(DE PROPRIS L. and LAZZERETTI L. Measuring the decline of a Marshallian industrial district: the Birmingham Jewellery Quarter, Regional Studies. This paper presents the findings of a study on the decline of a typical Marshallian industrial district: the Birmingham Jewellery Quarter in the UK. The paper contributes to the current debate on clusters’ life cycle by presenting a multidisciplinary methodology that combines historical and economic analyses with demography and organizational ecology models. The paper seeks to explore the patterns of firms’ birth and mortality rates, as well as firm density across branches of production activities to measure and understand the decline of the Jewellery Quarter over the last decades.

Marshallian industrial districts  Cluster life cycle  Ecological theory

DE PROPRIS L. et LAZZERETTI L. Mesurer le déclin d’un district industriel du type Marshall: le quartier de la bijouterie à Birmingham, Regional Studies. Cet article cherche à présenter les résultats provenant d’une étude au sujet du déclin d’un district industriel du type Marshall: à savoir, le quartier de la bijouterie à Birmingham (R-U). L’article contribue au débat actuel sur le cycle de vie des regroupements d’entreprises, en présentant une méthodologie pluridisciplinaire qui associe des analyses chronologiques et économiques aux modèles de la démographie et de l’écologie organisationnelle. On cherche à étudier la structure des taux de naissance et de décès des entreprises, ainsi que la densité du parc d’entreprises à travers des branches d’activités de production afin de mesurer et comprendre le déclin du quartier de la bijouterie pendant les décennies récentes.

Districts industriels du type Marshall  Cycle de vie des regroupements  Théorie écologique

Marshallsche Industriekreise  Lebenszyklus von Clustern  Ökologische Theorie

DE PROPRIS L. y LAZZERETTI L. Medición del declive de un distrito industrial marshalliano: el Jewellery Quarter de Birmingham, Regional Studies. En este artículo presentamos los resultados de un estudio sobre el declive de un distrito industrial marshalliano: el Jewellery Quarter (barrio de las joyas) en Birmingham (RU). Aquí contribuimos al debate actual sobre el ciclo de vida de las aglomeraciones presentando una metodología multidisciplinaria que combina los análisis históricos y económicos con los modelos demográficos y la ecología organizativa. Lo que pretendemos es analizar los patrones de tasas de nacimientos y mortalidad de las empresas, así como su densidad en todos los sectores de las actividades de producción para medir y entender el declive del Jewellery Quarter en las últimas décadas.

Distritos industriales marshallianos  Ciclo de vida de aglomeración y teoría ecológica

JEL classifications: L23, N80, O14

(Received December 2006: in revised form December 2007)
INTRODUCTION

Over the last two decades there has been a flourishing debate on the nature, structure, and functioning of various forms of clustering and networking. However, contributions to the life cycle of local systems have been much fewer and have mainly tended to look at their emergence, growth, and decline/revival through either qualitative or quantitative analyses (Swann et al., 1998; Scott, 2000; Wolfe and Gertler, 2004; Maskell, 2001; Bresnahan et al., 2001).

The present paper contributes to such a debate with a composite and multidisciplinary methodology (i.e. Historical, Economic, Demographic, Ecological, and Economic (HEDRON)) that combines historical, economic, and industrial analyses with demographic and ecological modelling. Demography and population ecology models (Hannan and Freeman, 1989; Carroll, 1984) were originally used to study variations in the organizational diversity of society and were only later applied to economics. Indeed, the novelty of this methodology is to extend the application of firm demography and population ecology models to organizational forms like local production systems and, in particular, to industrial districts, as systems of co-located firms grouped in specific sectors and interlinked by complementarities and synergies. This paper presents an example of cross-fertilization between industrial organization and the organization ecology models (Boone and Van Witteloostuijn, 1995). In fact, it refers to a dynamic community approach centred on understanding populations' co-evolution (the latter being one of the most interesting streams of the organization ecology; Amburgey and Rao, 1996).

Such a methodology is applied in the study of the decline of the Birmingham Jewellery Quarter in Birmingham, UK, from 1880 to today. The jewellery trade first appeared in Birmingham in the mid-18th century and embedded itself in the vital and vibrant industrial atmosphere that the city had to offer being at the heart of the Industrial Revolution. The Birmingham Jewellery Quarter grew in size and its organization of production started to become networked and complex until 1860s when it presented the characteristics of a typical Marshallian industrial district (Marshall, 1895, 1919; De Propris and Lazzeretti, 2007). Its fortunes, however, depended on external factors such as fashion, input prices and availability, and technological changes, as well as major historical events like the two World Wars.

This paper seeks to explore whether and how the patterns of firms' and sectors' birth and mortality rates explain the decline of the Birmingham Jewellery Quarter as an exemplary case of a typical Marshallian industrial district. This study investigates the decline rather than the 'death' of a Marshallian industrial district, since the Quarter is still the home of a concentration of jewellery manufacturing and retailing activities within a tight web of streets. Despite a shrinking of the manufacturing base, it can be argued that the Quarter is transforming itself in an 'urban creative district' with a move towards small batch/customized and more design-intensive productions.

The paper will proceed as follows. The second section will present an historical background of the Birmingham Jewellery Quarter. The third section will introduce the current debate on the theories of the life cycle of local production systems and present the composite methodology applied in the final part of the paper. After describing the data collection in the fourth section, the findings of the application are detailed in the fifth section. Finally, some final remarks will conclude the paper.

HISTORICAL BACKGROUND OF THE BIRMINGHAM JEWELLERY QUARTER

By the mid-19th century, Birmingham had become one of the most industrialized towns in England. The local economy heavily relied on the metal industries – iron, brass, guns, buttons, pins and toys – together with jewellery and some minor industries such as coin minting. In this vibrant context, the Birmingham Jewellery Quarter established itself in a triangle of roads around St Paul's Square, to the north of Birmingham, where it is still situated today (Fig. 1).

