimuli is not removed.

Additional clinical findings of SCI may include numbness, tingling, or burning; priapism; weakness; and loss of bowel and bladder control.

Neurogenic shock occurs as a result of a disruption in the descending sympathetic pathways with loss of vasomotor tone and sympathetic innervations to the cardiovascular system. Hypotension, bradycardia, and peripheral vasodilation occur as a result of neurogenic shock.

Children with suspected SCI may have suffered multiple injuries (e.g., head injury); therefore clinical manifestations may occur that mask those of an SCI.

Therapeutic Management. Initial care begins at the scene of the accident with proper immobilization of the cervical, thoracic, and lumbar spine. Because of the complexity of these injuries, it is usually recommended that those with injuries be transported to a spinal injury centre for care by specially trained health care providers as soon as possible after the injury for appropriate diagnostic evaluation and intervention.

The initial assessment of the child with a suspected SCI should begin with an assessment of CAB: **C**irculation, **A**irway, and **B**reathing. The airway should be opened using the jaw-thrust technique to minimize damage to the cervical spine. The child is monitored for cardiovascular instability, and measures are taken to support systemic blood pressure and maintain optimal cardiac output. Because MVCs and other trauma in children may involve internal organ damage and potential bleeding, abdominal distension and other signs are acted on immediately to prevent further systemic shock. After the child is stabilized and transported to a regional trauma centre, a thorough evaluation of neurological status and any other associated trauma is carried out by the interprofessional team. In the emergency department, spinal immobilization should be maintained until a thorough neurological assessment has been completed and SCI is ruled out; in children, this typically involves a CT scan and possibly an MRI. Additional interventions are discussed in the Nursing Care section.

Administering IV methylprednisone within the first 8 hours after the injury to decrease inflammation and minimize further injury is a recommendation for adults with SCI (Fehlings et al., 2017); however, it is not recommended in children because of increased risk of serious complications and unsubstantiated benefit (Caruso et al., 2017).

A number of progressive rehabilitation modalities have been developed that have the potential for increasing the quality of life for children with SCI. One such treatment is functional electrical stimulation (FES), also referred to as *functional neuromuscular stimulation,* or *neuromuscular electrical stimulation.* With this treatment, an electrical stimulator is surgically implanted under the skin in the abdomen and electrode leads are tunnelled to paralyzed leg muscles, enabling the child to sit, stand, and walk with the aid of crutches, a walker, or other orthoses. The stimulator can also be used to elicit a voluntary grasp and release with the hand. Before the latter can be accomplished, a number of surgical tendon transfers may be required for elbow extension, wrist extension, and finger and thumb flexion. In addition, FES has therapeutic benefits, which include increased muscle strength, improved gait function, and increased cardiovascular fitness. Tendon transfers have been shown to be successful in enhancing hand and arm function, increasing pinch force, and facilitating independence in ADLs (Hosalkar et al., 2009). Restoration of hand and arm function enables children with SCI to perform self-catheterization and achieve greater independence in personal hygiene.

Exercise is considered an integral part of SCI rehabilitation; exercise may enhance neuroplasticity and decrease further muscle atrophy. Examples of exercise modalities in SCI patients include upper body strength training and hand cycling (Hosalkar et al., 2009).

Administration of pharmacological agents such as clonidine hydrochloride may improve ambulation in patients with partial SCIs. Exercise therapy through interactive locomotor training has also helped some individuals with SCI regain ambulatory function.

A number of orthoses or ambulation aids such as braces may still be necessary to achieve upright mobility, yet as robotic technology advances, so do the chances for improved mobilization in children with SCI. Mechanical or robotic orthoses may be used in conjunction with FES to enable ambulation in persons with SCI. Knee-ankle-foot orthosis and reciprocating gait orthosis may also be used to assist with early rehabilitation and ambulation (Vogel et al., 2012). Gait training may be achieved with a number of different modalities, including a stationary cycle; however, no specific method has proved superior to the others. FES has also been effective in reducing complications from bladder and bowel incontinence and in assisting males in achieving penile erection.

Surgical interventions for SCI include early cord decompression (decompression laminectomy) and cervical or thoracic fusion. Crutchfield, Vinke, or Gardner-Wells tongs and skeletal traction may be used for early cervical vertebral stabilization. A halo vest may be suited for ambulation after the acute phase (see also Types of Traction, Chapter 53). After cervical spinal fusion, a hard cervical collar or sterno-occipital-mandibular immobilizer brace may be worn until the fusion is solidified. When SCI occurs in young children and preteens, scoliosis develops over time and often requires surgical consideration (Parent et al., 2011).

The Rick Hansen Foundation and Accreditation Canada are developing Canadian standards for SCI services. This foundation provides research and resources as well as information on SCI. Spinal Cord Injury Canada also offers various useful services, such as assistive devices and assistive living and information and support about living with a SCI (see Additional Resources at the end of this chapter).

Nursing Care. The nursing care of the child affected by SCI child is complex and challenging. An interprofessional SCI team is equipped to manage the acute phase of the injury, and some members, including the nurse, may follow the patient to eventual recovery. Nursing care is concerned with ensuring adequate initial stabilization of the entire spinal column with a rigid cervical collar with supportive blocks on a rigid backboard. The traumatic event causing the injury may or may not be recalled if the child lost consciousness; such events are frightening to the child. The young child may also be frightened by the immobilization process and the inability to move the extremities; therefore, it is important to reassure and comfort the child during this process.

During the acute phase of the injury it is imperative that airway patency be maintained and respiratory function monitored. The extent of the neurological damage must be evaluated early in order to establish a baseline for neurological functioning; continual assessment of function should occur to prevent further deterioration of neurological status as a result of spinal cord edema. The American Spinal Injury Association (ASIA) Impairment Scale may be used to assess neurological function on a routine basis during the patient's recovery (Box 54.9) (see Additional Resources at the end of this chapter). Once the patient is admitted, further evaluation of the patient's abilities to perform ADLs and need for assistance is ongoing.

Nursing care during the acute phase should also focus on frequent monitoring of neurological signs to determine any changes in neurological function that require further intervention (e.g., level of consciousness using the Glasgow Coma Scale; see Chapter 50). In addition to airway maintenance, the nurse should monitor for changes in hemodynamic status that may require immediate medical attention. Neurogenic shock consists of hypotension, bradycardia, and vasodilation. Inotropic medications may be required to maintain adequate perfusion. Renal function is closely monitored by measuring urinary output and fluids administered. The child with a brain injury may experience elevated intracranial pressure; therefore, changes in neurological status are reported to the health care provider. Fluid restriction may be required if intracranial pressure is elevated, so fluid intake should be closely monitored.

The nursing care of the child with an SCI is, in most respects, the same as that for any immobilized child (see The Immobilized Child, Chapter 53). Additional aspects of care that should be addressed on an individual basis include hypercalcemia in adolescent males, deep venous thrombosis, latex sensitization, pain, hypothermia and hyperthermia, spasticity, autonomic dysreflexia, and sleep-disordered breathing (Vogel et al., 2012).

Respiratory care often focuses on maintaining an adequate airway and effective ventilation. The child with a high-level cervical injury (C3 and above) requires continuous ventilatory assistance. In most instances a tracheostomy is the method of choice for greater ease in clearing secretions and for less trauma to tissues during long-term ventilatory dependence. In some children breathing pacemaker devices (phrenic nerve stimulators) are implanted to stimulate the phrenic nerve and produce diaphragmatic contractions and lung expansion without assisted ventilation. In the child who does not require mechanical ventilation, special attention to clearance of secretions is vital because of decreased pulmonary function. In addition to chest physiotherapy, the child may require a cough-assist device to clear secretions effectively (see Duchenne Muscular Dystrophy: Therapeutic Management, above).

Temperature is often poorly regulated in children with SCI; thus, body temperature must be monitored closely for fluctuations. Response to environmental temperature changes may be slow or absent, and the ability to dissipate heat through the process of shivering may be compromised.

Children with SCI have unique needs in relation to skin care. Because of decreased sensation and impaired mobility, they depend on others to assess and assist in the management of intact skin. Skin care practices are the same as those for any child who is immobilized. A skin score scale such as the Braden QD Scale should be used to objectively evaluate risks for skin breakdown and skin conditions (Chamblee et al., 2018). An alternating-pressure mattress or other pressure relief or reduction device should be kept underneath the child, and the skin needs to be thoroughly inspected at least once a day (or more often if there is increased risk) for signs of pressure and breakdown, especially over bony prominences. Children and adolescents confined to a wheelchair also require meticulous skin care to prevent skin breakdown on insensate areas; frequent position changes and air or gel cushions are helpful but do not eliminate the need for close observation of skin status.

Bowel and bladder function is often affected in the child with SCI. CIC may be required to regularly empty the neurogenic bladder and prevent urinary tract infections. A regular bowel management program should be tailored to the child's needs.

Pain management is vital in children and adolescents with SCI. In children with upper motor neuron involvement, the spasticity that develops may require administration of an antispasmodic medication such as diazepam. Baclofen is considered the medication of choice for reducing muscle spasticity. Gabapentin may be used to treat neuropathic pain. Botulinum toxin type A and α_2-adrenergic agonists may be used in older children with SCI to decrease muscle spasticity.

The child with some lower extremity function progresses to parallel bars and then to a walker; the child with tetraplegia learns to use a wheelchair—among the most valuable aids available to the child with an SCI (Figure 54.8). The wheelchair should be selected carefully in relation to where it will be used, the architectural barriers, and the child's functional capacity. For children with severe upper extremity paralysis, a variety of motorized wheelchairs are used; however, the more complex they are, the greater their cost, weight, and tendency

BOX 54.9 American Spinal Injury Association Impairment Scale

A—complete: No motor or sensory function is preserved in the sacral segments S4 to S5.

B—incomplete: Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4 to S5.

C—incomplete: Motor function is preserved below the neurological level, and more than one-half of key muscles below the neurological level have a muscle grade less than 3.

D—incomplete: Motor function is preserved below the neurological level, and at least one-half of key muscles below the neurological level have a muscle grade of 3 or more.

E—normal: Motor and sensory function are normal.

Clinical Syndromes (Optional)

Central cord
Brown-Séquard
Anterior cord
Conus medullaris
Cauda equina

to break down. Wheelchair tolerance can be gained over time and is accompanied by measures to prevent orthostatic hypotension and pressure ulcers.

A variety of orthoses and other appliances can be adapted for use by many children. The primary purpose of lower extremity bracing in the child with an SCI is for ambulation.

Children with lesions at level T6 or higher are susceptible to the development of autonomic dysreflexia, a life-threatening emergency that requires prompt action to prevent intracranial hemorrhage, cardiac complications, retinal detachment, seizures, and death (Mahanes et al., 2016). Early recognition of autonomic dysreflexia by caregivers is essential, especially in small children who are unable to verbalize their feelings. At the first signs of autonomic dysreflexia symptoms, the patient must be positioned immediately to sit upright and their blood pressure must be checked. Attempts are made to identify the trigger and measures are taken to ameliorate or remove the noxious stimuli, such as loosening tight clothing, unkinking a catheter, catheterizing, disimpacting stool, or smoothing out wrinkled sheets and checking for objects in the bed or wheelchair that may be causing irritation (Solinksy et al., 2016). Medications such as nitropaste, nifedipine, prazosin, or terazosin may be administered to counteract the effects of the condition depending on the child's response to interventions (Vogel et al., 2012).

The child and family with SCI need to be prepared for eventual discharge from the acute care facility to a rehabilitation centre. The major aims of physical rehabilitation are to prepare the child and family to achieve normalization and resume life at home and in the community. Additional goals of rehabilitation in children with SCI are to promote independence in mobility and self-care skills, academic achievement, independent living, and employment.

The nurse is a crucial member of the health care team in helping the family cope with the magnitude of the injury and disability, understand the extent of the disability, verbalize expected outcomes, and move toward eventual rehabilitation and normalization within the child's capabilities. The goals of rehabilitation include preparing the child and family to live at home and function as independently as possible.

KEY POINTS

- Clinical manifestations of CP include delayed gross motor development; abnormal motor performance; alterations of muscle tone; abnormal postures; reflex abnormalities; and associated complex conditions such as cognitive impairment, seizures, and sensory impairment.
- Therapy for CP takes into account the nature of the physical disability, defects associated with the disorder, and interpersonal and social influences encountered by the affected child.
- Care of the infant and child with myelomeningocele is directed toward protecting the meningeal sac, preventing infection and skin breakdown, observing for signs of urological and bowel complications, and planning appropriate interventions to optimize the child's development and overall well-being.
- SMA is characterized by progressive weakness and wasting of skeletal muscles caused by degeneration of anterior horn cells of the spinal cord.
- Major complications of DMD include joint contractures, disuse atrophy, obesity, and respiratory and cardiac conditions.
- Nursing care of the child with GBS consists of monitoring vital signs, providing respiratory support and physiotherapy, managing pain, and providing support to the child and family.
- Therapeutic management of SCI is directed toward immobilizing the entire spinal column at the scene of the traumatic event, safely transporting the patient by health care personnel trained to transport possible spinal trauma victims, evaluating neurological damage, preventing further neurological damage, and implementing an aggressive rehabilitation program designed to help achieve independence and movement.

Caring for the Mental, Emotional, and Behavioural Health Needs of Children and Adolescents

Cheryl L. Pollard

http://evolve.elsevier.com/Canada/Perry/maternal

OBJECTIVES

Upon completion of this chapter the reader will be able to:

1. Identify characteristics of positive mental and emotional health in children and adolescents.
2. Explore factors contributing to mental illness in children and adolescents.
3. Describe the clinical and behavioural symptoms of at least three mental health disorders commonly experienced by children and adolescents.
4. Discuss at least three nursing care considerations when completing a mental status examination with a child or an adolescent.
5. List nursing responsibilities when caring for a child or an adolescent with suicidal ideation.
6. Discuss the nurse's role in helping the child or adolescent and family cope with substance use.

MENTAL, EMOTIONAL, AND BEHAVIOURAL HEALTH

Mental and emotional health are foundational to overall health and well-being. *Mental health* represents an individual's ability to process information. For example, when people experience a clinical depression, an anxiety disorder, or attention deficit disorder, the way in which the brain organizes and stores information is affected. Their ability to remember, problem-solve, pay attention, and learn new information is decreased. These issues represent mental health issues that are caused by a mental illness. *Emotional health* is related to a person's ability to express feelings. Emotional health is about how one feels. It is the emotional response to what the person has observed and interpreted. For example, feeling proud of oneself for completing a challenging assignment or going for a walk is an emotional response to one's thoughts about the assignment or exercise. *Behavioural health* is related to what a person does; what other people can see. This includes behaviours such as eating, drinking, playing, sleeping, relational engagement, touch, substance use, fighting, and yelling. All three aspects of mental health are involved in manifestations of mental disorders. See Table 55.1 for a comparison of mental, emotional, and behavioural symptoms of select mental disorders.

