

Farmers have to make hard choices between protecting soil from erosion and controlling weeds. For example, large-scale farming relies heavily on tillage. Tilling breaks up the soil to kill weeds and prepare for planting. But intense tillage can compact soil, cause erosion, and deplete nutrients. As a result, some farmers are turning to cover crops for weed control.

Cover crops are planted after harvest as an in-between crop. Cover crops improve the soil with living roots that protect it from erosion and add nutrients. Cover crops are usually plowed down, but another option is flattening the cover crop to form a thick carpet, or mat. This is done with a roller crimper.

The farmer then uses a no-till planter to plant seeds into the flattened mat for the next season. The new crop grows through the cover crop residue, which helps suppress weeds.

This method - called cover crop-based rotational no-till - allows farmers to skip spring tillage and weeding. By simply flattening a cover crop, farmers don't have to disturb the soil for a new crop. The flattened cover crop suppresses weeds and retains soil moisture.

However, like many farming practices, this method has trade-offs. For example, if you flatten it too late, the cover crop might produce seeds. The result is a volunteer, or weedy, cover crop competing with next season's cash crop. And if you flatten the cover crop too early, it may regrow.

It's all in the timing, says crop scientist Clair Keene who is a researcher at The Pennsylvania State University. Keene and her colleagues wanted to find that perfect timing. So they planted an experiment in three different states: Delaware, Maryland, and Pennsylvania. For three years, they planted cover crops like hairy vetch-triticale and cereal rye, followed by cash crops like corn and soybeans.

The researchers flattened the cover crops at different stages of growth to find the right combination. Was it possible to have a cover crop that was big enough to suppress weeds, but not too big that it produced seeds?

They found that generally, letting the cover crop grow longer produces the best, if not perfect, results.

"There's always trade-offs," said Keene. "A bigger cover crop is better at suppressing weeds as a mulch, but that comes with the cost of letting that crop grow longer, restricting the growing season for the corn or soybean."

Farmers want to plant their cash crop as early as possible, especially in northern states. If the cover crop is too small to be flattened, then they have to till it under, which defeats the purpose of improving soil quality. But if a cover crop reigns in a field for too long, it might start to produce seeds.

Every cover crop is a little different. For instance, the group found that cereal rye needs to be rolled in the middle of grain fill so that it doesn't produce seed and show up when it isn't wanted. And although hairy vetch is great at adding nitrogen to the soil, it can survive the roller crimper and compete with cash crops.

The researchers also found rolling the cover crops twice instead of once helped ensure the cover crops were killed.

Despite the tricky timing, Keene says rolling cover crops to form a mat has a lot of potential. Without it, "you'd have to plow the field multiple times, harrow it, plant it, and do a lot of weeding," she warns. "That's a lot of time in the tractor and a lot of diesel fuel."