Several factors combined to contribute to the development of the jewellery industry in Birmingham, including the following:

- The decline of the buckle, toys and button trades which provided skilled labour that could easily be employed in jewellery-making.
- Gold discoveries in California (1848), Colorado (1860), Idaho (1861) in the USA, and in Australia (1860); silver discoveries in Nevada (mid-1850); and turquoise, amethyst and diamond stone discoveries in Australia and South Africa (1850) made jewellery more affordable and popular.
- Birmingham was then at the centre of regional and national transport networks – including roads, canals and trains – that provided cheap and easy access to raw materials (e.g. coal) and ensured that commodities could reach consumers across the country and overseas easily and quickly.
- Finally, local and national demand for jewellery was booming as trade with the colonies made the British middle-classes wealthier and personal adornment more fashionable (Timmins, 1866).

It was so that by the mid-19th century Birmingham became the centre of Britain jewellery trade and in 1880 the Birmingham Jewellery Quarter was well established and at its peak. De Propris and Lazzeretti (2007) provide evidence that at this time it had all the characteristics of a mature Marshallian industrial district (for a discussion on this, see the fifth section).
The First World War damaged the Jewellery Quarter quite badly, although the jewellery trade picked up again afterwards. The recessions of the 1920s and 1930s, and shortly after the Second World War hit the Quarter so deeply that it never really recovered. In the post-War period (1940s and 1950s), the jewellery trade struggled with weak demand due to the post-War purchase tax,1 and with labour shortages as other
growing industries in Birmingham attracted labour by offering higher salaries. The decision taken decades before to focus on mass production and, to some extent, on the bottom-end of the jewellery market became a serious weakness in the 1970s to 1980s. Tough competition from low-cost countries like China, India and Thailand eroded domestic markets; and, at the same time, the export of creative and high-quality output from Italy flooded the European market, reducing the possibility for Birmingham jewelers to penetrate foreign markets. Overall, the post-War period was characterized by a slow but steady decline caused by firms’ inability to adjust to production changes that were filtering down from technological change as well as their inability to respond to a new competitive environment. The lack of competitiveness of the manufacturing base in the 1970s (SMITH, 1990) led to its erosion and consequently to a steady employment fall (Fig. 2).

A major change in the composition of activities in the Quarter was the opening of shops in the 1970s. Workshops and small firms started to sell their goods directly to customers (rather than through a networks of salesmen), virtually setting up counters in their front rooms. This paved the way for the Quarter to become not only a manufacturing, but also a retailing centre. Indeed, from 1970 to 2005, the proportion of retailing-related activities in the Quarter rose from less than 5% to more than 40% of the total jewellery activities (DE PROPRIS and Wei, 2007). This move has been accompanied by an effort to distance itself from mass production and cheap jewellery by increasingly aiming at high-value added segments of demand with designer jewellery, and unique and customized pieces. This is reflected in Advantage West Midlands having classified the jewellery industry in the Quarter as a high-value-added consumer cluster (also BIRMINGHAM AND SOLIHULL ECONOMIC FORUM, 2005). A shift from manufacturing to design-intensive, creative jewellery would still mean a restructuring for the industry, but it could offer better prospects for its long-term sustainability. At the same time there is serious pressure to open the area to mixed development (office space and residential) in a push to turn the Quarter into the Birmingham’s ‘Greenwich Village’.

A MULTIDISCIPLINARY METHODOLOGY TO STUDY THE BIRMINGHAM JEWELLERY QUARTER: HEDRON

Current debate

The ever-growing literature on local production systems has studied the nature, structure, and functioning of various forms of clustering and networking, creating some ‘chaos’ (MARTIN and SUNLEY, 2003) in their definitions and labelling. For this reason, it is worth clarifying that the present paper will refer to local production systems to include all forms of complex geographical agglomeration of firms in specialized activities. These include complex systems like industrial districts (BECATTINI, 1990, 2004), clusters (PORTER, 1998; SCOTT, 1998), innovative milieux (CAMAGNI, 1991), and urban clusters (CUMBERS and MACKINNON, 2004). In particular, this paper will study a typical ‘Marshallian’ industrial district as a...
localized trade in Birmingham already established at the turn at the 20th century is considered.

The debate on the evolution of local production systems is, on the other hand, much thinner. It has included qualitative case studies that have tended to investigate the (endogenous and exogenous) factors and conditions that impact on local systems’ evolution; or quantitative studies that have measured the evolution of local systems by evaluating changes in their size and structure (i.e. firms’ entry and exit; emergence or disappearance of specific tasks/functions).

In particular, qualitative studies have analysed in detail the life cycle of local production systems as a sequence of stages: emergence, growth, maturity, decline, and revival. Those contributions that actually focus on the emergence of local production systems consider firms’ location choices, as well as the advantages of agglomeration and proximity (e.g. agglomeration and external economies, and urbanization externalities) (Baptista, 1998). In contrast, Scott’s (1998) market-led theory of ‘clustering’ stresses the role of demand in determining the structure of the inter-firm division of labour, in that it is market diversification and uncertainty that determine the vertical and horizontal production segmentation internal to the cluster. In other words, demand determines the structure of production within clusters and impacts on their growth and/or decline. Scott appreciates that after a certain point co-location can engender agglomeration dis-economies reducing firms’ benefits from proximity. In the same line of argument, drawing on a case study on the Silicon Valley cluster in California, Bresnahan et al. (2001) argue that clusters’ emergence and growth can depend on technology and market opportunities, as well as on increasing returns and external economies. Similarly, Glasmeier (1994) analyses the evolution of the Hong Kong watch industry as it had to adjust to global market forces and technological shocks. Somewhat differently, Maskell’s (2001) theory on cluster dynamics pivots around the role of knowledge, whereby the emergence and the growth of clusters can be driven by processes of knowledge creation and accumulation in specific localities. In line with this, Belussi (1996) looks at the evolution of Italian industrial districts also considering the dynamics of the intra-district division of labour and the processes of knowledge accumulation. The path dependency of knowledge accumulation, however, means that clusters can face phases of stagnation or decline if they become over-specialized, locked into obsolete practices and/or closed to external knowledge flows (Bathe1t et al., 2002), unless they find ways of coordinating adjustment actions (for a study of the evolution of the Prato Textile district by means of a Hirschmanian voice-exit approach, see Dei Ottati, 2003).