The Role of the Nurse

Mental, emotional, and behavioural health are closely related. Working with children and adolescents who have care needs in these areas requires that the nurse take the time to assess each of these areas as all types of mental illnesses have mental, emotional, and behavioural symptoms. Nurses often focus interventions on the just the behavioural and mental symptoms of the illness. It is not helpful to tell someone to "stop feeling depressed" or to "stop worrying so much." Nurses can determine if their interventions are effective when there are changes in how a person is feeling. If mental illnesses that present during childhood are not treated, many of them will continue into adulthood; people do not simply "grow out of it." The symptoms change on the basis of mental and emotional development of the child or adolescent. The impact of functioning changes because of the coping skills developed and the strategies used to accommodate or reduce the limitations the individual experiences because of the disorder. This process is similar to how a child with diabetes mellitus type 1 learns to live with diabetes. How the child understands diabetes depends on their developmental stage. As the child matures, their understanding of diabetes, responsibilities in managing their diabetes and associated symptoms, and reactions to the accommodations needed (regular blood testing, meal and exercise management) to manage the disorder all change.

Mental and emotional health issues at a young age can affect healthy child development. This includes the child's ability to form healthy relationships (behavioural), regulate attention (mental), manage anxiety and mood (emotional), regulate impulsivity and activity (behavioural), and cooperate with others (behavioural). Up to 50% of mental disorders occurring in adulthood have their onset during adolescence, and approximately 20% of children and adolescents experience mental illness (World Health Organization, 2018). Sadly, those individuals with mental illness, regardless of age, continue to experience stigmatization and discrimination. This results in delays in seeking

TABLE 55.1 Examples of Mental, Emotional, and Behavioural Symptoms in Select Mental Illnesses of Children and Adolescents

Illness	Mental Symptoms	Emotional Symptoms	Behavioural Symptoms
Major depressive disorder	All-or-nothing thinking Memory is usually unimpaired Slower cognitive processing	Sadness Loss of interest Loss of pleasure (anhedonia)	Sleep difficulties Poor hygiene Decreased motivation Poor school performance Slowed motor behaviour Substance use
Separation anxiety disorder	Overestimation of the dangerousness of a situation	Worry Fear Panic	Reluctance to leave attachment figure Sleep difficulties Poor school performance
Bulimia nervosa	Potential changes in self-regulatory and reward neural systems	Sense of loss of control Overeating Guilt Shame Sadness	Eating larger amounts of food than most individuals in a similar period of time under similar circumstances Self-induced vomiting Excessive exercise
Autism spectrum disorder	Deficits in social-emotional reciprocity Difficulty understanding relationships May be with or without intellectual impairment	May have difficulty understanding and identifying their own emotions (alexithymia)	May not show emotion in ways that other people will recognize Avoid eye contact Difficulty developing and maintaining relationships Repetitive motor movements Ritualized patterns of verbal and nonverbal behaviour
Attention-deficit/hyperactivity disorder	Difficulty with sustained focus Disorganization of thoughts Inability to delay gratification Impulsivity Challenges processing emotions	Feelings may be more frequent and intense (flooding) Extreme sensitivity to disapproval Fear Denial Sadness Low frustration tolerance Impatience Irritability Excitability	Wandering off task Excessive fidgeting, talkativeness, restlessness Social intrusiveness Difficulty in school Fights with peers Substance use
Schizophrenia	Fixed beliefs not amenable to change despite conflicting evidence (delusions) Perception-like experiences that occur without external stimuli (hallucinations) Loosening of associations	Decreased motivation (avolition) Lack of interest Decreased range of emotionality	Disorganized motor behaviour Difficulty in school Decreased interactions with peers Poor hygiene Sleep difficulties Decreased emotional expression

support and treatment and is compounded by the lack of recognition of the burdens of these diseases. From a population health perspective, one important nursing care goal is to decrease the stigma associated with living with a mental illness.

In line with this goal, the United Nations member states adopted 17 Sustainable Development Goals (SDGs) in 2015 as a universal call to action to ensure that all people enjoy peace and prosperity by 2030 (United Nations, 2020) (see Figure 1.3). Mental, emotional, and behavioural health are important factors in many of the SDGs. The concepts of privilege, marginalization, power, wealth, culture, and attitudes are at the foundation of advancing mental, emotional, and behavioural health. These factors can also contribute to stigma and stigmatization.

Developing a Collaborative Treatment Relationship. Working with young people can be very different from working with adults. Differences arise when young people have developmentally limited communication skills and cognitive and mental processing abilities or when they do not see the relevance of the mental, emotional, or behavioural issues. The first step to successful care planning is to develop a collaborative treatment relationship. Creating this type of relationship requires empathetic engagement. Such engagement is built when the young person feels noticed, heard, and appreciated. When developmentally appropriate, nurses should offer to talk to the young person first without the parent present. Initiating a conversation about an innocuous observation is a good starting place. For example, the nurse can point something out about the weather, sports, music, a piece of art, or even a recent piece of news or movie and ask the young person what they think about it. The nurse can then gradually introduce conversation that moves toward the intended therapeutic goal. It is important to ensure that the young person knows that they have been heard and that their perspective is appreciated. Nurses should work toward becoming a treatment partner rather than just one more adult the child has to talk to. As a collaborative treatment relationship develops the nurse can use the young person's own chief concern as a guide to shaping further assessment and evaluation questions.

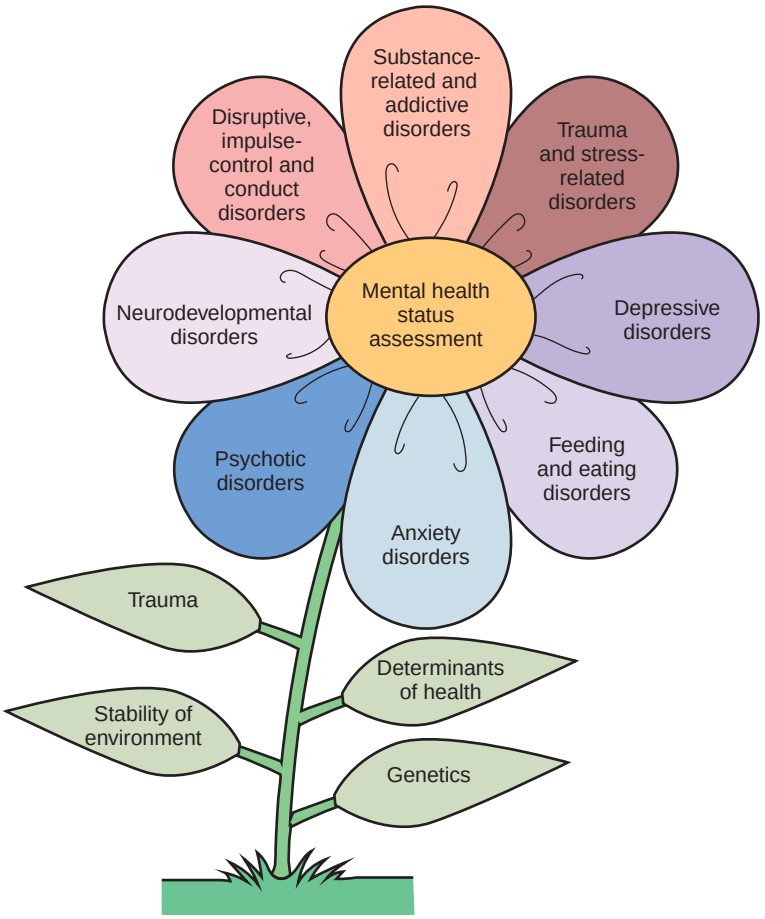

Fig. 55.1 Select mental disorders of children and adolescents. (Adapted with permission from Hamilton Family Health Team Health Initiative: Child & Youth Mental Health Tool Kits. http://www.shared-care.ca/toolkits.)

Factors Contributing to Mental Illness in Children and Adolescents

As with other illnesses, the personal experience of living with a mental illness is shaped not only by the treatment children and adolescents receive but also by the living conditions they experience (Figure 55.1). In bolstering a person's ability to respond to the mental, emotional, and behavioural symptoms of their illness, the determinants of health are key factors to keep in mind and how they shape the health and well-being of children and adolescents. These determinants include social support networks, education, level of family prosperity, culture, availability of health services, physical environment, family health, and coping practices (see Box 1.1).

SPECIFIC MENTAL ILLNESSES IN CHILDREN

Children can, and many do, experience a range of mental disorders, including anxiety disorders, psychotic disorders, neurodevelopmental disorders, conduct disorders, substance-related and addictive disorders, trauma- and stress-related disorders, depressive disorders, and feeding and eating disorders. The prevalence of childhood-onset mental disorders is dependent on the stability and safety of the environment in which the child is raised. More information about adverse childhood events and toxic stress can be found in Chapter 30, Toxic Stress. As an introduction to the mental, emotional, or behavioural health needs of children and adolescents, this chapter will focus on symptoms and experiences common among multiple mental illnesses. These symptoms include anxiety, depression, suicidal ideation, substance misuse, and disturbances in eating and social behaviours. The focus is not on a specific diagnosis as these symptoms are present in many different mental illnesses.

Assessing for the presence of symptoms and effect they are having on physical and psychosocial functioning is essential, as children and adolescents can often have clinically significant suffering without meeting the diagnostic criteria to officially diagnose a mental disorder (Bobevski et al., 2017). It is also important to note that children, adolescents, and adults can experience more than one mental disorder at a time, just as someone might experience diabetes and a thyroid disorder at the same time. One of the more common combinations of comorbid disorders is an anxiety disorder combined with a depressive disorder (Wiens et al., 2020).

Anxiety

All children have worries and fears. However, some children develop anxiety disorders that interfere with their enjoyment of life and get in the way of accomplishing the tasks they need to do. There are many different types of anxiety disorders that can affect children and adolescents. Disorders that present with a significant anxiety component include separation anxiety, generalized anxiety, obsessive-compulsive, panic, phobia, and post-traumatic stress disorder. Some symptoms common to many of the anxiety disorders include expressing worry or showing mental and behavioural symptoms of anxiety most days, trouble concentrating, being unusually irritable or easily upset, difficulty sleeping at night, or being unusually tired and sleepy in the daytime. Children and adolescents who experience anxiety that verges on

BOX 55.1 Assessing Anxiety

Many beginning nurses are hesitant to ask questions related to others' mental illnesses. Some worry that they might make the symptoms worse if they ask their patients to talk about how they are feeling or how the mental illness is affecting their life. This is a cognitive distortion embedded in a fear of not knowing what to do if the person responds that they are in some type of emotional pain. A *cognitive distortion* is a way that our mind convinces us of something that really is not true (asking about thoughts, emotions, or experiences makes them worse)—for example, "If I ask about anxiety, it will make it worse for my patient." These types of inaccurate thoughts reinforce negative thinking by telling ourselves things that sound rational and reasonable but only serve to undermine our professional self-confidence and volition.

The following questions may be used during a conversation about anxiety with a child, adolescent, or caregiver. Nurses can adjust the phrasing of the questions depending on the child's or adolescent's level of functioning and cognitive development. If an affirmative one-word answer is provided, then the nurse can explore the area further by stating, "Please, tell me more about this."

- Do you feel afraid, tense, restless, or worried most of the time?
- Do these worries affect your sleep, performance at school, or relationships with your family and friends?
- Do you have nightmares?
- Is it hard to leave your house, or hard to leave your mom or dad, because of worries?
- Has anything or anyone made you feel uncomfortable or unsafe?
- Have you been hurt recently or been in any accidents?
- When you feel overwhelmed, do you think about hurting yourself?
- Is there something in particular, or a situation, that makes you afraid?
- Do you get sudden surges of fear that make your body feel shaky or your heart race?

panic can develop symptoms as a protective mechanism to keep them from facing the situation that distresses them. Physical symptoms can emerge and may affect any part of the body (e.g., weight loss, nausea, vomiting, diarrhea, dizziness, headache, leg pains, abdominal pains, or even a low-grade fever). Children and adolescents whose anxiety manifests through physical symptoms may have an inability to adequately use words to describe their emotional experiences; this inability is referred to as *alexithymia*.

Anxiety disorders have complex causes, including a genetic basis. Children and adolescents are particularly apt to develop anxiety disorders if they have a parent with depression or anxiety (Scaini et al., 2021). It is not clear if this is because of an environment in which the child is repeatedly exposed to parental responses on the anxiety spectrum, if there is a genetic predisposition to developing an anxiety disorder, or both.

Nursing Care. Treatment for anxiety depends on the cause. Completing an assessment of mental, emotional, and behavioural symptoms can be useful in determining the etiology of anxiety (Box 55.1). The primary goal is for the child to resume typical activities for their stage of development. Coping with anxiety is a learned response, thus teaching of relaxation techniques can be useful for the child with anxiety. Children should also be encouraged to play out their stresses and worries and to discuss their feelings. If they are unable or not encouraged to do this, they may become unable to process the causes of the anxiety and require specialized professional help.

When physical symptoms convey the experience of anxiety, the nurse can help the child and their family understand how stress affects the autonomic nervous system. Examples of such physical reactions include a decrease in gastric pH level and a decrease in gastric mobility, which can result in nausea or abdominal pain. Headaches can be caused by changes in blood vessel smooth muscle tone. When children, adolescents, and their families recognize a biological connection to emotional experiences they may more readily engage in treatments such as cognitive behavioural therapy and the use of medication. Generally, the first choice of medication is an antidepressant as these types of medications also help to reduce the severity of anxiety (Bushnell et al., 2018).

Depression

Depression in childhood is often difficult to detect because children may be unable to express their feelings and tend to act out their issues and concerns. Some states of depression are temporary (e.g., acute depression precipitated by a traumatic event, such as a pandemic

Fig. 55.2 Girl feeling alone and bored with social restrictions imposed during the pandemic.

[Figure 55.2]) (Box 55.2). Depression might be related to a period of hospitalization; loss of a parent through death or separation; or loss of a significant relationship with something (a pet), someone (a friend or family member), or a place (due to a move from a familiar home, neighbourhood, or city). Children with depression may demonstrate a variety of behaviours (Box 55.3). Most responses in children are not sustained and can be modified with social and family support. More serious and less common are the depressive responses to chronic stress

BOX 55.2 Potential Mental, Emotional, and Behavioural Responses to a Pandemic

During a pandemic there are often physical distancing requirements that result in the loss of connections. Schools are closed. Visits with extended family members are postponed. Children's and adolescents' ability to engage with their friends and family is restricted. Mental responses to this situation include changes in the ability to pay attention, remember, or put thoughts together. Emotional responses can include feeling sad, bored, helpless, lonely, scared, hopeless, or angry. The following behavioural responses may also be seen; difficulty sleeping, wanting to be near parents, spending an increased amount of time in one's room, detachment, crying spells, changes in eating or substance use patterns, increased frequency of verbal arguments, or physical altercations.

BOX 55.3 Expressions of Depression in Children or Adolescents

Behaviour
Predominantly sad facial expression
Solitary play or work; tendency to be alone
Withdrawal from previously enjoyed activities and relationships
Lowered grades in school
Refuses to wake up for school
Diminished motor activity
Tearfulness or crying
Dependent and clinging or aggressive and disruptive behaviours

Emotional
Feelings of lowered self-esteem, sense of hopelessness or guilt
Lack of interest in doing homework or achieving in school
Tiredness
Absence or diminished range of affective response (most of the day)
Lack of interest in play with friends

Mental
Inability to concentrate
Slower cognitive processing
All-or-nothing thinking
Recurrent suicidal thoughts

Physiology
Constipation
Loss of energy; fatigue
Nonspecific statements of not feeling well
Change in appetite resulting in weight loss or gain
Alterations in sleeping pattern, sleeplessness, or hypersomnia

and loss; these are frequently observed in children with chronic illness or complex conditions when other family members are having difficulty mentally processing the consequences of these conditions. A history of frequent disruptions in important relationships is a significant risk factor in children and adolescents for developing a depressive disorder (Lawrence et al., 2019).

Nursing Care. Nurses should be aware that depression can easily be overlooked in the child and can interrupt normal growth and development. Identification of depression in a child requires a careful history (health, growth and development, social, and family health); interviews with the child; and observations by the nurse, parents, and teachers. Children who answer affirmatively to queries about a distressing life experience or a depressed or irritable mood should be offered the opportunity to talk about the situation. By engaging in a collaborative therapeutic relationship and actively listening the health care provider can assess the severity of the symptoms, distress, and functional impairment. For children and adolescents who are experiencing depression and anxiety, thoughts about suicide need to be explored. Thoughts of suicide are an expression of pain experienced by the individual. Suicide will be explored more fully in the next section.

Treatment offered to individuals with depression generally involves a three-pronged approach. First, methods such as cognitive behavioural therapy may be used to change thought patterns. Many individuals, including children and adolescents, experience thought patterns that are false or inaccurate and have the potential to cause psychological harm. Their thinking is distorted. Treatment focuses on identifying, correcting, and replacing distorted systems and patterns of thinking. With children this type of "talk therapy" is augmented through the use of play.

The second approach is pharmacological, with antidepressants. If antidepressants are prescribed, the child and family need to know that antidepressants must be at a therapeutic level for 2 to 4 weeks in order to achieve a beneficial effect. The family also needs to monitor the child for adverse effects of the medication prescribed and for any interactions with other medications. There have been reports that antidepressant medications may cause increased suicidal thinking and behaviours in pediatric patients, thus all antidepressant use requires careful monitoring during the initial stages of treatment and following dose adjustments (DeMaso & Walter, 2020).

The third approach is related to environmental supports. Environmental strategies include ensuring the safety of the child or adolescent if there is suicidal ideation, supporting the child or adolescent to have continued engagement with their caregivers, and maintaining routines related to hygiene, school, and extracurricular activities.

Recognizing depression and suicidal ideation in depressed children and making appropriate referrals are important nursing functions. Depression manifests differently in children and adolescents than in adults. In teens it may be masked by impulsive, aggressive behaviours. Defiance, disobedience, behaviour issues, and psychosomatic disturbances can indicate underlying depression, suicidal ideation, and impending suicide attempts. The nurse must have the skills and ability to assess, triage, and initiate strategies that will meet the needs of the child, adolescent, or family unit. Box 55.4 provides some initial questions for consideration.

Suicide

Suicide is a symptom, not a specific disease or illness. *Suicide* is defined as the deliberate act of self-injury with the intent that the injury results in death. Suicide is the second most common cause of death among Canadian adolescents, representing one quarter of all deaths among adolescents 15 to 19 years of age in 2011 (Korczak et al., 2015/2019). Common warning signs of death by suicide are listed in Box 55.5. Individual, family, and social or environmental factors have all been implicated in death by suicide. In one study, approximately 90% of youth who died by suicide met criteria for a psychiatric disorder before the suicide (Korczak et al., 2015/2019). Depression is considered the highest single risk factor for youth suicide (Stewart et al., 2020). Children and adolescents who have died by suicide are reported to have higher rates not only of depression but also of conduct disorder, bipolar disorder, substance misuse, interpersonal struggles with parents.

Family factors contributing to suicide risk include parental loss; family disruption; a family history of suicide, depression, substance use disorder, or emotional disturbance; child maltreatment or neglect;

BOX 55.4 Assessing Depression

It is important to start any assessment by building a collaborative treatment relationship. Phrase the questions in a manner that respects the child's or adolescent's developmental stage and cultural uniqueness and demonstrates authenticity.

- When did you, or your parent, first notice that something had changed related to your mood or how you were feeling?
- Did your sad or down mood start right after a stressful event in the past few months?
- Has there ever been a period of multiple days in a row when you were the opposite of depressed, with very high energy and little need for sleep?
- Did your symptoms seem to start with fatigue?
- Have you felt really down, depressed, or uninterested in things you used to enjoy?
- Have you been using drugs or alcohol?
- Have you been thinking about hurting yourself?
- Have you ever hurt yourself or attempted suicide?
- Do you have any plans to hurt yourself?

BOX 55.5 Warning Signs of Death by Suicide

- Preoccupation with themes of death—focuses on morbid thoughts
- Wants to give away cherished possessions
- Talks of own death, desire to die
- Loss of energy, loss of interest, listlessness
- Exhaustion without obvious cause
- Changes in sleep patterns—too much or too little
- Increased irritability, argumentativeness, or stubbornness
- Physical issues—recurrent stomach aches, headaches
- Repeated visits to the physician, nurse practitioner, or emergency department for treatment of injuries
- Reckless behaviour
- Antisocial behaviour—engages in drinking, uses drugs, fights, commits acts of vandalism, runs away from home, becomes sexually promiscuous
- Sudden change in school performance—lowered grades, cutting classes, dropping out of activities
- Resists or refuses to go to school
- Remains distant, sad, remote—flat affect, frozen facial expression
- Describes self as worthless
- Sudden cheerfulness following deep depression
- Social withdrawal from friends, activities, interests that were previously enjoyed
- Impaired concentration
- Dramatic change in appetite

unavailable parents; poor communication and isolation within the family; family conflict; and unrealistically high parental expectations or parental indifference with low expectations. Families who respect individuality, are cohesive and caring, balance discipline with a supportive and understanding relationship, have good systems of communication, and have at least one attentive and caring parent available to the child can help protect adolescents from suicidal outcomes.

Social or environmental factors include incarceration, isolation, acute loss of a boyfriend or girlfriend, lack of future options, and availability of firearms in the home; all of these increase the risk of a child or adolescent dying by suicide. Cyberbullying and messages on some Internet sites that encourage suicide may also have an impact on suicide rates among children and adolescents (Korczak et al., 2015/2019).

Most experts distinguish between suicidal ideation, suicide attempt (or parasuicide), and suicide. *Suicidal ideation* involves a preoccupation with thoughts about death by suicide and may be a precursor to actually dying by suicide. Although it is not uncommon for children or adolescents to experience occasional suicidal thoughts, a preoccupation with suicide should be taken seriously. This may involve a referral to a specialized mental health care provider. A *suicide attempt* is intended to cause injury or death. The term *parasuicide* refers to behaviours ranging from gestures to serious attempts to kill oneself. All parasuicidal activity should be taken seriously.

Suicidal ideation is common among adolescents. It can represent numerous fantasies, such as relief from suffering, a means of gaining comfort and sympathy, or a means of revenge against those who have hurt them. Adolescents have the erroneous perception that the act of suicide will evoke remorse and pity and that they will be able to return and witness the grief. Angry adolescents who are unable to directly punish those who have injured or insulted them may take revenge on those who love them through self-destruction ("They'll be sorry when they find me dead"; "They'll be sorry they were mean to me"). No threat of suicide should be ignored or challenged. Too often, suicidal threats or minor attempts are confused with bids for attention. It is also a mistake to be lulled into a false sense of security when the youth's depression is apparently relieved. The improvement in attitude may mean that the youth has made the decision and found the means to carry out the threat.

For adolescents who are severely depressed, suicide seems to be the only release from their despair. These individuals rarely provide evidence of their intent and frequently conceal their suicidal thoughts. Some, however, tell their peers of their suicidal thoughts or plans but avoid telling adults. Peers or other confidants are valuable observers and excellent sources of information about **suicide potential**. They may not be able to diagnose depression, but they can sense when a friend has undergone a marked personality change. The peer who detects any changes in a friend is a potential rescuer and should not remain silent about their observations. Social isolation is a significant factor in distinguishing youth who will die by suicide from those who will not.

The most common method used to cause self-injury or die by suicide is overdose or ingestion of a potentially toxic substance, such as drugs. The second most common method of self-harm is self-inflicted laceration.

The frequency of contagion, or "copycat" suicides (i.e., an increase in adolescent suicide that occurs after the suicide of one teenager is publicized), is disturbing and may indicate that teenagers perceive suicide as glamorous. In addition, young people may not realize the finality of suicide because they have become desensitized from constantly viewing violence and death on television, in video games, or in movies.

! NURSING ALERT

Given what is known about youth suicide, nurses should ask parents, especially those with at-risk teenagers, if firearms are available in the house and, if so, recommend their removal. Parents must ensure that their children—especially those who are depressed, have poor problem-solving skills, or use drugs or alcohol—do not have access to firearms. Parents must be educated on the warning signs of suicide (see Box 55.5).

! NURSING ALERT

A history of a previous suicide attempt is a significant indicator for possible death by suicide in the future. Studies of youth suicides have found that as many as half of the individuals had made previous attempts.

Indigenous teens and gay, lesbian, bisexual, and transgender teens may be at particularly high risk for death by suicide, depending on their own sense of self-esteem and the community in which they reside (Ferlatte et al., 2020). There is a disproportionately high rate of death by suicide among Indigenous adolescents. Over the last 10 years the suicide rate for Indigenous Canadians remains approximately 5 to 7 times higher and for the Inuit population 11 times greater than that of non-Indigenous Canadians (Ansloos, 2018).

Nursing Care. Care of people with suicidal ideation includes early recognition, management, and prevention. The most important aspect of management is the recognition of warning signs that indicate a person is troubled and might attempt suicide. Threats of suicide should always be taken seriously. Threats that include plans and means (the ability to follow through with the plan) are a crisis. Children and adolescents need to know that someone cares, and they must be provided with swift and efficient crisis intervention. Although nonspecialized health care providers can manage an acute depressive illness without difficulty, the child or adolescent who has seriously injured themselves or has a specific plan for death by suicide should receive immediate attention by specialized mental health care providers and hospitalization may be in order. Children and adolescents who are actively suicidal need inpatient care, monitoring, and treatment.

Medications used to treat illnesses associated with suicidal ideation often take several weeks to reach therapeutic levels. The time until medications and therapy begin to take effect can be trying for the child and the family. It is important to encourage families to support their child or teen in adherence to the regimen prescribed.

! NURSING ALERT

Children who express suicidal feelings and have a specific plan should be monitored at all times. They should not have access to firearms, prescription or over-the-counter medications, belts, scarves, shoestrings, sharp objects, matches, or lighters. If they are intoxicated, they must be placed in a protective environment until a psychiatrist or psychologist can assess them.

Nurses play a pivotal role in reducing youth suicide. Nurses have the opportunity to provide anticipatory guidance to parents and their children. They can teach parents to be supportive and to develop positive communication patterns that help children and teens feel connected with and loved by their families. To foster healthy development, caregivers can be encouraged to provide children and adolescents with creative outlets and to assist them in accepting strong emotions—pain, anger, and frustration—as a normal part of the human experience.

Although confidentiality is an essential part of nursing care, in the case of self-destructive behaviours, a promise of confidentiality cannot be honoured. Nurses have an ethical and legal obligation to report attempted or suspected attempted suicides (Canadian Nurses Association, 2017). It is critical that the rest of the health care team be aware of the severity of the suicidal symptoms and that treatment plans be adjusted to ensure the child's or adolescent's safety. Such action conveys an important message to the child or adolescent: that the professionals understand and care.

Routine health assessments of children and adolescents should include questions that assess for the presence of suicidal ideation or intent. Box 55.6 provides some initial questions for health care providers to use when they are assessing the level of risk of suicide.

Nurses must also capitalize on opportunities or experiences that promote the healthy development of self-esteem in individuals with

BOX 55.6 Assessing Suicidal Ideation

- Do you consider yourself more a happy person, an unhappy person, or somewhere in the middle?
- Have you ever been so unhappy or upset that you felt like being dead?
- Have you ever thought about hurting yourself or taking your own life?
- Have you ever developed a plan to hurt yourself or kill yourself?
- Do you have the means to carry out your plan?
- Could you get what you needed to carry out your plan (gun, pills, rope)?
- Have you ever done something to hurt yourself or tried to kill yourself?
- Do you have any recent relationship issues or big disappointments?
- Do you have anyone in your life who helps support you?
- Have you been using drugs or alcohol?

Adapted from Government of Canada. (2019). *Preventing suicide: Warning signs and getting help*. Retrieved from https://www.canada.ca/en/public-health/services/suicide-prevention/warning-signs.html.

what may be considered a nontraditional sexual orientation (see Family-Centred Care box: Suicide, Sexual Identity, and Sexual Orientation). Educational programs to raise the public's level of consciousness about the risk factors for and warning signs of suicide are one example. Another possibility is programs conducted in or outside of school that are designed to foster peer relationships and competency in social skills among high-risk adolescents, such as support groups and social organizations.

FAMILY-CENTRED CARE

Suicide, Sexual Identity, and Sexual Orientation

A significant number of teenage deaths due to suicide occur among lesbian, gay, bisexual, transgender, queer, and 2-spirited (LGBTQ2) adolescents. LGBTQ2 adolescents who live in families or communities that do not accept them are likely to suffer low self-esteem, self-loathing, depression, and hopelessness as a result. Such internalization, without treatment and support, can lead to substance use and, eventually, suicide. Adolescents most at risk are those who struggle with gender identity issues, such as LGBTQ2 identity formation at a young age, intrapersonal conflict regarding sexuality, nondisclosure of orientation to others, and identifying as transgender.

Sexual- and gender-minority LGBTQ2 adolescents face a greater risk of suicide and substance use than that of their heterosexual peers (Ream, 2020). In addition, bisexual and transgender individuals are overrepresented among low-income Canadians (Kia et al., 2020), which puts them at even greater risk. LGBTQ2 adolescents can experience stigma and discrimination and can be targets of sexual and physical assault, harassment, and hate crimes (Angeles & Roberton, 2020).

Supportive parents and friends serve as protective agents against suicide. However, many LGBTQ2 individuals do not feel supported, understood, or accepted by their friends, parents, and families. Nurses who interact with adolescents must be aware of the association between suicide and youth, LGBTQ2 sexuality, and gender nonconformity. Nurses may be the first individuals to discuss issues of sexual identity and orientation with teenagers or their families. In their professional capacity, nurses can serve as support persons for these adolescents. Nurses can also provide guidance and resources to families so that they understand how best to nurture and support their child.

Substance Use

Children and adolescents often initiate drug use out of curiosity; most drug use begins with experimentation. Although experimentation with drugs during childhood and adolescence is widespread, most children and teens do not become high-risk users. The Government of Canada

(2019) reports in the 2018–19 Canadian Student Tobacco, Alcohol and Drugs Survey (CSTADS) that alcohol is the most used substance by Canadian students in grades 7 to 12. Many students had tried their first alcoholic beverage by the time they were 14 years old. Nearly 20% of the students had also used cannabis. Smoking was the most common means of consumption. Approximately 7% of the survey respondents had also used psychoactive pharmaceuticals (sedatives, tranquilizers, stimulants, and prescription analgesics) in the last 12 months. Indigenous children tend to be at particular risk for substance use; they are likely to commence drug use 2 to 6 years younger than their non-Indigenous peers (Snijder et al., 2020).