In summary, qualitative studies have analysed the evolution of local production systems by considering their historical development as well as the economic and ‘industrial’ factors that have influenced them, such as demand, innovation, and knowledge.

On the other hand, quantitative studies have aimed at measuring the structural changes that local production systems experience over time as a reflection of their evolution. In Klepper and Graddy (1990), the emergence of new industries is measured in terms of firm entry and growth. Interestingly, they introduce the idea that the rate of firm entry can explain the formation of a new industry, and suggest that firms’ entries peak at a certain point and then stabilize. The main limit of their study is that it considers industries that do not have a geographical dimension. Staber (2001) applies the population ecology model to study the decline of the textile district in Baden–Württemberg, Germany, looking in particular at how the tension between competition and legitimation processes impact on firms’ births and deaths.

More interestingly, given the remit of the present paper, Swann (1998) presents a quantitative model that studies cluster life cycle by looking at new firm formation, incumbent firm growth and cross-sector effects. In particular, a life cycle comprises four stages:

- A cluster emerges when new firms are attracted to the cluster by ‘entry attracting’ factors, thus contributing to creating a critical mass of firms.
- A cluster experiences its ‘take off’ stage when agglomeration economies kick in and incumbent firms grow either in the same sector or in different sectors (‘growth-promoting’ factors).
- Clusters reach maturity when the entry of new firms peaks and the cluster is no longer attractive for new entrants; this is due to congestion especially in mono-sector highly specialized clusters.
- Finally, clusters reach saturation when no new firms are attracted to it.

Swann suggests a model where firms’ entry and growth are measured and linked to a cluster’s sector composition, size and life cycle. In so doing, Swann’s model introduces a new methodology to measure and quantify clusters life cycle with more intangible and contextual variables at the core of the qualitative models becoming fixed.

The contribution is framed in this debate and presents a composite and multidisciplinary methodology that integrates an historical analysis of the evolution of the local system with an analysis of its economic and industrial structure. In addition, in order to measure such evolution, firm demography and organizational ecology models are drawn on that rely on concepts like firms’ entry and exit, and firm and sector density.

**THE HEDRON METHODOLOGY**

The Historical, Economic, DemogRaphic, ecOlogical, and ecoNomic (HEDRON) methodology is a...
composite and multidisciplinary methodology developed by LAZZERETTI (2006). It analyses local production systems as ‘communities of organizations’ by decomposing their internal structure at different levels, namely firm, sector and overall system, in order to trace their evolutionary dynamics.

The methodology comprises five levels of analysis. The historical and economic analyses aim at identifying the key historical stages of the phenomenon under study through a survey of the historical and economic literature and a recount of key events, shocks, moments and turning points. The aim is to identify a valid start date for the demographic and ecological analyses as well as crucial dates and critical periods. Following from these, the industrial analysis should provide a picture of the productive filière and how it has changed over time. In this analysis, firstly, firms are grouped in sectors, specializations or trades, then the latter are linked up according to their position along the value chain; finally, the evolution of such groups is explored by means of data or anecdotal information. The demographic and ecological analyses are meant to measure the life cycle of the local system under study by means of quantitative data, namely firms’ births and deaths.

*Demography and organizational ecology models*

The organizational ecology theory draws on ecological and evolutionary models and it has emerged as an approach to study long-term organizational changes, focusing on organizational diversity and the processes that influence the evolution of organizational forms (SINGH and LUMSDEN, 1990; HANNAN and FREEMAN, 1987, 1989).

Ecological theories contemplate three levels of analysis. Firstly, organization demography models analyse the evolution of organizations. Secondly, population ecology models assume organization inertia and look at the evolution of and interactions between populations of organizations, the latter being defined as meaningful groupings of organizations sharing some form of similarity (HANNAN and FREEMAN, 1977). Finally, community ecology models study ‘the collection of populations that live together in some region’ (CARROLL, 1984, p. 72). In particular, population ecology looks at populations’ vitality flows (births and deaths) as determined by the interactions between coexisting populations, and their impact on the evolution of the organizational community as a whole (BAUM and SINGH, 1994; HANNAN and FREEMAN, 1987).

In the present application of the organizational ecology model, organizations correspond to firms, populations of organizations to groups of firms, such as sectors or specializations, and the community of populations coincides with the collection of interrelated sectors that characterizes the district.

There is a wide variety of approaches to organizational evolution (SINGH and LUMSDEN, 1990), but the most appropriate to investigate long-term organizational evolution is density dependence. Two pioneering empirical studies by HANNAN and FREEMAN (1987, 1988) try to explain changes in populations’ density (i.e. the number of organizations within a population) and empirically show that there is a relationship between population density and vitality rates (birth and mortality rates), and that therefore population density influences the evolution of the population itself. In other words, the density dependence approach relates the evolution of populations of organizations to their density. In particular, the evolution of populations and communities is driven by two main processes: competition and legitimation. The legitimation process takes place when a population or a community consolidates its position by strengthening the set of social, political and economic aspects that consistently characterize its organizational form. Legitimation affects the population’s vitality rates, so that as birth rates increase more than mortality rates, firm density rises (HANNAN and FREEMAN, 1988). More formally, the legitimation coefficient increases with density at a decreasing rate. On the other hand, the competition process is triggered by the entry of an additional competitor in the population or community so as to induce a process of crowding out due to fighting over a limited set of resource; during the competition process mortality rates increase and the total number of firms decreases. Therefore, the competition coefficient increases with density at an increasing rate.

Both competition and legitimation processes impact on populations’ vitality rates, in that populations’ births and mortality rates vary with populations’ density rates. In particular, the relationship between the birth rate (or mortality rate) and the density of a population is represented by the rate multiplier coefficient, which is defined as the ratio of the birth rate (or mortality rate) to the rate calculated for the lowest observed population density. In particular, at low density, increasing birth rates have a positive effect on density due to the legitimation process. When the density of a population peaks, it means that it has reached its carrying capacity. After this point, as competition forces become stronger, the mortality rate increases and the population’s density falls. Therefore, HANNAN and FREEMAN (1987, 1988) find that the relationship between the density of a population and the multiplier of its founding rate to be non-monotonic and shaped as an inverse ‘U’-shape (Fig. 3). In economic terms, a population’s carrying capacity reflects the fact that a population (an industry) has reached its critical mass and its growth is peaking.

Sociologists and organization theorists have mainly applied the organization ecology theory to the study of industries (including brewing, computer and automotive industries) and trade unions (for a review, see, for instance, CARROLL and HANNAN, 2004), where industries are considered as populations and firms are the basic...
The HEDRON methodology is applied to study the decline of the Birmingham Jewellery Quarter. Since 1860, the Quarter has appeared as a localized jewellery industry situated within a tight web of streets just off Birmingham's city centre. Since its geographical borders have been the object of extensive research in the past (Smith, 1989; Wise, 1950; Gilbert, 1972), and this has generated a broad consensus on its location, it was decided to collect data on jewellery and jewellery-related firms in the 45 streets located within such borders.

A database of firms from 1880 to 1973 was collated. Due to data constraints, the analysis had to be started at a time when the Birmingham Jewellery Quarter was already established. The database contains records of 11,400 firms that have existed for any period over the 90 years covered by the data: 513 firms were still operating in 1973.

The database was collated by transferring data and information from three historical Birmingham Directories (Kelly’s Directory of Birmingham, 1880, 1883–1874; Bull’s Directory of Birmingham, 1881; Houghton’s Directory of Birmingham, 1882) into a spreadsheet.

The database comprised a set of information to trace the life and death of firms. For each firm the name, address, production activity and ownership status were recorded. As the production activities of artisans, craftsmen and workshops are being analysed, the activity or specialization associated with the firm and the name of the owner (or craftsman) are both crucially important to identify the firm itself.

Reliance on the above Directories presented some problems due to the degree of imprecision in the actual data collection at the time. For instance, the present study is interested in tracing firms’ births and deaths, and for this it is crucially important to ascertain whether the disappearance of a firm from the Directory for one year corresponded to an actual death or just a firm being overlooked. To offset this level of imprecision, a firm was considered as surviving if it was missing for one year, but reappeared the year after. In the same way, the wording used to define production activities tended to vary, so it was decided to classify production activities into broader categories which were also more manageable from a statistical point of view. (For instance, a ‘gold wedding ring maker’ was classified as ‘gold ring maker’ so that information about the material – that is very important for the organizational forms. Recent contributions have applied the organization ecology theory to industrial economics. In particular, the organization demography model has been used to study the evolution of organizational forms such as industries, clusters and industrial districts. More generally, Van Wissen (2004) suggests applying the organization demography model to study the life cycle of industries and firm agglomeration. Fortis and Maggioni (2002) adopt a population ecology model to study the impact of both agglomeration economies and diseconomy in the evolution of some Italian industrial districts. More specifically, for instance, Belussi and Scarpet (2002) analyse the evolutionary pattern of the women’s footwear industrial district in Italy (Brenta) by means of historical and demographic analyses. Similarly, a community-based organization ecological model (density dependence) is applied to the Prato textile industrial district (Lazzeretti and Storai, 2003), and the Arezzo jewellery district (Lazzeretti, 2006) in Italy. With a different focus, Grabher (2001) looks at the relevance of competition processes (rivalry) in the transformation of the British advertising industry as an organizational form; likewise, Staber (2001) adopts the organization ecology theory to study inter-firm relations, mortality rates (competition processes) and spatial proximity in a declining industrial district in Baden-Württemberg. Drawing from these, it has emerged that industrial districts can be studied as complex organizational forms comprising organizations (firms) and populations (sectors) that taken together constitute a community (the district) of organizational forms.

This paper studies the evolution of the Birmingham Jewellery Quarter as a collection of populations related to the jewellery trade in a specific geographical area; in other words, it considers a typical Marshallian industrial district as a community of populations. The possibility to study, in particular, industrial districts with the organization ecology model is endorsed by Foster (1993), who argues that Marshall (1895), in Principles of Economics, was ‘acutely aware of the socio-economic relevance of organizational analogies drawn from biology’ (Foster, 1993, p. 987). In fact, self-organization and the organization ecology model can describe the growth of systems that are non-linearly density dependent. Indeed, Marshall’s law of increasing returns can be seen as mirroring the density dependence of the organization ecology theorized by Hannan and Freeman.

**DATA COLLECTION AND UNIT OF ANALYSIS**

The HEDRON methodology is applied to study the decline of the Birmingham Jewellery Quarter. Since 1860, the Quarter has appeared as a localized jewellery industry situated within a tight web of streets just off Birmingham’s city centre. Since its geographical borders have been the object of extensive research in the past (Smith, 1989; Wise, 1950; Gilbert, 1972), and this has generated a broad consensus on its location, it was decided to collect data on jewellery and jewellery-related firms in the 45 streets located within such borders.

A database of firms from 1880 to 1973 was collated. Due to data constraints, the analysis had to be started at a time when the Birmingham Jewellery Quarter was already established. The database contains records of 11,400 firms that have existed for any period over the 90 years covered by the data: 513 firms were still operating in 1973.

The database was collated by transferring data and information from three historical Birmingham Directories (Kelly’s Directory of Birmingham, 1880, 1883–1874; Bull’s Directory of Birmingham, 1881; Houghton’s Directory of Birmingham, 1882) into a spreadsheet.

The database comprised a set of information to trace the life and death of firms. For each firm the name, address, production activity and ownership status were recorded. As the production activities of artisans, craftsmen and workshops are being analysed, the activity or specialization associated with the firm and the name of the owner (or craftsman) are both crucially important to identify the firm itself.

Reliance on the above Directories presented some problems due to the degree of imprecision in the actual data collection at the time. For instance, the present study is interested in tracing firms’ births and deaths, and for this it is crucially important to ascertain whether the disappearance of a firm from the Directory for one year corresponded to an actual death or just a firm being overlooked. To offset this level of imprecision, a firm was considered as surviving if it was missing for one year, but reappeared the year after. In the same way, the wording used to define production activities tended to vary, so it was decided to classify production activities into broader categories which were also more manageable from a statistical point of view. (For instance, a ‘gold wedding ring maker’ was classified as ‘gold ring maker’ so that information about the material – that is very important for the
jewellery industry – and the degree of specialization were kept.) Even with this ‘rounding’, more than 350 specializations were identified (De Propris and Lazzeretti, 2007).