For many individuals the goal is peer acceptance. This means their substance use occurs most frequently when engaged with peers, and as a result most children and adolescents are infrequent or intermittent users. For others the goal is intoxication or the sustained intense effects from using a particular drug. They may engage in periodic heavy use, or binges. The groups of greatest concern to health care providers are those whose patterns of use involve high doses or mixed drugs with the danger of overdose, and those individuals vulnerable to dependence, withdrawal syndromes, and an unhealthy lifestyle.

Any drug can be used for nonmedical purposes, and most are potentially harmful to children and adolescents still going through formative life experiences. Although rarely considered drugs by society, the chemically active substances frequently used are the xanthines and theobromines contained in chocolate, tea, coffee, energy drinks, and colas. Ethyl alcohol, nicotine, and marijuana are other drugs that are legally sanctioned. Any of these substances can alter mental processing and can lead to physical and psychological dependence.

Drugs with mind-altering abilities that are of medical and legal concern are the hallucinogenic, opioid, hypnotic, and stimulant drugs. In addition, there has been a notable increase in the use of alcohol and volatile substances (such as gasoline, antifreeze, plastic model airplane cement, typewriter correction fluid, and organic solvents) that are inhaled to achieve an altered sensation. Nonmedical use of prescription and synthetic medications such as oxycodone, alprazolam (Xanax), and amphetamine-dextroamphetamine (Adderall) has become a concern for health care providers who work with children and adolescents. Studies show that adolescents prefer pain relievers to stimulants, sedatives, or tranquilizers; females tend to prefer pain relievers to stimulants; and misuse of these substances was also strongly correlated with use of other illicit substances (Schepis et al., 2020). Others report that youth often believe that prescription medications, although not taken under practitioner orders, are safer than illicit substances. Many of the prescription medications are available at a cheaper cost than that of the more exotic drugs of use and are often found in the medicine cabinet at home.

Tobacco. Although the number of adult and youth smokers has declined in recent years, cigarette smoking is still considered the chief avoidable cause of death. The hazards of smoking at any age are undisputed; a preventive approach to teenage smoking is especially important (see Family-Centred Care Box: Early Sexual Maturation, Alcohol, and Cigarettes). Because of its addictive nature, smoking begun in childhood and adolescence can result in a lifetime habit, with increased morbidity and early mortality. Research indicates an association between current use of tobacco and the development of depression (Sunderland et al., 2021) and sleep issues (Brett et al., 2020) in adolescence. Cigarettes are considered to be a gateway drug; children and adolescents who smoke are more likely to use illicit drugs.

Indigenous youth experience similar influences to those of other populations regarding drug use among family and friends. However, Indigenous adolescents smoke at greater rates than the general population. There are few studies that explore historical contributing factors to higher rates of use, such as traditional tobacco use, the trauma of colonization, sequelae of intergenerational trauma and discrimination, and the role of cultural connections (Heris et al., 2019). These issues need to be investigated further.

FAMILY-CENTRED CARE

Early Sexual Maturation, Alcohol, and Cigarettes

Cigarette smoking and alcohol use by youth are complex behaviours not explained by any one factor. Some investigators believe there is a relationship between biological maturation and risk-taking behaviours. For example, girls who are sexually mature at an earlier age than their peers are often attracted to older girls and boys who may engage in risk-taking behaviours. If older teens smoke, drink, and drive while under the influence of alcohol with no adverse consequences (e.g., no motor vehicle accidents), younger teens may believe that they, too, will be safe while smoking, drinking, or riding in an automobile with friends who are drinking.

Although parents and nurses cannot influence the time of biological maturation, they can identify young girls who are at risk for the initiation of risk-taking behaviours because of early puberty. Parents need to understand that an early-maturing daughter might be uncomfortable with her body, and they should take advantage of opportunities to build her self-esteem. Parental sensitivity to the importance of peer-group acceptance and parental support of a teenage daughter who feels left out or different are crucial. Nurses can provide anticipatory guidance to these girls and help them role play coping strategies for situations that involve offers to smoke and drink. In addition, nurses can provide information about physical development during puberty and emphasize that not all teenagers mature at the same time or rate.

Teachers, coaches, and community and religious leaders can provide opportunities for these girls to "fit in" with their same-age peers through activities that stress mutual goals. For example, an early-maturing girl is typically taller than her age-mates and can be an asset in sports such as basketball and track and field.

Electronic cigarettes. Electronic cigarette (e-cigarette) use is on the rise among adolescents in Canada. These cigarettes are tobacco free and do not produce secondhand smoke, but they may contain nicotine and different flavourings. Various other chemicals and metals in e-cigarettes are harmful, especially to children and adolescents. Flavourings and propylene glycol (a chemical) in the e-liquid can irritate the lungs and worsen breathing conditions like bronchitis and asthma; when heated, these ingredients change form and create toxins; formaldehyde (a colourless gas) can be produced at levels higher than those seen with regular cigarettes. The heating process also releases heavy metals from the materials used in the manufacturing of the e-cigarettes at levels higher than in regular cigarettes. The vapour can be harmful to the user and to people exposed to the secondhand e-cigarette smoke.

E-cigarettes remain controversial; there is debate over how effective they are and whether they are a gateway to tobacco smoking. The Canadian Paediatric Society (CPS) (2020) warns against the growing industry of e-cigarettes and the misperceived safety of their use.

Smokeless tobacco. The term *smokeless tobacco* refers to tobacco products that are placed in the mouth but not ignited (e.g., chewing tobacco). This substitute for cigarettes continues to pose a hazard to youth. Many children and adolescents believe that smokeless tobacco is a safe alternative to cigarette smoking and is not addictive, and they believe they can stop using it at any time. These products have also been proved to be carcinogenic. Regular use can cause dental issues, foul-smelling breath, and tooth erosion or loss.

Nursing care. Prevention of regular smoking among teenagers is the most effective way to reduce the overall incidence of smoking. A CPS position statement on preventing smoking in children and adolescents has put forward recommendations for related practices and policy

(Harvey et al., 2016). A variety of methods have been employed to communicate the hazards of smoking, such as posters, charts, displays, statistics, and the use of examples of actual damaged lungs. The use of films and demonstrations may also be useful. For the most part, smoking-prevention programs that focus on the negative, long-term effects of smoking on health have been ineffective. Youth-to-youth programs and those emphasizing the immediate consequences are more effective, but primarily in improving teenagers' attitudes toward not smoking.

School-based programs are an important health promotion strategy. Smoking bans in schools accomplish several goals: (1) they discourage students from starting to smoke, (2) they reinforce knowledge of the health hazards of cigarette smoking and exposure to environmental tobacco smoke, and (3) they promote a smoke-free environment as the norm (see Family Centred Care box: Nonsmoking Strategies). The impact of school-based antismoking programs can be strengthened by expanding these programs to include parents, mass media, youth groups, and community organizations. For example, mass media efforts that involve antismoking radio campaigns have been identified as the most cost-effective mass media intervention. The more effective interventions included eliciting a high-impact positive emotional response (Rath et al., 2019).

FAMILY-CENTRED CARE

Nonsmoking Strategies

Nurses who work in schools, hospitals, and community agencies can take advantage of all opportunities to provide education about the dangers of smoking, discourage smoking initiation by children and adolescents, encourage smoking cessation, and promote smoke-free environments. In particular, community or school nurses must be alert to the vulnerability of young preteens when they enter middle school. These nurses are in an ideal position to assess stress, personal conflict, weight concerns, peer pressures, and other factors that place preteens at risk for smoking initiation. Nurses can serve as counsellors to student, teacher, and parent groups and as advocates for antismoking legislative efforts. The following additional strategies are recommended*:

- Provide only brief information about long-term health consequences (e.g., cardiovascular and cancer risks).
- Discuss immediate physiological consequences (e.g., changes in heart rate, blood pressure, respiratory symptoms, and blood carbon monoxide concentrations).
- Mention alternatives to smoking that also establish a self-image that appears independent, mature, or sophisticated (e.g., weight lifting; jogging; dancing; joining a boys' or girls' club; engaging in volunteer work for a hospital, political, religious, or community group).
- Mention the negative effects in detail (e.g., earlier wrinkling of skin; yellow stains on teeth and fingers; tobacco odour on breath, hair, and clothing).
- Mention the increasing ostracism of smokers by nonsmokers, both legal and informal, in the workplace and in public places.
- Mention the increasing evidence that secondhand smoke is injurious to the health of nonsmokers who are regularly exposed, especially small children.
- Acknowledge that many adults who were enticed to start smoking as teenagers because of its social benefits now wish they could stop smoking.
- Give adolescents effective arguments to deal with peer pressure (e.g., by not smoking, a teenager demonstrates independence and nonconformity, traits normally prized by adolescents).
- Request posters or pamphlets from local agencies (e.g., Canadian Cancer Society, Canadian Heart and Stroke Foundation, and Canadian Lung Association) to display in prominent places at school.

*Health Canada has information on the effects of tobacco, smoking cessation, and tobacco control programs at http://www.hc-sc.gc.ca/hc-ps/tobac-tabac/index-eng.php.

Alcohol. The most noticeable effects of alcohol occur within the central nervous system and include changes in cognitive and autonomic functions such as judgement, memory, learning ability, and other intellectual capacities. Acute or chronic use of alcohol (ethanol) is responsible for many acts of violence, suicide, accidental injury, and death. Some children and adolescents will rely on the substance as a coping mechanism when experiencing depression, anxiety, fear, or anger. Severe physical and psychological symptoms can accompany abrupt withdrawal, and long-term use leads to slow tissue destruction, especially of the brain and liver cells. Alcohol drinking is likely to begin in the middle-school years and increases with age.

Central Nervous System Depressants. Central nervous system depressants include a variety of hypnotic drugs that produce physical dependence and withdrawal symptoms on abrupt discontinuation. They create a feeling of relaxation and sleepiness but impair general functioning. Drugs in this category include barbiturates, nonbarbiturates, and alcohol. Barbiturates combined with alcohol produce a profound depressant effect. Flunitrazepam (Rohypnol), known as the "date rape drug," is a hypnotic drug used by some adolescents. Many people have reported being raped after unknowingly being given flunitrazepam in a drink. Flunitrazepam is 10 times more powerful than diazepam (Valium). It produces prolonged sedation, a feeling of well-being, and short-term memory loss.

Opioids. Opioids include heroin and morphine and opiate-like drugs, such as hydromorphone (Dilaudid), hydrocodone, fentanyl, meperidine (Demerol), and codeine. These drugs produce a state of euphoria by removing painful feelings and creating a pleasurable experience and a sense of success accompanied by clouding of the consciousness and a dreamlike state. Physical signs of opioid use include constricted pupils, respiratory depression, and, often, cyanosis. As these substances can be injected, needle marks may be visible when completing a physical assessment. Physical withdrawal from opiates is extremely unpleasant unless controlled with supervised tapering doses of the opioid or substitution of methadone. Health issues also result from self-neglect of physical needs (nutrition, cleanliness, dental care); overdose; contamination; and infection, including HIV and hepatitis B and C infection.

Central Nervous System Stimulants. The use of amphetamines and cocaine can produce strong psychological dependencies. Acute intoxication can lead to violent aggressive behaviour or psychotic episodes characterized by paranoia, uncontrollable agitation, and restlessness. When combined with barbiturates, the euphoric effects are particularly addictive.

Cocaine. The use of cocaine has increased in recent years because of its availability and affordability, its association with persons in glamorous occupations, peer pressure, and its reputation as a sexually enhancing drug. Cocaine creates a sense of euphoria, or an indefinable high. Withdrawal does not produce the dramatic symptoms observed in withdrawal from other substances. The effects are those commonly seen in depression, including lack of energy and motivation, irritability, appetite changes, decrease in psychomotor activity, and irregular sleep patterns. More serious symptoms include cardiovascular manifestations and seizures. Physical withdrawal should not be confused with the so-called crash after a cocaine high, which consists of a long period of sleep.

Methamphetamine. Methamphetamine can be snorted, injected, swallowed, or smoked and produces a burst of energy in its users, along with intense, alternating attacks of boldness and paranoia. It provokes excitement far more intense than that caused by cocaine. The drug, with the street names speed, crank, meth, ice, and crystal, is inexpensive and has a longer period of action than that of cocaine. Instead of a short

(few minutes) high, as achieved with cocaine, a user can remain "up" for hours on a similar dose of crank.

Inhalants. The use of various volatile substances, or inhalants such as gasoline, model airplane cement, and organic solvents, is also of concern. The person breathes or places these substances into a paper or plastic bag or soft drink can from which they rebreathe the fumes to produce a feeling of euphoria and altered consciousness. These substances contain chemical solvents and are extremely hazardous. Dusters contain Freon, a substance that can cause fatal cardiac arrhythmias. Common inhalant substances are inexpensive and easily obtained, such as gasoline, paint, propane/butane, air fresheners, and formalin (Baydala & Canadian Paediatric Society, First Nations, Inuit and Métis Health Committee, 2010/2018). Many young children are unaware of the dangers of "sniffing" or "huffing." In addition to rapid loss of consciousness and respiratory arrest, these substances may cause visual-scanning difficulties, language deficiencies, motor instability, memory deficits, and impaired attention and concentration. One in five Indigenous youth reported having used inhalant solvents (one out of three users were under 15 years of age) and over half had started to use solvents before age 11. In response to this danger to Indigenous children, the National Youth Solvent Program was established by Health Canada and Indigenous communities to promote a stronger cultural identity and cultural healing.

Hallucinogens. *Hallucinogens* (psychedelics, psychotomimetics, psychotropics, or illusionogenics) are drugs that produce vivid hallucinations and euphoria. These drugs do not produce physical dependence, and they can be abruptly withdrawn without ill effect. However, the acute and long-term effects are variable, and in some individuals the dissociative behaviour may be prolonged.

Nursing Care. Nurses play an important role in education as well as in individual observation, assessment, and therapy related to substance use. Box 55.7 provides some initial questions for nurses to use when they are assessing substance use. In recent years, a variety of educational programs have been applied, with promising results. The most effective prevention strategies are part of a broader, more general effort to promote overall health and success. Health-compromising behaviours are often interconnected and have common antecedents. Prevention efforts that focus on changing only one behaviour (e.g., alcohol, other drug use) are less likely to be successful. Successful programs are those that have promoted parenting skills, social skills among distractible children, academic achievement, and skills to resist peer pressure.

The nurse will encounter children and adolescents who use drugs when they are (1) experiencing overdose or withdrawal symptoms, (2) manifesting bizarre behaviour or confusion secondary to drug ingestion, (3) worried that they are or will become addicted, or (4) worried about a friend or family member who is addicted. Youth experiencing toxic drug effects or withdrawal symptoms are usually seen initially in the emergency department. Experienced emergency department personnel are familiar with the management of acute drug toxicity and the signs, symptoms, and behavioural characteristics associated with a variety of substances. When the drug is questionable or unknown, such expertise can help facilitate management and treatment. Often, observation or a description of the child's or adolescent's behaviour is more valuable than reports by patients or their friends.