Since the production activities of artisans, craftsmen and workshops are being analysed, both the activity/specialization of the firm and the name of the owner (or craftsman) are crucially important to identify the firm itself. A firm’s founding is defined as the year when it first appeared in the Directory (new name—new activity—new address) or the year it first appeared with a new name or a new activity (same address—same activity—new name or same address—same name—new activity). With this, for each year the firms’ birth rate within the Quarter was computed. A firm’s death is defined as the year the firm disappeared from the Directory. Given the lack of further information, it was assumed that if a firm disappeared from the Jewellery Quarter, it was, for the purpose of this study, ‘dead’. The reason for this is that the authors are interested in analysing the evolution of the production activities within the area as an organizational form, i.e. a community of populations. A firm’s survival corresponds to the presence of the same firm (same address—same name—same activity or same name—same activity—change of address still within the Quarter) year after year.

THE DECLINE OF A MARSHALLIAN INDUSTRIAL DISTRICT: THE BIRMINGHAM JEWELLERY QUARTER

This section presents the results of the application of the HEDRON methodology to the Birmingham Jewellery Quarter by carrying out historical, economic, industrial, demographic and ecological analyses of its evolution from 1880 to present.

The historical analysis

Jewellery craftsmanship in Birmingham can be recorded as early as 1308 (Mason, 1998), but the first agglomeration of jewellers emerged around 1750–70 in the Newhall and the Colmore Estates. In the 18th century the Jewellery Quarter went through its pre-district stage thanks to the skilled labour made available from the declining buckle, toys and button trades. Important landmarks in the establishment of the Quarter were the opening in 1766 of Soho Manufactory in Soho by Matthew Boulton as the first large factory in Birmingham; in 1773, the establishment of the Birmingham Assay Office for silver goods only; and in 1794 the setting up of the Birmingham Mint.

Until 1800 the Birmingham Jewellery Quarter was an emerging agglomeration of jewellers with production activities not yet clearly identified and integrated (a pre-district stage).

Gold and silver discoveries, as well as technological change, contributed to its growth throughout the 1800s, so that by 1860 the Jewellery Quarter was a fully formed Marshallian industrial district. Not only was it a district at the time of Marshall’s writing (Marshall, 1895), but also its production organization and social context were intertwined and structured like Marshall’s industrial districts. The Jewellery Quarter was, in fact, an agglomeration of small firms specialized in the jewellery industry; production was segmented but perfectly integrated along production stages. The combination of an external division of labour with specialization generated external economies that resulted in innovation and learning. In addition, production activities were imbued in a thick social environment given by the presence of a living population, strong personal and social relationships, and the existence of political, social and production-related institutions.

From 1880 to 1920 the Quarter experienced a consistent period of expansion, which was abruptly interrupted by the First World War when most of the jewellers turned to manufacturing munitions or went into the Army. In this period, although the jewellery trade remained mostly craft based, some manufacturing activities such as electroplating and stamping forced firms to grow in size due to the increasing use of mechanization associated with mass production and standardization (Hopkins, 2001), as well as the introduction of gas-powered machinery (Allen, 1929). These larger factories included the Argent Centre, Bates & Fallows, and Elkington, which, for instance, in 1887 had about 2000 employees. Over this period, production activities in the Birmingham Jewellery Quarter also started to diversify as new branches of trade were introduced such as silver decorated objects, ornamental medals, cups, sport-related articles, shields, as well as jewellery decorated with diamond and other precious stones. The expansion and the multiplication of jewellery activities coincided with the search for workshop premises. So, if until then there was an overlap between living and working communities, by the early 20th century space was reallocated from residential to trading purposes, so that the Quarter became mainly a business area (see 1).

Between 1880 and 1910 a process of institutional thickening also took place: in 1887 the Birmingham Jewellers and Silversmiths Association was set up; in 1880 the School of Art was opened, followed in 1890 by the Jewellery School, and in 1901 the Vittoria School of Jewellery and Silversmiths, finally in 1908—09 the University of Birmingham began to organize a course on jewellery management.

In 1911 employment reached its maximum with more than 30 000 workers. The First World War stalled its growth. After the War the jewellery trade resumed its activities, but the recessions of the 1920s and 1930s, and, shortly after, the Second World War hit the Quarter so badly that it never really recovered.
## Measuring the Decline of a Marshallian Industrial District

Source: based on De Propris and Lazzeretti (2007).
The historical analysis would seem to suggest that by 1920 the Quarter was a mature and dynamic industrial district, aware of being a complex and efficient production system whereby shared benefits could be reaped by collective actions as the process of institutional thickening around the industry demonstrates.

The economic and industrial analyses

Drawing on the information gathered in the database, it is found that the Birmingham Jewellery Quarter has been an agglomeration of firms, artisans and workshops specialized in jewellery-related activities. A total of 357 task specializations were found overall, each corresponding to a stage in the production process and to a firm/craftsman. Smith (1989) refers to the external division of labour in the Quarter as firms being:

effectively linked by a human conveyor belt which carried small but valuable articles from one workshop to another around nearby streets and within factories.

(p. 96)

Lazzaretti and Storai (2003) argue that specialization variety is evidence of the maturity for a local production system; therefore, the highly segmented division of labour especially for the manufacturing and hand-craft tasks is proof of the Jewellery Quarter's maturity at the time (for an historical comment, see Gledhill, 1988).

In particular, from the historical records gathered in the database, the production chain or filière of the jewellery trade was reconstructed, which is summarized in Fig. 4. The main production stages are: tools; raw materials; jewellery manufacturing (including goldsmithing, silversmithing, electroplating, gilting and non-jewellery manufacturing); first, second and third processing stages; and sales and retail. Some categories contain several specializations. The arrows in Fig. 4 help to identify the direction of the production links between stages.