Nurses who work in schools or in the community can play an essential role in identifying children, adolescents, and families with substance use disorders. These nurses may be the first to identify a child or adolescent who has ingested a particular drug by the child's erratic behaviour in class or on the school grounds. Early identification of those at risk for substance use issues is an essential aspect of prevention. Pediatric health care providers can also prevent substance use by creating trusting relationships with children and adolescents so that they feel comfortable asking questions about drugs. Nurses can alert them to websites and other cultural aspects that may actually encourage experimentation with drugs.

A major factor in the treatment and rehabilitation of substance use disorders includes careful assessment during the nonacute stage to determine the function the drug plays in the youth's life. Rehabilitation begins when the person decides that they can and are willing to change. Rehabilitation involves fostering healthy interdependent relationships with caring and supportive adults and exploring alternative mechanisms for problem solving while simultaneously reducing or eliminating drug use. Most treatment programs for substance users are based on adult 12-step models such as Alcoholics Anonymous. Research is needed to determine whether these adult models are effective for children and adolescents.

The Government of Canada has a National Anti-Drug Strategy that also provides help for parents seeking to prevent youth substance use. A group that has had some success in reducing injury from drunk driving is Mothers Against Drunk Driving (MADD). Techniques used by this group include peer counselling, parental guidelines for teenage parties, and community awareness.

BOX 55.7 Assessing Substance Use

- Have people asked you to cut down on smoking, drinking, or using drugs?
- How have your relationships changed since you started using?
- How has using affected your mood or anxiety?
- Do you ever smoke, drink or use drugs when you are alone?
- What is it like for you when you are drunk or high?
- Have you blacked out or done things you regret while drunk or high?
- Do you get more moody or anxious while your alcohol or drugs are wearing off?
- Has the same amount of drug or alcohol been losing its effect over time?
- Are there any issues that you wanted the alcohol or drugs to resolve?
- Have you injured yourself while you were drunk or high?

Disturbances in Eating Related Behaviours

There are many factors that affect eating behaviours of children and adolescents, including relationships with their peers and caregivers, stress, exposure to adverse events, digestive tract changes such as an ulcer or cancer, and hormonal changes. Although there are other types of eating disorders, anorexia nervosa (AN) and bulimia nervosa (BN) will be the focus of this section. See Table 55.2 for a comparison of AN and BN symptoms. The cause of these disorders remains unclear.

AN and BN are most common among adolescent girls, although boys tend to have a substantial incidence of binge-eating disorders. These disorders appear to be caused by a combination of genetic, neurochemical, psychodevelopmental, and sociocultural factors. Changes in eating patterns may be triggered by a developmental milestone, such as the onset of menstruation, or a traumatic interpersonal incident. Situations of severe family stress (such as parental separation or divorce) or circumstances in which the person perceives a lack of personal control (such as teasing at school, changing schools, going to college, or loss of socialization due to a pandemic) may precipitate a desire for control and the decision not to eat. Individuals with eating disorders commonly have additional psychiatric conditions, including depression, anxiety, and suicide risk (Landry, 2020). Patients with eating disorders also tend to have higher than average reported rates of substance use, with alcohol misuse being more common in those with BN than in those with AN (Bahji et al., 2019).

TABLE 55.2 Characteristics of Individuals With Eating Disorders

Factors	Anorexia Nervosa	Bulimia
Food	Turns away from food to cope	Turns to food to cope
Personality	Introverted	Extroverted
	Avoids intimacy	Seeks intimacy
	Negates feminine role	Aspires to feminine role
Behaviour	"Model" child Obsessive-compulsive	Often acts out Impulsive
School	High achiever	Variable school performance
Control	Maintains rigid control	Loses control
Body image	Body image distortion	Less frequent body image distortion
Health	Denies illness	Recognizes illness Health fluctuates
Weight	Body weight <85% of expected norm	Within 2.3–7 kg (5–15 lb) of normal body weight or may be overweight
Sexuality	Usually not sexually active	Often sexually active

Nursing Care. A complete history and physical examination are important for ruling out other causes of changes in eating behaviours. Box 55.8 lists some sample questions that can assist a nurse in assessing individuals with disturbances in their eating patterns. The assessment of an eating disorder should focus on the complications of altered nutritional status and purging. A careful history includes weight changes, dietary patterns, frequency and severity of purging and excessive exercise, and the identification of malnutrition or other associated complications.

Nurses need to be aware of the physical effects of eating disturbances. Patients frequently adjust their fluid intake. Urinary tract issues are common, and ketones and protein may be detected in the urine as a result of breakdown of fat and protein. Vital-sign instability can be severe and can include orthostatic hypotension; the pulse becomes irregular, and the rate decreases markedly. Electrolyte imbalances can be life-threatening, and bradycardia and hypothermia can result in cardiac arrest (see Clinical Reasoning Case Study: Anorexia Nervosa).

BOX 55.8 Assessing Eating-Related Behaviours

- How would you describe your appearance?
- Are there aspects of your appearance that you are dissatisfied with?
- Have you been losing weight despite wanting to maintain weight?
- Do you worry about losing control when you eat?
- Do you feel guilty after eating?
- Do you prefer to eat alone?
- Have you had recurring times when you overeat and then feel the need to compensate afterward?
- Do you use laxatives or vomit after meals?
- Have you felt really down, depressed, or uninterested in things you used to enjoy?
- Have you been smoking or using drugs or alcohol?"
- Have you been thinking about hurting yourself?
- Have you ever hurt yourself?

CLINICAL REASONING CASE STUDY

Anorexia Nervosa

Jane is a 13-year-old whose grades have been excellent and whom the teachers describe as a "model student." Jane has told the nurse practitioner that her parents are in the middle of a "messy divorce." In addition, several of Jane's friends told the nurse practitioner that they are concerned about Jane because she runs every day at lunchtime and seldom eats lunch with them. Jane told her friends that she gained weight over the winter months and that she is running because she wants to qualify for the track team this spring. At the time of her routine physical, the nurse practitioner notes that Jane's oral temperature is 36°C and that she weighs 35 kg. Jane has lost 9 kg since her last physical. When discussing her menstrual periods with the nurse practitioner, Jane states that she has not had her period for 3 months.

1. Evidence—Is there sufficient evidence to draw any conclusions about Jane's behaviour?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Personality characteristics of individuals with anorexia nervosa (AN)
   b. Factors influencing the development of AN
   c. Clinical manifestations of AN
   d. Treatment of AN
3. What priorities for nursing care should be established for Jane at this time?
4. Describe the roles and responsibilities of members of the interprofessional health care team who may provide care to Jane.

The treatment and management of eating disorders involves three major goals: (1) reinstitution of normal nutrition or reversal of the severe state of malnutrition, (2) resolution of disturbed patterns of family interaction, and (3) individual psychotherapy to correct deficits and distortions in psychological functioning. The treatment of eating disorders requires the collaborative efforts of an interdisciplinary team composed of a primary health care practitioner, nurse, dietitian, and mental health care provider with pediatric health care experience. Because of the psychogenic nature of the disorder, the treatment may be long. Most youth are treated on an outpatient basis with cognitive behavioural therapy, medications, and family therapy, but individuals with health conditions requiring immediate medical attention, such as severe malnutrition or electrolyte or psychiatric disturbances (severe depression or suicidal ideation), require hospitalization. Therapy is most successful when it is started soon after the onset of illness and directed toward correcting cognitive distortions and resolving malfunctioning processes in the family.

BEHAVIOURAL HEALTH NEEDS

Many children develop maladaptive behaviour patterns that impede psychosocial adjustment while they try to cope with cognitive dysfunction. Maladaptive behaviour patterns are not unique to a specific psychiatric disorder. However, socially challenging behaviour evokes negative responses from others, and repeated exposure to negative feedback adversely affects the individual's self-concept. Common behavioural symptoms that evoke this negative feedback are developmentally inappropriate degrees of inattention, impulsiveness, and hyperactivity. Attention-deficit/hyperactivity disorder (ADHD) or learning disorder (LD) are diagnoses commonly given to children experiencing these symptoms.

Nursing Care

Nurses are active participants in all aspects of management of the child with behavioural health needs. Nurses in the community work with families and school personnel on a long-term basis to help plan and implement therapeutic regimens and to evaluate the effectiveness of therapy. They coordinate services and serve as a liaison between health and education professionals directly involved in the child's therapy program. Nurses in any setting (community, school, hospital, health care provider's office) provide support and guidance to children and families during the difficult period of the child's growing up with behavioural health needs.

A history, both developmental and medical, and a description of the child's behaviour should be obtained from as many observers of the child as possible (especially the parents and teachers, along with the health care providers involved). Descriptions of the child's behaviour in home and at school should be included. In obtaining descriptive materials, the interviewer must question observers carefully because some persons, especially parents, may be so concerned with gross behaviours that they overlook less distressing but equally important symptoms. For example, parents may report a child who began to run soon after walking, a toddler who was compelled to touch everything in sight, and a child who resisted sleep until exhausted. A pregnancy and birth history may provide clues to a situation that might have produced a hypoxic episode.

A physical examination including vision and hearing screening and a detailed neurological evaluation will help rule out any severe neurological disorder. Psychological testing, especially projective tests, is valuable in identifying visual or perceptual difficulties, issues with spatial organization, and other phenomena that suggest cortical or diencephalic involvement; it also helps to identify the child's intelligence and achievement levels.

An important aspect of nursing care is to help the parents and child understand the diagnosis, including the nature of the issue. Most parents are confused and feel some measure of guilt. To some parents, a diagnosis of ADHD is confirmation of the fear that their child has some irreversible, serious disease; to others, it is a relief. All parents need the opportunity to vent their feelings and suspicions. A common concern of parents is that health care providers do not listen to what they have to say about their children. The health care provider should focus on building the family's self-esteem by encouraging the family to focus on developing the child's strengths (e.g., sports, hobbies, and talents) rather than focusing on the weaknesses (Elliott et al., 2020).

If a child has an LD, nurses must understand which type of LD a child has, in order to provide direction for the child, parents, and teachers. Children with an auditory perceptual deficit are often unable to follow directions or to comprehend large amounts of verbal teaching. These children need diagrams, pictures, demonstration, and written lists. Children with visual perceptual deficits may have difficulty reading, lining up numbers for mathematic operations, or judging distance. These children may have dyslexia (letter reversals) and do better with demonstration and a verbal approach. Children with an integrative deficit may have difficulty sequencing data or storing and retrieving sensory data. Multisensory techniques should be used, and comprehension should be checked frequently throughout instruction. These children need to find an alternative to physical competition that requires coordination of movement.

Parents need information about the prognosis and an understanding of the treatment plan. The greater their understanding of the disorder and its effects, the more likely they will be to carry out the recommended program of therapy. It is important that they understand that the therapy is not necessarily a panacea and that it will extend over a long period. Reassessment is essential to determine the effectiveness of the treatment plan and to assess family interaction.

KEY POINTS

- Mental and emotional health are foundational to overall health and well-being.
- Creating a collaborative treatment relationship built on empathetic engagement is essential to effective treatment planning.
- Signs of depression in children and adolescents are often subtle and require astute observation by parents and health care providers.
- Suicide, the deliberate act of self-injury with the intent to kill, may occur because of difficulties coping with stress, disturbed family environment, substance use or dependency, or a mental health disorder.
- No threat of suicide by a child or adolescent should be ignored or challenged.
- The substances used by children and adolescents are tobacco, alcohol, central nervous system depressants, central nervous system stimulants, hydrocarbons and fluorocarbons, and mind-altering drugs.
- Tobacco use is widespread among teenagers.
- Disturbances in eating-related behaviour include anorexia nervosa and bulimia nervosa.

Canada's food guide

Eat well. Live well.

Healthy eating is more than the foods you eat

Be mindful of your eating habits

Cook more often

Enjoy your food

Eat meals with others

Use food labels

Limit foods high in sodium, sugars or saturated fat

Be aware of food marketing

Health Canada Santé Canada

Discover your food guide at

B APPENDIX

Common Laboratory Tests and Normal Ranges

Abbreviations Used in Laboratory Tests

Abbreviation	Term
cap	capillary
conc.	concentration
CSF	cerebrospinal fluid
EDTA	ethylenediaminetetraacetate
g	gram
HF	heart failure
Hgb	hemoglobin
HgbF	fetal hemoglobin
hr	hour
IU	international unit
L	litre
m	metre
mEq	milliequivalent
min	minute
mm	millimetre
mm Hg	millimetres of mercury
mm H_2O	millimetres of water
mm^3	cubic millimetre
mo	month
mol	mole
Na	sodium
Pa	Pascal
RBC	red blood cells
sec	second

Continued

Abbreviations Used in Laboratory Tests—cont'd

Abbreviation	Term
temp	temperature
therap	therapeutic
U	international unit of enzyme activity
vol	volume
WBC	white blood cells
wk	week
yr	year
$>$	greater than
$\geq$	greater than or equal to
$<$	less than
$\leq$	less than or equal to
$\pm$	plus/minus
$\cong$	approximately equal to

Prefixes Denoting Decimal Factors

Prefix	Symbol	Amount
Deci	d	one tenth (10^{-1})
Centi	c	one hundredth (10^{-2})
Milli	m	one thousandth (10^{-3})
Micro	mc	one millionth (10^{-6})
Nano	n	one billionth (10^{-9})
Pico	p	one trillionth (10^{-12})
Femto	f	one quadrillionth (10^{-15})