Tool manufacturing and the supply of raw materials feed into the first processing stage, whose output is then passed onto jewellery manufacturing. Jewellery manufacturing is also linked to production services and the second processing stage. The former supplies manufacturers with non-jewellery services such as boxes and design, while the latter provides extremely specialized hand skills that jewellery manufacturers contract out. The final stage of production before sales and retail is the third processing stage which includes skills that are at the very end of the jewellery production process, such as polishing and engraving.

In order to apply the organizational ecology model, the 357 specializations have been translated into

Source: Based on De Propris and Lazzaretti (2007)
populations. The evident difficulty in tracing their individual evolution has been overcome by the definition of multi-populations as meaningful groups of populations. In particular, five multi-populations are identified on the basis of the production stages just described: raw materials and tools; jewellery manufacturing; processing manufacturing; service providers; and sales and retailing (Fig. 5).

The largest multi-population is ‘processing manufacturing’, followed by ‘jewellery manufacturing’ (as it will be shown below, these are actually the core populations that have survived throughout the evolution of the Jewellery Quarter).

Demographic analysis

The main steps of a demographic analysis are the calculation of firms’ births and deaths, and firm total density first at the community level (in this case at the level of the industrial district, the Birmingham Jewellery Quarter), and then at the multi-population level. This enables one to measure the evolution of the district in terms of its structure and size. This is the first step in a rigorous analysis of the district’s life cycle and it therefore integrates and expands on the historical and economic analysis already presented.

The Birmingham Jewellery Quarter’s firm density measures the number of firms \( N_t \) actually operating in the Quarter each year. It is calculated as the sum of firm density \( N_{t-1} \) at \( t-1 \) and the difference between firms’ births \( B_t \) and deaths \( D_t \) at time \( t \), as described below:

\[
N_t = N_{t-1} + (B_t - D_t) \quad \text{with} \quad t = 1881, 1882, \ldots, 1973
\]

In particular, to calculate firm density in 1885, for instance, the firm density in 1884 needs to be calculated, to which is then added the difference between firms’ births and deaths in 1885 (Fig. 7).

As expected, firms’ birth rates are very high in 1880–81 as this is the beginning of the database. Nevertheless, the high birth rate in the early 1880s is in line with the historical analysis that found that the Jewellery Quarter was well established and at its zenith. From...

**Fig. 5. Multi-populations**

Note: Numbers in the boxes for each multi-population correspond to the number of populations, i.e. specializations, in each of them. Source: Authors’ calculation drawing on the database
1890 to the First World War the internal dynamics of the district show signs of ‘vitality’, as the fluctuations of the birth and death rates show. As deaths outnumber births, firm density drops between 1915 and 1919 (First World War). In fact, firms’ deaths peak in 1915 without a corresponding number of births. This period is followed by a period of great recovery as firm density increases by 20%. Indeed, in 1923 the number of firms peaks with 1691 firms. Between the two World Wars the recovery is dampened by the 1929 crisis as firm density decreases over time and, at the same time, fluctuations in deaths and births peter out. After the First World War, the district moved from its consolidation phase to a phase of decline that the limited recovery in the 1920s could not stop, as shown by the steady drop in firm density. The Second World War again shakes the district and firm density plummets. The small recovery in the period 1945–48 (in this period firm births outnumber firm deaths) does not take the district back to the size it had in the 1920s and the continuous decline of firm density thereafter validates the hypothesis that it was in continuous ‘free fall’. In 1973 there are only 494 firms against 1650 in 1881 (Fig. 7).

For the multi-population analysis, firms’ births and deaths for each of these five multi-populations were computed and density functions were drawn. In order to calculate the density of each multi-population, the following formula is used:

\[ N_{tj} = N_{t-1j} + (B_{tj} - D_{tj}) \]

where \( t \) is years; and \( j = 1, \ldots, 5 \) multi-populations.

Fig. 8 summarizes the evolution of the shares of the five multi-populations, providing a picture of the

*Source: DE PROPRIS and LAZZERETTI (2007)*
composition of activities. It is worth noticing that the two major groups over the entire period remain ‘process manufacturing’ and ‘jewellery manufacturing’. It must be noted that these include all the key manufacturing stages of the external division of labour through which semi-finished and finished goods pass. This is evidence that throughout the period of study the Quarter has remained heavily manufacturing and handcraft-based as a traditional Marshallian industrial district. The other three groups look small in size, especially the ‘sales and retail’ and ‘raw materials and tools’. This is not a surprise given that the historical analysis has shown that, for instance, shops started opening only in the 1970s.

The trend of each individual multi-population is shown in Figs 9–13. From these it emerges that the number of firms in the ‘jewellery manufacturing’, ‘service providers’ and ‘process manufacturing’ categories shows signs of a slow decline over the entire period with visible dips for the two World Wars. On the other hand, the trend of the ‘sales and retail’ category is the only one that has increased after the Second World War and remained high in the post-War period.

The ecological analysis

The fifth section finds that the firm density curve for the Birmingham Jewellery Quarter is non-monotonic and inversely ‘U’-shaped (Fig. 7). Given that this is a necessary condition for the ecological analysis to be applied, it is possible to proceed to the ecological analysis.

The contribution of ecological modelling is to measure the life cycle of the industrial district by means of a density dependence model. A methodology to study social or economic events is the event history analysis. In particular, event history analysis uses different

methodologies according to the kind of event being studied. When analysing firm foundings, the most frequently models are those that consider recurring events as outcomes of stochastic processes. As a consequence, the cumulative number of events observed up to a certain point in time $t$ is assumed to be a non-decreasing stochastic process (Allison, 1988).

Firm births are considered discrete events, therefore the stochastic process – and the underlying distribution of probability – must be discrete. In particular, Poisson processes are used (Hannan and Freeman, 1989; Lomi and Levie, 1995). A Poisson process assumes that the rate of arrival is independent of the history of previous arrivals and from the current state of the system. Among other things, this assumption implies that the order of events does not affect the arrival rate. If the rate at which new organizations are born in a population follows a Poisson process, then the rate is a time-independent constant. Since the number of births per year is known, the model of the founding rate is based on a simple Poisson model:

$$
\lambda(t) = \exp(\theta_1 N_t + \theta_2 N_t^2 + \delta_{1B-1} + \delta_{2D}) \exp(\Sigma \phi_i X_i)
$$

where $\lambda(t)$ is the multiplier of the founding rate; the two orders of density are represented by $N_t$ and $N_t^2$; $X_i$ is the vector of covariates; and the vector of parameters $\phi_i$ corresponds to the period variables. Finally, introduced into the model are firms’ births at $t - 1$ ($B_{t - 1}$) and firms’ deaths ($D_t$) in order to ascertain how they influence the density rate over the period.