TABLE B.1 Chemistry: Blood, Urine, Cerebrospinal Fluid*

Test/Specimen	Age/Gender/ Reference	NORMAL RANGES			
		International Units (SI)		Conventional Units	
Acetaminophen					
Serum or plasma	Therap. conc.	66–200 mcmol/L		10–30 mcg/mL	
Ammonia nitrogen					
Plasma or serum	Newborn	52–88 mcmol/L		90–150 mcg/dL	
	Adult/child	6–47 mcmol/L		10–80 mcg/dL	
Arterial blood gases (ABG)					
pH	Newborn	7.32–7.49		7.32–7.49	
	2 mo–2 yr	7.34–7.46		7.34–7.46	
	Adult/child	7.35–7.45		7.35–7.45	
Partial pressure of carbon dioxide (Pco_2)	<2 yr	26–41 mm Hg		26–41 mm Hg	
	Adult/child	35–45 mm Hg		35–45 mm Hg	
Bicarbonate ion (HCO_3)	Newborn/infant	16–24 mmol/L		16–24 mEq/L	
	Adult/child	21–28 mmol/L		21–28 mEq/L	
Partial pressure of oxygen (Po_2)	Newborn	60–70 mm Hg		60–70 mm Hg	
	Adult/child	80–100 mm Hg		80–100 mm Hg	
Oxygen saturation	Newborn	85–90%		85–90%	
	Adult/child	95–100%		95–100%	
Oxygen content	Arterial	15–22 volume percent			
Base excess/deficit					
	Newborn	(−10)–(−2) mmol/L		(−10)–(−2) mEq/L	
	Infant	(−7)–(−1) mmol/L		(−7)–(−1) mEq/L	
	Child	(−4)–(+2) mmol/L		(−4)–(+2) mEq/L	
	Thereafter	(–3)–(+3) mmol/L		(–3)–(+ 3) mEq/L	
Bilirubin, total		**Premature** mcmol/L	**Full term** mcmol/L	**Premature** mg/dL	**Full term** mg/dL
Serum	Cord	<34	<34	<2.0	<2.0
	0–1 day	<137	<103	<8.0	<6.0
	1–2 days	<205	<137	<12.0	<8.0
	2–5 days	< 274	<205	<16.0	<12.0
	Thereafter	<340	<171	<20.0	<10.0
Bilirubin, direct (conjugated)					
Serum		0–3.4 mcmol/L		0.0–0.2 mg/dL	
Calcium, ionized					
Serum, plasma, or whole blood					
	Newborn	1.05–1.37 mmol/L		4.20–5.58 mg/dL	
	2 mo to 18 yr	1.20–1.38 mmol/L		4.80–5.52 mg/dL	
Calcium, total					
	Newborn, 3–24 hr	2.3–2.65 mmol/L		9.0–10.6 mg/dL	
	24–48 hr	1.75–3.0 mmol/L		7.0–12.0 mg/dL	
	4–7 days	2.25–2.73 mmol/L		9.0–10.9 mg/dL	
	Child	2.2–2.7 mmol/L		8.8–10.8 mg/dL	
	Thereafter	2.1–2.55 mmol/L		8.4–10.2 mg/dL	
Cerebrospinal fluid (CSF)					
Pressure		100–200 mm H_2O		100–200 mm H_2O	
Volume	Child	0.06–0.10 L		60–100 mL	
	Adult	0.10–0.16 L		100–160 mL	

Continued

TABLE B.1 Chemistry: Blood, Urine, Cerebrospinal Fluid—cont'd

Test/Specimen	Age/Gender/ Reference	NORMAL RANGES			
		International Units (SI)		Conventional Units	
Chloride					
Serum or plasma	Cord	96–104 mmol/L		96–104 mEq/L	
	Newborn	96–106 mmol/L		96–106 mEq/L	
	Thereafter	90–110 mmol/L		90–110 mEq/L	
Sweat	Normal (homozygote)	<50 mmol/L		<50 mEq/L	
	Equivocal	50–60 mmol/L		50–60 mEq/L	
	Abnormal	>60 mmol/L		>60 mEq/L	
Cholesterol, total		**Male** mmol/L	**Female** mmol/L	**Male** mg/dL	**Female** mg/dL
Serum or plasma	Newborn	0.98–4.50	1.45–5.04	38–174	56–195
	Infant (7–12 mo)	2.15–5.30	1.76–5.59	83–205	68–216
	10–11 yr	3.10–5.90	3.16–6.26	120–228	122–242
Creatine kinase (CK, CPK)					
Serum					
	Newborn	65–580 U/L		65–580 U/L	
	Male	20–215 U/L		20–215 U/L	
	Female	20–160 U/L		20–160 U/L	
Creatinine					
Serum	Newborn	53–97 mcmol/L		0.6–1.1 mg/dL	
	Infant	18–35 mcmol/L		0.2–0.4 mg/dL	
	Child/adolescent	18–62 mcmol/L		0.2–0.7 mg/dL	
Urine, 24 hr	Premature	72–133 mcmol/kg/24 hr		8.1–15.0 mg/kg/24 hr	
	Full term	92–174 mcmol/kg/24 hr		10.4–19.7 mg/kg/24 hr	
	1.5–7 yr	88–133 mcmol/kg/24 hr		10–15 mg/kg/24 hr	
	7–15 yr	46–362 mcmol/kg/24 hr		5.2–41 mg/kg/24 hr	
Creatinine clearance (endogenous)					
Serum or plasma and urine	Newborn	1.2 mL/sec		72 mL/min	
	Male	1.78–2.32 mL/sec		107–139 mL/min	
	Female	1.45–1.78 mL/sec		87–107 mL/min	
Digoxin					
Serum, plasma; collect at least 12 hr after dose	Therap. conc.				
	HF	1.0–1.9 nmol/L		0.8–1.5 ng/mL	
	Arrhythmias	1.9–2.6 nmol/L		1.5–2.0 ng/mL	
	Toxic conc.				
	Child	>3.2 nmol/L		>2.5 ng/mL	
	Adult	>3.8 nmol/L		>3.0 ng/mL	
Galactose					
Serum	Newborn	0–1.11 mmol/L		0–20 mg/dL	
	Thereafter	<0.28 mmol/L		<5 mg/dL	
Urine	Newborn	≤3.33 mmol/L		≤60 mg/dL	
	Thereafter	<0.08 mmol/day		<14 mg/24 hr	

Continued

TABLE B.1 Chemistry: Blood, Urine, Cerebrospinal Fluid—cont'd

Test/Specimen	Age/Gender/ Reference	NORMAL RANGES			
		International Units (SI)		Conventional Units	
Glucose					
Serum	Cord	2.5–5.3 mmol/L		45–96 mg/dL	
	Premature infant	1.1–3.3 mmol/L		20–60 mg/dL	
	Neonate (0–28 days)	1.7–3.3 mmol/L		30–60 mg/dL	
	Infant	2.2–5.0 mmol/L		40–90 mg/dL	
	Child <2 yr	3.3–5.5 mmol/L		60–100 mg/dL	
	>2 yr to adult: Fasting (no calories × 8 hours)	<6.1 mmol/L		<110 mg/dL	
	Random (any time of day)	<11.1 mmol/L		<200 mg/dL	
CSF	Adult	2.8–4.2 mmol/L		50–75 mg/dL	
Urine (quantitative)		<2.78 mmol/day		<0.5 g/day	
Urine (qualitative)		Negative		Negative	
Glucose tolerance test (GTT), oral					
Serum					
Dosages		**Normal**	**Diabetic**	**Normal**	**Diabetic**
Adult: 75 g	Fasting	4.0–6.0 mmol/L	≥7.0 mmol/L	70–110 mg/dL	≥126 mg/dL
Child: 1.75 g/kg of ideal weight up to maximum of 75 g	30 min	<11.1 mmol/L	≥11 mmol/L	<200 mg/dL	≥200 mg/dL
	60 min	<11.1 mmol/L	≥11 mmol/L	<200 mg/dL	≥200 mg/dL
	120 min	<7.8 mmol/L	≥11 mmol/L	<140 mg/dL	≥200 mg/dL
	240 min	<6.4 mmol/L	>11 mmol/L	<70–115 mg/L	>200 mg/dL
Growth hormone (GH, somatotropin)					
Plasma	0 to <7 yr	<1–13.6 mcg/L		<1–13.6 ng/mL	
	7 to <11 yr	<1–16.4 mcg/L		<1–16.4 ng/mL	
	11 to <15 yr	<1–14.4 mcg/L		<1–14.4 ng/mL	
	15 to <19 yr	<1–13.4 mcg/L		<1–13.4 ng/mL	
	Adult male	<5 mcg/L		<5 ng/mL	
	Adult female	<10 mcg/L		<10 ng/mL	
Iron	Age	Male mcmol/L	Female mcmol/L	Male mcg/dL	Female mcg/dL
Serum	Newborn	12.9–36.3	13.4–42.1	72–203	75–235
	Child (4–10 yr)	2.7–22.9	5.0–21.8	15–128	28–122
	Thereafter	13–31	5–29	75–175	28–162
	Moderate toxicity	63–90 mcmol/L		350–500 mcg/dL	
	Severe toxicity	>90 mcmol/L		>500 mcg/dL	
Iron-binding capacity, total (TIBC)					
Serum	Newborn	16.8–41.50 mcmol/L		94–232 mcg/dL	
	Thereafter	45–73 mcmol/L		250–410 mcg/dL	
Lead					
Whole blood	Child	<0.48 mcmol/L		<10 mcg/dL	
Osmolality					
Serum	Child	275–290 mmol/kg		275–290 mOsm/kg	
	Adult	285–295 mmol/kg		285–295 mOsm/kg	
Urine, random		50–1200 mmol/kg H_2O, depending on fluid intake; after 12-hr fluid restriction: >850 mmol/kg H_2O		50–1200 mOsm/kg H_2O, depending on fluid intake; after 12-hr fluid restriction: >850 mOsm/kg H_2O	
Urine, 24 hr		≅300–900 mmol/kg		≅300–900 mOsm/kg

C APPENDIX

Pediatric Vital Signs and Parameters

Centigrade to Fahrenheit Temperature Conversions

°C	°F	°C	°F	°C	°F
35.0	95.0	37.0	98.6	39.0	102.2
35.2	95.4	37.2	99.0	39.2	102.6
35.4	95.7	37.4	99.3	39.4	102.9
35.6	96.1	37.6	99.7	39.6	103.3
35.8	96.4	37.8	100.0	39.8	103.6
36.0	96.8	38.0	100.4	40.0	104.0
36.2	97.2	38.2	100.8	40.2	104.4
36.4	97.5	38.4	101.1	40.4	104.7
36.6	97.9	38.6	101.5	40.6	105.1
36.8	98.2	38.8	101.8	40.8	105.4
				41.0	105.8

Conversion Formulas

°F = (°C × 9/5) + 32 or (°C × 1.8) + 32

°C = (°F − 32) + 5/9 or (°F − 32) + 0.55

Normal Temperature Ranges

Measurement Method	Normal Temperature Range
Rectal	36.6°C–38.0°C (97.9°F–100.4°F)
Oral	35.5°C–37.5°C (95.9^{0}F – 99.5°F)
Axilla	36.5°C–37.5°C (97.8^{0}F–99.5°F)
Tympanic	35.8°C–38°C (96.4°F–100.4°F)

Updated Definitions of Blood Pressure (BP) Categories and Stages

For Children Aged 1–13 years	For Children Aged ≥13 years
Normal BP: <90th percentile	Normal BP: <120/<80 mm Hg
Elevated BP: ≥90th percentile to <95th percentile or 120/80 mm Hg to <95th percentile (whichever is lower)	Elevated BP: 120/<80 to 129/<80 mm Hg
Stage 1 hypertension: ≥95th percentile to <95th percentile + 12 mmHg, or 130/80 to 139/89 mm Hg (whichever is lower)	Stage 1 hypertension: 130/80 to 139/89 mm Hg
Stage 2 hypertension: ≥95th percentile + 12 mm Hg, or ≥140/90 mm Hg (whichever is lower)	Stage 2 hypertension: ≥140/90 mm Hg

Source: Flynn, J. T., Kaelber, D. C., Baker-Smith, C. M., et al. (2017). Clinical practice guideline for screening and management of high blood pressure in children and adolescents. *Pediatrics, 140*(3). http://pediatrics.aappublications.org/content/140/3/e20171904.

Normal Vital Signs According to Age

Age	Heart Rate (beats/min)	Blood Pressure (mm Hg)	Respiratory Rate (breaths/min)
Premature	120–170*	55–75/35–45†	40–70‡
0–3 mo	100–160*	65–85/45–55	30–60
3–6 mo	90–120	70–90/50–65	30–45
6–12 mo	80–120	80–100/55–65	25–40
1–3 yr	70–110	90–105/55–70	20–30
3–6 yr	65–110	95–110/60–75	20–25
6–12 yr	60–95	100–120/60–75	14–22
12+ yr	55–85	110–135/65–85	12–18

*In sleep, infant heart rates may drop significantly lower, but if perfusion is maintained, no intervention is required.

†A blood pressure cuff should cover approximately two thirds of the arm; too small a cuff yields spuriously high pressure readings, and too large a cuff yields spuriously low pressure readings.

‡Many premature infants require mechanical ventilatory support, making their spontaneous respiratory rate less relevant.

Source: Hartman, M. E., & Cheifetz, I. M. (2020). Pediatric emergencies and resuscitation. In R. M. Kliegman, J.W. St. Geme, N. Blum, et al. (Eds.), *Nelson textbook of pediatrics* (21st ed.). Elsevier.

Screening Blood Pressure (BP) Values Requiring Further Evaluation According to Age and Gender

	BP (MM HG)			
	BOYS		GIRLS	
Age (years)	Systolic	Diastolic	Systolic	Diastolic
1	98	52	98	54
2	100	55	101	58
3	101	58	102	60
4	102	60	103	62
5	103	63	104	64
6	105	66	105	67
7	106	68	106	68
8	107	69	107	69
9	107	70	108	71
10	108	72	109	72
11	110	74	111	74
12	113	75	114	75
≥13	120	80	120	80

This simplified table is designed as a screening tool only for identification of children and adolescents who need further evaluation of their BP starting with repeat BP measurements. It should not be used to diagnose elevated BP or hypertension by itself.

  stimulants, 1512–1513
Central precocious puberty (CPP), 1381
Central shunt, 1257*t*
Central venous access devices (CVADs), 1096–1097
Centration, in preoperational thought, 938*b*
Centrencephalic system, 1336
Cephalic presentation, in labour, 344, 344*f*
Cephalocaudal, 166, 906
Cephalocaudal development, 749–750
Cephalohematoma, 576, 577*f*
Cephalopelvic disproportion (CPD), 458
Cerebellar function, pediatric examination of, 808, 809*b*
Cerebral cortex, 1363
Cerebral dysfunction, 1340
  assessment of cerebral function, 1336–1343
    altered states of consciousness, 1337–1338, 1340*f*
    general aspects, 1336–1337
    increased intracranial pressure, 1337, 1338*b*, 1348*b*
  cerebral malformations and, 1371–1374
  intracranial infections and, 1358–1362
    bacterial meningitis, 1358–1361
    encephalitis, 1361–1362
    nonbacterial (aseptic) meningitis, 1361
  nervous system tumours and neuroblastoma, 1357–1358
  neurological examination, 1338–1341

Cerebral dysfunction (*Continued*)
seizure disorders and, 1363–1371
special diagnostic procedures, 1341–1343, 1341–1342*t*
unconscious child and, 1343–1346
altered pituitary secretion in, 1345
elimination of, 1345
hygienic care of, 1345–1346
intracranial pressure monitoring of, 1344–1345
medications for, 1345
nursing care for, 1343–1346
nutrition and hydration of, 1345
positioning and exercise and, 1346
respiratory management for, 1343–1344
thermoregulation in, 1345
Cerebral edema, in head injury, 1350
Cerebral palsy, 1481–1486
clinical classifications of, 1482
clinical manifestations of, 1488*b*
diagnostic evaluation of, 1482–1483
family-centred care for, 1486*b*
nursing care for, 1485–1486
pathophysiology of, 1487–1488
prognosis of, 1490
support for
family, 1491
hospitalized child, 1486
therapeutic management of, 1488–1490
Cerebrospinal fluid (CSF), laboratory tests for, 1521–1525*t*
Cerebrovascular accident (CVA), 1283*f*, 1286
Cervical cancer, genital herpes and, 108
Cervical injuries, during labour, 389
Cervical insufficiency, 284
Cervical length, in preterm labour, 448
Cervical mucus characteristics, 133*b*
Cervical ripening agents, 463–465
chemical agents for, 463–464, 463–464*b*
mechanical and physical methods, 464–465
Cervical ripening methods, alternative methods, 465
Cervix, 86, 87*f*
bimanual palpation of, 81
dilation of, 348, 349*f*
effacement of, 348–349, 350*f*
outer, 87
postpartum changes in, 486
Cervix, premature dilation of, 284–285
cerclage correction of recurrent, 284*f*
diagnosis, 284
etiology, 284
nursing and interdisciplinary care, 284–285
follow-up care, 285

  hospitalized child and, 1050–1051
    parental reactions to, 1050–1051, 1051*b*
    sibling reactions in, 1051
  immigrant, 744
  impact on parents, 994–995, 994*b*
  impact on siblings, 995, 995*b*
  infant and, 906
  LGBTQ marriages and, 740–741
  lone parenting and, 740
  in North America, 743–744
  nursing, interventions, 735, 736*b*
  organization, 16
  parental tasks and responsibilities, 518–519, 518*b*
  parenting adopted child and, 737–738, 737*f*
  of preterm infants, support and involvement of, 679–681, 680*b*, 681*f*
  qualities of strong, 736*b*
  reconstituted, 740
  roles, relationships, and strengths, 735–736
  school-age child and, 963
  social context for, 15
  in society, 15
  structure of, 16, 770–771, 770*b*
    functioning and, after childbirth, 506–507, 507*f*
Family (*Continued*)
  transition to parenthood and, 518, 518*b*
    for adolescent father, 525
    for adolescent mother, 524–525
    among LGBTQ couples, 525–526, 526*f*
    becoming a
      father, 520–521, 520*t*
      mother, 519–520, 519*t*
    culture in, 527
    father-infant relationship and, 520–521, 520*f*
    grandparent adaptation in, 523–524, 523*f*, 524*b*
    for hearing-impaired parent, 528–529, 529*b*
    in Indigenous families, 527
    infant-parent adjustment in, 521–522
    nursing care for, 529–530, 529–530*b*
    for older mothers, 524*b*, 525
    personal aspirations and, 528
    sibling adaptation in, 522–523, 522–523*b*
    social support for, 526–527
    socioeconomic conditions and, 527–528
    for visually impaired parent, 528, 528*b*
Family-centred care, 44, 723–724, 988*b*, 1239*b*
  on bed bugs, 1422–1423
  for cerebral palsy, 1486*b*
  cimicidae in the home, 1422*b*
  on controlling diaper rash, 1427*b*
  core concepts of, 45
  establishing therapeutic relationships, 992
  family–health care provider communication, 992
  philosophy of, 723
  SickKids model of, 725*f*
  sun protection, 1441*b*
  teaching strategies, 72*b*
Family-centred home care
  caregiver stress, 1012
  culturally safe care, 1010
  nursing process, 1011
  parent–professional collaboration, 1010–1011
  safety issues in home, 1011–1012
Family-centred maternity and newborn care (FCMNC), 44–48, 45*b*
Family-centred teaching
  "allergy-proofing" the home and community, 1148*b*
  caring for colicky infant, 924*b*, 924*f*
  decreasing childhood exposure to environmental tobacco smoke, 1143*b*
  guidance during infant's first year, 922*b*
  maintaining contact, 1352*b*
  media viewing, 765*b*
  safe sleep for infants, 928*b*
  for type 1 diabetes mellitus, 1400*b*
Family-controlled analgesia, 829*b*
Family history, cerebral dysfunction and, 1336
Family-newborn relationships, 394–395, 395*f*
Family nursing, 17–20
  assessment framework, 18, 18*b*
  Calgary Family Assessment Model (CFAM), 18, 19*f*
  as relational inquiry, 19–20, 20*b*
  theories/models for, 17, 17–18*t*
Family nursing interventions, 735, 736*b*
Family role
  cultural sensitivity to, 24–25
  learning, 736–737
Family violence, 66
FAMs. *See* Fertility awareness methods (FAMs)
Fanconi anemia, 1291
Fanconi syndrome, 1291
Fantasy, toddler, 940
FAS. *See* Fetal alcohol syndrome (FAS)
Fat, 938
  in human milk, 641
  for infant nutrition, 638–639
Father, transition to parenthood of, 520–521, 520*t*
Fatigue
  after childbirth, 500–501, 501*b*
  Hodgkin disease and, 1287
Fat-soluble vitamins, 236
Faucial tonsils, 1124, 1124*f*
Fear
  pain and, during labour, 400, 400*f*
  preschoolers and, 952–953
  of school-age child, 966–967, 967*b*
  of strangers, 918–920, 918*f*
Febrile seizures, 1370–1371
Febrile urinary tract infection, 1316
Feeding
  cleft lip/cleft palate and, 1210–1211, 1211*f*
  of infants, with congenital heart disease, 1254
  sick child and, 1078–1079, 1079*b*
Feeding-readiness cues, 642
Feet, physical assessment of, 807–808
Female condoms, for STI prevention, 102
Female genital cutting (FGC), 52, 65, 389
Female genitalia
  in newborns, 575, 575*f*
  pediatric examination of, 806–807, 807*f*, 807*b*
  physical assessment of newborn, 592–602*t*
Female genital mutilation (FGM), health risks of, 65
Female infertility
  assessment of
    diagnostic testing, 123–124
Female pelvic organs, 87*f*
Female pelvis, 89*f*
Female reproductive system, 85–90
  bony pelvis, 88, 88–89*f*
  breasts, 89–90, 89*f*
  disorders of, in adolescents, 988
  external structures of, 85–86, 86*f*
  internal structures of, 86–88, 87–88*f*
  of newborns, physiological adjustments, 575, 575*f*
Female sterilization (bilateral tubal ligation), 143–144, 143*f*
Femoral hernia, 804, 805*f*
Femoral venipuncture, positioning for, 1086, 1086*f*

Fentanyl citrate, for pain, during labour, 409, 409*b*
Fentanyl, for children, 825, 836
Ferning test, 360, 360*b*
Fertility, health promotion and, 56
Fertility awareness–based (FAB) methods, 131–134
  basal body temperature (BBT), 132
  calendar days method, 131
  cervical mucus ovulation-detection method, 132–133
  home predictor test kits, for ovulation, 134
  standard days method (SDM), 132
  symptothermal method, 133
  two-day method, 133–134
Fertility rates, trends in, 49
Fertilization, 159*f*
Fetal adaptation, to labour, 353
  circulation in, 353
  heart rate in, 353
  respiration in, 353
Fetal alcohol spectrum disorder, intellectual disability, 1024–1025
Fetal alcohol syndrome (FAS), 704*t*, 706*f*, 706*b*
Fetal anatomy, 252–253
Fetal assessment, 204–205
  fundal height, 204
  gestational age, 204
  group B streptococcus (GBS), 206
  health status, 205
  STIs, in pregnancy, 205–206, 205*t*
Fetal attitude, 344*f*, 345–346, 346*f*
Fetal causes, 458–459
Fetal circulation, adaptation, to labour, 353
Fetal fibronectin test (FFN), in preterm labour, 448
Fetal growth, 252
Fetal head, size of, 343–344, 344*f*
Fetal health surveillance (FHS), 353, 424
  admission fetal monitor strips for, 432
  adverse outcomes, conditions associated with, 427*t*
  amnioinfusion in, 443
  basis for, 424–426
    fetal assessment, 426
    fetal response, 424–425, 425*b*
    uterine activity, 425–426, 426*f*
  documentation of, 443–444, 444*f*
  electronic fetal monitoring in, 429–432, 430*b*, 431*t*
    pattern recognition of, 440–442, 442*b*
  intermittent auscultation for, 427–429, 427–429*f*, 428*b*
  during labour, 424–426, 432–444
  normal intrapartum, findings of, 426*t*
  nursing care for, 440–442, 441*b*, 441*f*
  patient and family teaching in, 442
  rate patterns, 432–442
  techniques for, 426–432
  umbilical cord acid-base determination, 443, 443*t*
Fetal heart activity, 251–252
Fetal heart rate (FHR)
  accelerations of, 434–435, 436*f*, 436*b*
  adaptation, to labour, 353
  baseline, 432–433
  decelerations of, 435–440
    early, 437, 438*b*
    late, 437, 438–439*f*, 439*b*

PID. *See* Pelvic inflammatory disease (PID)
Piercing, body, 984
Pigeon bottle, 1211, 1211*f*
Pigeon toe, 808
Pinard stethoscope, in intermittent auscultation, 427–428, 428*f*
Pincer grasp, 912, 912*f*
Pinch test, 208*f*
Pinworms, 1196–1197, 1197*b*
PIPEDA. *See* Personal Information Protection and Electronic Documents ACT (PIPEDA)
Pituitary function, disorders of, 1345, 1377–1383
  diabetes insipidus, 1382
  hypopituitarism, 1377–1380
  pituitary hyperfunction, 1380–1381
  precocious puberty, 1381–1382
  syndrome of inappropriate antidiuretic hormone, 1382–1383, 1388*b*
Pituitary hormones, after childbirth, 487
Pituitary hyperfunction, 1380–1381
  diagnostic evaluation for, 1382
  nursing care for, 1382
  therapeutic management of, 1382
Pituitary secretion, altered, in unconscious child, 1345
Placenta
  endometrial regeneration at site, 485
  position and function of, 253
  retained, causing PPH, 534
  separation and expulsion of, during third stage of labour, 390–392, 390*b*, 392*f*
Placenta accreta, 293, 534
Placenta increta, 293, 534
Placental abruption (premature separation of placenta), 291–293
  classification systems, 292
  clinical manifestations, 292
  diagnosis, 293
  incidence and etiology, 292
  management, 293
  maternal, fetal and newborn outcomes, 292–293
  partial and complete placental separation, 292*f*
  third-trimester vaginal bleeding, 292*b*
Placental biopsy, 255
Placental hormones, after childbirth, 486–487
Placenta percreta, 293, 534
Placenta previa, 288–291, 290*t*
  clinical manifestations, 290
  complete placenta previa, 289
  diagnosis, 291
  incidence and etiology, 289–290
  marginal placenta previa, 289
  maternal and fetal outcome, 291
  nursing and interprofessional care, 291
    active management, 291
    expectant management, 291
    home care management, 291
  types of, 290*f*
Plan of care, in nursing care, 37
Plants, poisonous, 1225–1226*b*
Plaque, 1409*f*
Plasma volume, 1526–1528*t*
Plastic deformation, fractures, 1450*f*, 1450*b*
Plastic membrane perforator, hook end of, 370*f*
Platelet count (thrombocyte count), 1526–1528*t*
  in newborns, 566
Platypelloid pelvis, 348, 348*t*
Play
  classification of, 759
  content of, 759–760
  functions of, 761–762
  hospitalized children and, 1057–1059, 1058*b*, 1058*f*
  during infancy, 918–919
  in pediatric procedures, 1073, 1074*b*
  preschoolers and, 950
  school-age and, 963
  in sensorimotor development, 916–917
  social character of, 760–761
  therapy, 1058, 1328
  toddlers and, 940, 940*f*
  toys and, 762
Plexus injury, birth process and, 692
Plse oximeter, 539

Plugged milk ducts, breastfeeding and, 657–658, 658*t*

diagnostic evaluation of, 1363–1366
emergency in, 1364–1365*b*
etiology of, 1363, 1364*b*
febrile seizures in, 1370–1371
nursing care for, 1368–1370
long-term, 1369–1370
triggering factors and, 1370
pathophysiology of, 1371–1372
precautions in, 1356
prognosis for, 1368
therapeutic management for, 1373
ketogenic diet in, 1367
medication therapy in, 1366–1367
surgical therapy in, 1352
vagus nerve stimulation, 1367
Seizures, hospital precautionary measures for, 272*b*
Selective serotonin reuptake inhibitors (SSRIs), 97, 708
Selenium, 1172–1174*t*
Self-awareness, through play, 762
Self-care
hospitalization and, 1056
special needs children and, 999
Self-concept
adolescents and, 978–980
development of, 759
school-age child and, 964
Self-esteem, 125–126
culture and, 742
development of, 759
Self-image, maternal, after childbirth, 505
Self-mastery, hospitalization and, 1060
Self-monitored glucose levels, in preconceptual period, 309*b*, 313–314
Sellick manoeuvre, 417
Semen analysis, 124–125, 125*b*
Semirecumbent position, during labour, 373*b*, 374*f*, 381–382
Sense of industry, school-age child and, 957–960, 960*f*
Sense of time, toddlers and, 937
Sense-pleasure play, 760, 760*f*
Sensitive periods, in growth and development, 751
Sensitization, 1175
Sensitizing agent, 1415–1417
Sensorimotor phase, in cognitive development, 757
in infants, 916
through play, 761
toddlers and, 936–937
Sensorineural hearing loss, 1034–1036
Sensory awareness, 168–169
Sensory changes, in toddlers, 933–934, 935–936*t*
Sensory impairment
hearing impairment, 1034–1038
hearing–visual impairment, 1043
of parents, 528–529
hearing, 528–529, 529*b*
visual, 528, 528*b*
retinoblastoma, 1044–1045
visual impairment, 1038–1043
Separation anxiety
development of, 918
hospitalization and, 1047–1049, 1048–1049*f*
in early childhood, 1048–1049
in later childhood and adolescence, 1049
manifestations of, 1048*b*
preventing or minimizing of, 1052–1055, 1055*f*
in sensorimotor development, 916–917
Separation-individuation phase
preschoolers and, 954
toddlers and, 939
Separation–individuation process, 949
Separation phases, 939
Separation, sensorimotor development and, 916
Sepsis, 1276, 1276*b*
Septic arthritis, 1471
Septic shock, 1276–1277, 1276*t*
Sequential trends, in growth and development, 750
Sequestration crisis, 1286
Serology, common laboratory tests in, 1528–1529*t*
Serotonergic-activating agents, 97
Set point, 1079
Severe acute malnutrition, 1175
Severe combined immunodeficiency disease, 1305
Severe hypertension, 265–266, 266*t*
Sex chromosome abnormalities, 154, 970–971, 970*t*
Sex differences, in general growth patterns, 977–978
Sex Information and Education Council of Canada (SIECCAN), 986
Sex-typing, preschoolers and, 949
Sexual abuse, during labour, 362
Sexual activity
after childbirth, 508–509
risks related to, 64
Sexual dysfunction, 98
from dyspareunia, 98
Sexual health, 986
Sexual Identity, and Sexual Orientation, 1510*b*
Sexuality
adolescents, 974*t*
development of, in preschoolers, 949
education, for adolescents, 986
Sexually transmitted infections (STIs), 56, 64, 100–102, 100*b*
bacteria, 103–107, 103–104*t*
chlamydia, 103–104
gonorrhea, 104–105, 105*b*
pelvic inflammatory disease, 106–107
syphilis, 105–106, 105*f*, 106*b*
drug therapies for women and, 103–104*t*
focused risk assessment for, 101*b*
HIV prevention and, 64, 65*b*
pregnancy and, 64
prevention of, 64, 100–102, 102*b*
risk factors for, 101*b*
vaginal, 112–114
bacterial vaginosis, 113, 113*t*
candidiasis, 113–114, 113*t*