The model

Table 2 reports the maximum likelihood estimates of the Poisson model of density dependence for firms’ foundings in the Jewellery Quarter. All parameters are significant and in line with the hypothesis, except for model (1) where the parameter of the second-order effects (density $^2$) is positive.

Model (1) estimates first- (density) and second- (density $^2$) order effects of density. Model (2) includes also lagged births ($birth_{t-1}$). Model (3) also analyses the second-order effect of lagged births ($birth_{t-1}^2$). Model (4) also considers lagged deaths ($death_{t-1}$). Model (5) contains all the previous variables and it also adds period effects, allowing the study of different probabilities of births with respect to the period 1956–70 which is omitted in the model.

According to the present hypothesis, the first-order effect of density (density) is significant and positive in all models and the second-order effect (density $^2$) is significant and negative in all models except for Model (1): this confirms the inversely ‘U’-shape of the birth rate (Fig. 1). The first-order parameter associated with lagged births ($birth_{t-1}$) is positive and the second-order parameter ($birth_{t-1}^2$) is negative. Lagged births are therefore also found to be inversely ‘U’-shaped since the effect of the competition process prevails on the legitimation process in determining firms’ births. The parameters of firm deaths ($death_{t-1}$) are significant and negative as expected.

The analysis of firms’ births has focused on two aspects. Firstly, the maximum value of the multiplier of the entry rate ($\lambda$) shows the maximum level of the relative strength of legitimation and competition processes. A high value of $\lambda$ implies that the density effect on legitimation is relatively strong compared with that of competition. As evidence of this, the multiplier of the rate calculated for its maximum and minimum value of density observed is reported: $\lambda(N_{\text{max}})$ and $\lambda(N_{\text{min}})$.

Table 3 presents the main quantitative implications of the effects of density on founding rates. The first two columns show the range of density of models (4) and (5) over the period 1881–1973. The minimum
density \((N_{\text{min}})\) is 523 in 1973, while the maximum density \((N_{\text{max}})\) is 1689 in 1881 as the density curve is over the whole period decreasing. Column 3 reports the estimates for the multiplier of the founding rate when it reaches its maximum value \((\lambda^*/C_3)\), while columns 4 and 5 contain the estimates for the multiplier computed at the maximum \(l\) \((N_{\text{max}})\) and minimum \(l\) \((N_{\text{min}})\) observed population density. Column 6 shows the year when the density is at its maximum and column 7 shows the year when density is at its minimum. Columns 8 and 9 estimate the effect of density dependence legitimation and competition processes.

Table 3 shows the multiplier of the founding rates of models (4) and (5) for the Birmingham Jewellery Quarter. In both models, the organizational founding rate reaches its maximum when population density is close to 1 and, from there, it decreases because of null legitimation processes \((\lambda^*\text{ is around 1})\). At the maximum density in 1881 (1689 firms), the founding rate tends to zero \((\lambda(N_{\text{max}}))\) because of competition processes. In both models the hypotheses about density parameters are confirmed, but the second-order effects dominate the first-order effects over the entire range of density, therefore the multiplier of the founding rate curve is an inversely ‘U’-shaped as it declines immediately as the competition process prevails on the legitimation one.

To summarize, Fig. 14 delivers a very important result for the study of the decline of the Jewellery Quarter in that is it shows that at the staring point of the analysis (it is worth remembering that the start date was decided on the basis of data availability) it had passed its growth phase, it had reached its zenith and maturity, and was starting to decline. According to the density dependence approach this means that in 1880 the Quarter, as an organizational form (as a community of populations), was probably at its carrying capacity, since competition processes started to replace legitimation processes. In other words, as firms’ births increase the community total density decreases.

Source: Authors’ calculation.
CONCLUSION: FROM INDUSTRIAL DISTRICT TO URBAN CREATIVE DISTRICT

This paper has presented the findings of a study on the decline of the Birmingham Jewellery Quarter as a Marshallian industrial district. The first key result of the paper is to provide some qualitative and quantitative evidence that the Quarter peaked in its life cycle at the turn of the 20th century, followed by a period of stagnation and more recent contraction.

A second novelty is to present a composite and multidisciplinary methodology that contributes to the debate on the life cycle of local production system by integrating historical and economic analyses with demographic and ecological modelling (HEDRON methodology). This methodological novelty has relevant implications for studies on industrial districts – and of local production systems more generally – as dynamic organizational forms. In fact, not only does it acknowledge that external and internal events shape the historical context that frames the evolutions of such system, but also it appreciates how such events affect the organization of systems in terms of activities and specializations and, ultimately, impact on their overall evolution. In particular, quantitative evidence of the decline of the Birmingham Jewellery Quarter has been provided by means of business demography and organizational ecology.

Drawing on a unique database with more than 11,400 firm recorded, the paper has been able to describe the organization of production in the jewellery industry; to calculate firms’ births and deaths, and firms’ density curves by production activities and for the entire Quarter; and finally to run the ecological model.

The findings are that, in demography terms, firm density in the Jewellery Quarter peaked by the early 1900s and the multiplier of the founding rate decreased thereafter; while, in ecological terms, it can be concluded that the Quarter had by then reached its point of maximum expansion – the so-called carrying capacity. It was unfortunate that data were available only after 1880 because the stages of emergence and growth had taken place before that date.

Since the 1970s, the Jewellery Quarter has experienced a process of slow decline which is evident from employment figures (Fig. 2). On the demand side, this is due to a weakening of its domestic market and an inability to penetrate foreign markets. On the supply side, there has been a breakdown of the internal division of labour as some specializations have disappeared, retailing has expanded, and finally imports of cheaper finished or unfinished goods have replaced internal production and have flooded the domestic market. Nevertheless, the Jewellery Quarter is still a concentration of jewellery and jewellery-related manufacturing and service firms.