Sexually transmitted infections (STIs) (*Continued*)
trichomoniasis, 113*t*, 114
wet smear tests for, 113*t*
viral, 107–112
hepatitis, 109–111
herpes simplex virus, 108–109, 108*f*
human immunodeficiency virus, 111–112
human papillomavirus, 107–108, 107*f*
Zika virus, 112
Sexual maturation
in adolescents, 975, 975*b*, 976–977*f*
in boys, 975
in girls, 975
Sexual orientation, adolescents and, 979–980, 980*b*
Sexual practices, health care and, 64
Sexual sensation, breastfeeding and, 655
Shaken baby syndrome (SBS), 922–923, 923*b*, 1348
Shared decision making, chronic or complex conditions, 992–993, 993*b*
Shear, pressure ulcers and, 1078
Sheet graft, 1436, 1437*f*
Shigella species, 1184–1186*t*, 1187
Shock, 1273–1275, 1275*b*
cardiovascular support for, 1274
clinical manifestations of, 1275
diagnosis of special needs children, 996–997
diagnostic evaluation of, 1273–1274
as grief response, 552
nursing care for, 1274–1275
pathophysiology of, 1273
in postpartum hemorrhage, 537–539
septic, 1276–1277, 1276*b*, 1276*t*
therapeutic management of, 1274
types of, 1273*t*
ventilatory support for, 1274
Short-bowel syndrome, 1223–1224
Short stature, 969
Shoulder dystocia, 478, 478*f*
fractured clavicle after, 692, 692*f*
Shoulder presentation, in labour, 344, 345*f*
SIADH. *See* Syndrome of inappropriate antidiuretic hormone (SIADH)
Sibling rivalry, 506–507, 936
in toddlers, 943, 943*f*
Siblings
acceptance of newborn, 522–523, 522–523*b*
adaptation, 196–197
empowerment of, 1001
grief response of, 554–555
during labour, 378
preparation, 197
rivalry, 522
of special needs children, 995, 995*b*
supporting, during hospitalization, 1061*b*
Sick-child care, 920
SickKids model, 724, 725*f*
Sickle cell anemia, 1285–1289
blood transfusions, 1287
Sickle cell anemia (*Continued*)
clinical manifestations of, 1286
diagnostic evaluation of, 1286
educate family and child with, 1288
nursing care for, 1288–1289
oxygen therapy, 1287
pathophysiology of, 1285–1286, 1286*f*, 1287*b*
prognosis of, 1288
promote supportive therapies during, 1288–1289
recognize other complications in, 1289
support family in, 1289
therapeutic management of, 1286–1288
Sickle cell-C disease, 1285
Sickle cell disease (SCD), 327–328, 837
Sickle cell hemoglobinopathy, 327–328, 328*b*
Sickle cell trait (SCT), 327
Sickle thalassemia disease, 1285
Sickle-turbidity test (Sickledex), 1286
Side-lying position
for breastfeeding, 644*f*
during labour, 381–382
SIDS. *See* Sudden infant death syndrome (SIDS)
SIECCAN. *See* Sex Information and Education Council of Canada (SIECCAN)
Signs preceding labour, 350–351
Sinciput presentation, 346*f*
Single knee roll, 502*f*
Single-photon emission computed tomography (SPECT), 1341–1342*t*
Sinus arrhythmia, 911
Sinus bradycardia, 1267
Sinusoidal FHR pattern, 434, 436*f*
Sinus tachycardia, 1267
SIRS. *See* Systemic inflammatory response syndrome (SIRS)
Sitting, infants and, 913–914, 914*f*
Situational crisis, 49
Skateboard, safety, 870*b*
Skeletal growth
in childhood, 752
differences, 977
Skeletal injuries, birth process and, 691–692, 692*f*
Skeletal limb deficiency, 1464
Skeletal system
immobilization and, 1444–1446*t*
of newborns, physiological adjustments, 576–578
Skeletal traction, 1455*b*
Skeletal tuberculosis, 1471–1472
Skill play, 760, 760*f*
Skin
anatomy and physiology of, 1407, 1408*f*
cancer, tanning and, 985
cerebral dysfunction and, 1357
colour changes of racial groups, 789*t*
eczematous inflammation of, 1427
fold thickness, 783
incisions, for Caesarean birth, 472, 472*f*
influences during puberty, 977
of newborns, 586, 592–602*t*
nutritional status and, 775–776*t*
Skin (*Continued*)
pediatric examination of, 789–790, 790*f*
preterm infants and, 675, 677*b*
temperature measurement and, 784*b*
of younger children, 1430–1431
Skin fold thickness circumference, 783
Skin lesions, 1407–1408, 1409*f*
configuration and arrangement of, 1408
diagnostic evaluation of, 1408
distribution pattern of, 1408
history and subjective symptoms of, 1408
laboratory studies for, 1408
objective findings of, 1408
pathophysiology of dermatitis in, 1407–1408
primary, 1408
secondary, 1408
types of, 1408
Skin prick testing, asthma and, 1146
Skin punctures, 1090*b*
Skin-to-skin care, during painful procedures, 823–824
Skin-to-skin contact, 389
to control heat loss, 566, 567*f*
importance of, 586, 586*f*
for newborns, 642–643*b*
in parent-infant contact, 516
for preterm infants, 678–679, 678*f*
Skin traction, 1455*b*
Skull fractures, during birth, 692
Slate grey nevi, 574
SLE. *See* Systemic lupus erythematosus (SLE)
Sleep
developmental changes in, 753
disorders, 63
disruption, 820–821
position, sudden infant death syndrome and, 927
preschoolers and, 954
rest and activity integration, childhood, 855–858
adolescents, 858
infant, 856
preschooler, 857
school-age, 857–858
toddler, 856–857
transitional objects, 857*f*
Sleep Habits Questionnaire, 820–821
Sleep-wake states, 579–580
Sleepy newborn, breastfeeding and, 649, 649*f*
Slipped capital femoral epiphysis, 1466–1467
Slow-to-warm-up child, 754
Slow weight gain, in newborns, 650
Small-for-gestational-age (SGA) babies, health issues with, 49
Small-for-gestational-age infants classification of, 668
Smell, sense of, in newborns, 580
Smoke inhalation injury, 1142–1143
Smokeless tobacco, in children, 1511
Smoking, maternal nutrition and, 240
Smoking cessation, 59*b*
during pregnancy, 214*b*
intervention for, 60*b*
Snellen letter chart, 793
Snowstorm pattern, 288
Soaks, play activities for, 1073
Social-affective play, 760
Social character, of play, 760–761
Social determinant
of health, pediatric nursing and, 719–720
influences, 741–743
community, 742–743
culture, 741–742
peer groups, 743
school, 743
socioeconomic status, 742
Social development
adolescents and, 980–982
infants and, 917–919
attachment, 917–918
fear of strangers, 918–920, 918*f*
play, 918–919
separation anxiety, 918
preschoolers and, 949–951
school-age child and, 962–964
in toddlers, 939–940
Socialization
hospitalization and, 1060, 1060*f*
through play, 762
Social media, 8–9, 8*b*
child development and, 968
Social networking websites, 982
Social relationships and cooperation, 962
Social roles, culture and, 742
Social stressor, neonatal or pediatric critical care unit, 1065
Social support, during transition to parenthood, 526–527
Society, family in, 15

  blood, 1089–1090, 1090*f*, 1090*b*
  respiratory secretion, 1090–1091
  stool, 1089
  urine, 1087–1089, 1087*f*
    bladder catheterization and, 1088, 1088*b*
    clean-catch specimens, 1088
    twenty-four-hour collection, 1089
    urine collection bags, 1087–1088, 1087*f*
SPECT. *See* Single-photon emission computed tomography (SPECT)
Speech
  development of, 758
  issues, in preschoolers, 953–954
Spermatogenesis, 159
Spermicides, 126
Spina bifida, 1486*b*
  clinical manifestations of, 1488*b*
  cystica, 1487
  occulta, 1487, 1487*f*
Spinal anaesthesia, for pain, during labour, 411–413, 412*b*, 412*f*
Spinal cord concussion, 1498
Spinal cord injury (SCI), 335, 1497–1501
  antepartum care, 335
  clinical manifestations of, 1498–1499
  intrapartum care, 335
  mechanism of, 1498
  nursing care for, 1500–1501
  postpartum care, 335
  therapeutic management for, 1499
Spinal headache. *See* Postdural puncture headache (PDPH)
Spinal muscular atrophy, 1492–1494
Spinal shock syndrome, 1498–1499
Spine
  of newborns, assessment, 576
  pediatric examination of, 807, 807*b*
Spinnbarkeit, 92
Spiral, fracture line, 1450
Spiritual care, 23, 23*b*
Spiritual development
  adolescents and, 980
  preschoolers and, 949
  school-age child and, 961–962
  theory, 755*t*, 758
  in toddlers, 937–938
Spirituality, 23
Spironolactone, for heart failure, 1251*b*, 1253*t*
Splenectomy, 1294
  for beta-thalassemia, 1287
  for idiopathic thrombocytopenic purpura, 1302
Splenic sequestration, 1287
Spontaneous abortion, 280–284
  types of, 282*t*
  and usual management, 282*t*
Spontaneous preterm birth, 447, 447*b*
Sports, school-age child and, 967–968, 967*f*
Sports injuries, 872
Spot test, 1129
Sprains, 1448–1449
Squatting, during labour, 374*f*, 382
Stage of accomplishment, 960
Standards of care, 10, 10*b*
Standing position, during labour, 374*f*, 380–381
Staphylococcal scalded skin syndrome, 1413*t*
Staphylococcus, 1184–1186*t*
Statins, for hyperlipidemia, 1265–1266
Station, fetal, 346, 347*f*
StatLock, 1102, 1103*f*
Status asthmaticus, 1150
Status epilepticus, treatment for, 1367–1368
Stealing, school-age child and, 966
Stereopsis, 912
Stereotyping, ethnic, 21
Sterilization, 143–145
Stethoscope, infections and, 1083*b*
Stevens-Johnson syndrome, 1425–1426*t*
Stillbirths, 311
Stimulation
  of infants, 919
  unconscious child and, 1346
Stimuli, influencing behaviour of newborns, 580
STIs. *See* Sexually transmitted infections (STIs)
Stomatitis, 1300
Stools, of newborns, 569, 569*b*, 570*f*, 592–602*t*
Stool specimens, collection of, 1089
Storage of breast milk, 654
Strabismus, 1039–1040
  cerebral dysfunction and, 1339, 1372*b*
  testing for, 792
Strains, 1449
Stranger anxiety, in infants, 918
Strangulated hernia, 1214
Streptococcus, group B, 698–700*t*, 701

culture and sensitivity, 1313–1314*t*
Urine (*Continued*)
monitoring, in type 1 DM, 1399
protein values, 268*b*
specimen
analysis of, during first stage of labour, 367
collection of, 1087–1089, 1087*f*
for newborn screening, 615
tests, of renal function, 1314–1315*t*
volume, normal test ranges for, 1521–1525*t*
Urodynamics, 1313–1314*t*
Urosepsis, 1316
Urticaria, 1425–1426*t*
Urushiol, 1417
Usual maternal diet, in nutrition assessment, 239–240
Uterine activity (UA), 367*b*
abnormal, in dystocia, 456–457, 457*t*
active phase disorder, 456
latent phase disorder, 456
assessment of, 425
during first stage of labour, 365–367, 366*f*, 369*b*
comparison model for palpation of, 426*t*
components of, 426*f*
suppression of, in preterm labour and birth, 449–451
Uterine atony, 533
Uterine contractions, 258
during breastfeeding, 655
Uterine dehiscence, 480
Uterine incisions, for Caesarean birth, 472, 472*f*
Uterine inversion, 534
Uterine ischemia, 398
Uterine leiomyomas, 98
Uterine tenderness, 271
Uterine tubes, 87
Uteroplacental factors, in fetal oxygenation, during labour, 425
Uterus, 86, 88*f*, 177–180
afterpains, 485
bimanual palpation of, 83*f*
cervical changes, 180
contractility, changes in, 178
involuntary contraction of, 348
involution process of, 484, 485*f*
in normal labour, 349*f*
postbirth lochia, 485–486, 486*b*
rupture of, 479–481
size, shape and position, changes in, 177–178
subinvolution of, 533
tone of, maintenance of, 498, 498*f*
uteroplacental blood flow, 178–180
UTI. *See* Urinary tract infection (UTI)

V

Vacuum-assisted birth, 469–470, 470*f*
Vagina, 87–88*f*
postpartum changes in, 486
Vaginal birth after Caesarean (VBAC), 476
Vaginal examination, during first stage of labour, 367, 369*b*, 369*f*
Vaginal infections, 112–114
bacterial vaginosis, 113, 113*t*
candidiasis, 113–114, 113*t*, 114*b*
trichomoniasis, 113*t*, 114
wet smear tests for, 113*t*
Vaginal lacerations, during labour, 389
Vaginal vestibule, 86
Vaginal wall examination, 81
Vaginitis, 113
Vagus nerve stimulation, for seizure disorders, 1367
Valium, for pain , during labour, 408
Valsalva manoeuvre, 382–383
for cardiac dysrhythmias, 1267
in fetal health surveillance, 442
Values and beliefs, 1054
Valve replacement, pre-existing conditions, 322–323
Valvular aortic stenosis, 1242, 1245–1247*b*
Variability, of fetal heart rate, 433*t*, 434, 435*f*
Variable decelerations, of fetal heart rate, 438–439, 439–440*f*, 440*b*
Varicella zoster virus (VZV), 698–700*t*, 702
skin infections of, 1415*t*
Varicoceles, 125
Varicosities, after childbirth, 490, 490*f*
VAS. *See* Visual Analogue Scale (VAS)
Vasa previa, 293
Vascular dysfunction, 1270–1277
anaphylaxis and, 1275–1276
Kawasaki disease and, 1271–1273, 1271*b*
septic shock and, 1276–1277, 1276*t*
shock and, 1273–1275, 1273*t*, 1274*b*
systemic hypertension and, 1270–1271
Vasodilator therapy, for pulmonary hypertension, 1268
Vaso-occlusive crisis (VOC), 1286
Vasopressin, 1312
Vastus lateralis injection site, 1093, 1093–1094*t*
VBAC. *See* Vaginal birth after Caesarean (VBAC)
Vegans, 242
Vegetarian diets
maternal nutrition and, 242, 242*b*
nutritional disturbances and, 1171–1172
Velamentous insertion of cord, 293
Vena cava syndrome, 183
Venipuncture, in newborns, 615, 615*f*
Venous blood samples, 1089
Venous thromboembolism (VTE), in PPH, 539–541
Ventilator support, weaning from, 671
Ventricular puncture, 1341–1342*t*
Ventricular septal defect (VSD), 319, 1240, 1247–1248*b*
Ventriculoperitoneal shunt, 1373, 1373*f*
Ventrogluteal injection site, 1093, 1093–1094*t*
Verbal interactions, in labouring patient, 362*b*