Today there is a smaller but still significant manufacturing base, whilst retailing has been steadily expanding. If in 1973 there were fewer than 30 firms in sales and retails (corresponding to less than 5% of the total), a census of activities in the Quarter in 2005 (De Proprising and Wei, 2007) has found that there are 124 firms in retailing-related activities, corresponding to more than 40% of activities overall. The move to increase retailing activities has been accompanied by an effort to target high-value-added segments of demand with designers’ jewellery, and unique and customized pieces. This is reflected in local policy agencies increasingly recognizing the creative content of jewellery-making and the added value that this can bring to the industry. For instance, Advantage West Midlands has classified the jewellery industry in the Quarter as a high-value-added consumer cluster (also Birmingham and Solihull Economic Forum, 2005; Hall and Welch, 2005) and recognized that design can be central to business success. The shift from manufacturing to design-intensive, creative jewellery would still coincide with some restructuring in the industry but could also offer more hope its long-term sustainability. The authors, therefore, suggest that the decline of the Jewellery Quarter as a Marshallian industrial district is not coinciding with its death, rather with its reshaping and possible renaissance as an urban creative district, whereby differences in the nature of activities are coupled with continuity in the form of socio-production organization.

Acknowledgements – The authors gratefully acknowledge the financial support of the British Academy for the funding of this research (Grant No. SG-33827). The authors would also like to thank David Bailey, Gabi Dei Ottati, Marco Bellandi, Davide Parrilli, and two anonymous referees for useful comments and suggestions. The usual disclaimers apply.

NOTES

1. In 1947 taxes on luxury items like jewellery increased to 145%, remained as high as 75% in the 1950s, to be abolished only in 1973 when value added tax (VAT) was introduced (Mason, 1998).
2. Organizational populations could correspond, for instance, to sectors as defined by the standard SIC classification. For the Birmingham Jewellery Quarter, one could not rely on such a structured classification of economic activities; service and production activities, therefore, had to be grouped according to their role along the value chain.

3. If the density curve is not non-monotonic, some descriptive statistics (univariate, bivariate, multivariate, spatial, etc.) can be carried out in order to support the qualitative study of the phenomenon.

5. Data were not available for the following years: 1885, 1887, 1889, 1891, 1893, 1909, 1920, 1928, 1949, 1951, 1955, 1959, 1961 and 1962. When computing the density, these gaps have been filled by estimating proxies; it is standard procedure to calculate proxy values for each firm as the average between the density of the year before and the year after the gap. The following formula is applied:

\[ \text{Density}_z = \frac{\text{density}_{z-1} + \text{density}_{z+1}}{2} \]

where \( z \) is a missing year.

6. There is little information about how data were collected, but it is well accepted that the most likely way was for publishers to have had people who physically walked around the streets of Birmingham and stopped at every shop or household asking for names and types of economic activity/trade or looking at name plates.

In this way, data and information were gathered every year and then published in a Directory. Each Directory classified economic activities by street, name and trade.

7. For the history of the Birmingham Assay Office, see Ryland (1866) and Gledhill (1988).

8. For more information of the evolution of the Birmingham Jewellery Quarter, see De Propris and Lazzeretti (2007).

9. For more information, see Horton (1908) and Smith (2003).

10. Previous contributions that have described the organization of production in the Birmingham Jewellery Quarter include Roche (1927), Sargent Florence (1948) and Gilbert (1972).

11. This number is the sum of all firms in 1880 and the number of firms that were born between 1880 and 1973.

12. Firms’ births are considered as discrete events since they are computed at \( t_1, t_2, t_3, \) etc. usually corresponding to years, rather than as continuous events, because this would require the exact day, month and year of birth.

13. The most frequently used model to represent these relationships is the log-quadratic approximation (Hannan and Freeman, 1989; Hannan and Carroll, 1992). The log-quadratic approximation applied to the founding rates has the form:

\[ \lambda(t) = \frac{L_t}{C_t} = \frac{N_t}{\theta_1 N_t + \theta_2 N_t^2} \]

with hypotheses: \( H_1: \theta_1 > 0; \) and \( H_2: \theta_2 < 0. \) \( L_t \) captures the legitimation process; and \( C_t \) captures the competition process. This means that the effect of density due to \( N_t \), namely the first-order derivative of density, is positive but less than 1; whereas the second-order derivative due to \( N_t^2 \) is negative. The relationship is non-monotonic and has the form of an inverse ‘U’-shape with a maximum at:

\[ N_t^* = -\theta_1/2\theta_2 \]

Other models to represent these relationships are the generalized Yule models (GY) and the log-quadratic approximation model. However, some authors have demonstrated how these latter models do not always offer convergent estimates (Hannan and Freeman, 1989; Hannan and Carroll, 1992). In case the Poison distribution model does not adequately fit the model (because it does not pick up the tendency of the founding rate to vary faster than its average – over-dispersion), the negative binomial model might fit the relation better. Nevertheless, a valuation of the variance of the estimated of the Poison regression does not reveal high levels of over-dispersion.

14. Period variables have been computed as dummy variables each covering 15 years: 1881–95, 1896–1910, 1911–25, 1926–40, 1941–55 and 1956–70.

15. In density dependence models it is often the case that populations’ characteristics are considered as independent variables. In particular, when analysing firm birth in a population, it is reasonable to verify whether the firms’ founding rate at time \( t \) is correlated with the lagged variable at \( t - 1 \). A large wave of firm births at time \( t \) can increase the founding rate due to imitation processes, but at the same time, it can hinder the birth of new firms due to the depletion of resources that competition processes have put in motion. Again, the firm founding rate can be drawn as an inverse ‘U’-shape (Delacroix and Carroll, 1983).

16. To calculate the multiplier of the founding rate, the two parameters of the density setting equal to zero the covariates are considered. This is given by the ratio of the value of density function over the value the density function takes at \( N_{\text{min}} \).
