This abstract is under embargo until September 25 at 08:15 Eastern Time.
Lung cancer therapy has been transformed in recent years, especially for patients with advanced stage non-small cell lung cancer (NSCLC). Our understanding of the molecular landscape of different NSCLC types has been enhanced by pathological investigation and molecular analysis of tumours, in turn driving and refining tumour classification. Biological features have become targets of therapy. Established therapeutic approaches of surgery, radiotherapy and chemotherapy still prevail, but their usage has been refined by a better understanding of pathology.

New treatment approaches include the inhibition of receptor kinases and therapies which enable an existing but constrained immune response to attack the tumour. All of this progress has been driven by research conducted on tumour tissue. In the lung there are (at least) two pathways of carcinogenesis, involving transformation within two different stem cell populations in the bronchial and peripheral terminal respiratory unit (TRU) epithelium respectively. Our understanding of pre-neoplasia and its morphological progression has informed ideas about adenocarcinogenesis in particular, and improved radiological diagnosis of early lung cancer, and impacted lung cancer screening. These concepts also underpinned understanding of the pathology of squamous cell carcinoma, and adenocarcinoma, and tumours allied to these sub-genus, and drove changes in the 2015 WHO classification of lung cancer. In 2008, the JMDB trial demonstrated superiority of pemetrexed/platinum in advanced ‘de facto’ adenocarcinomas, rather than squamous cell carcinoma, making accurate subtyping of NSCLC an issue for the pathologist.

Differences in immunohistochemical profiles of lineage markers reflecting tumour origin from bronchial or TRU epithelium became a method of predicting NSCLC subtype when morphology was insufficient to reach diagnostic features in practice recommendations, and is now standard of care. All of this progress has been driven by research conducted on tumour tissue. The use of tyrosine kinase inhibitors in mutant EGFR oncogene-addicted adenocarcinomas was the first major step in the expansion of personalisation, precision medicine in the treatment of advanced NSCLC. Targeting ALK fusion gene proteins followed soon after, when it was recognised that ALK tyrosine kinase inhibitors were effective in treating adenocarcinomas bearing an ALK gene rearrangement identified by FISH analysis or multiple PCR testing to demonstrate abnormal mRNA fusion gene products. Then came the realization that these molecular events were associated with a modest elevation in tumour cell ALK protein, which is the oncological effector driving the tumour, and which is also the target of the drugs. The presence of the protein is associated with, and probably required for, efficacy of these drugs. The same scenario is now unfolding for ROS1 gene rearrangement, its protein product and the use of ROS1 tyrosine kinase inhibitors. BRAF V600 mutation are the latest genetic alterations to be regarded, as a management tool in advanced NSCLC due to the efficacy of BRAF kinase inhibitors.

Other targets in a predominantly non-squamous cell carcinoma patient population remain on the ‘waiting list’ and these may become mandatory pending trial data convincing for efficacy, and approval by appropriate regulatory authorities. The alterations, which have inhibitors targeting kinase activity include MET exon 14 skipping mutations, high levels of MET amplification, RET and NTRK gene rearrangements, and HER2 gene mutations. Some of these alterations represent extremely rare genomic drivers but still represent sufficient patient numbers to justify their investigation. Squamous cell carcinoma presents a rather different scenario. The dominance of tobacco carcinogenesis in this cell type means oncogenic addictive drivers are exceptionally unusual. Most squamous cell carcinomas have a complex genome, exhibiting many mutations, many of which cause loss-of-function in tumour suppressor genes, an unpromising situation for therapeutic intervention. All of this progress has been driven by research conducted on tumour tissue and fundamentally, the identification of the trial biomarker data and clinical detection if these genomic alterations is based upon detection in tumour tissue samples. Immunotherapy, particular the use of anti-PD1 and anti-PD-L1 agents, has had a major impact on standard of care treatment in advanced stage NSCLC, and biomarker testing to enrich treatment populations for optimal benefit has had a major impact on pathological diagnosis. The principle clinical trial-validated and approved biomarker for these drugs is PD-L1 immunohistochemistry (IHC). Whilst the testing algorithms for the approved drugs, or those drugs in advanced stage of validation, will need to be standardized, consider PD-L1 expression in tumour cells, the algorithm for atezolizumab also includes expression on tumour-infiltrating immune cells. Other assessments of the tumour microenvironment and tumour inflammation are poorly developed in context of immunotherapy biomarker assessment at present but there is plenty of scope for pursuing this in the future. A little data exists for NSCLC using mRNA immune gene expression signatures but there is almost nothing based upon morphological assessment of tumour inflammation. Tumour mutation burden, as a surrogate for neoantigenicity is another emerging biomarker in this arena, and is also capable of enriching for effective response. Once again, the data, majority of the trial data, and all validated clinical biomarker assessment is based upon examination of the tumour tissue. Lung cancer pathology has ‘come of age’ in the last 10 years. Of course, pathologists can rightly argue that it always was important and relevant, but it is only in recent years that has such a pivotal role in clinical biomarker assessment to facilitate personalized, precision medicine for patients with NSCLC. More or less everything we know about lung cancer biology comes from pathological analysis of tumour tissue. Although the so-called ‘liquid biopsy’ PD-L1, the attractive source of biomarker data, it cannot provide the detailed, structural (spatial) pathological information about the patients disease, suffers from sensitivity issues which means it does not work for all patients, and is as abstract assessment – it is presumed findings in the blood relate to the patients tumour, but this may not always be so. In the field of immunotherapy is clear that the tumour microenvironment and cellular relationship are set to assume importance. Pathologists need to work to maximize the amount of data that can be derived from the limited tissue samples that we usually have available.

Keywords: tissue diagnosis, biomarkers

It is a standard of care to treat patients with non-small cell lung cancer (NSCLC) harboring driver oncogenes with respective tyrosine kinase inhibitors (TKI). The list of driver genes started with the EGFR gene and now it is further expanding to include ALK, ROS1 and BRAF. Survival of NSCLC patients with EGFR mutations has greatly prolonged since the advent of EGFR-TKI. At the turn of the 21st century, the median survival time of patients with metastatic lung cancer was around 2 year. However, overall survival of patients with EGFR mutation exceeds 3 years and in some studies, it is close to 4 years. However, acquisition of resistance against EGFR-TKI is almost inevitable and it is exceptional to see patients whose disease is controlled for a long period. Detection of mutation of oncogenic tyrosine kinases into lung cancer care was a great progress, it is still on the way from the viewpoint of conquering lung cancer. What is needed for further improving patients’ outcome? Identification of new targets in addition to above-mentioned driver genes to which each targeted therapy is approved by the regulatory authorities, RET, MET, HER2. NTRK1 gene mutations are emerging molecular targets and clinical trials to test each inhibitor for clinical activities are actively conducted. Gene alterations such as KEAP1/ Nrf1 whose mutations are relatively frequent in NSCLC is also sought for possibilities to become a therapeutic target other than receptor tyrosine kinase. Development of strategies to cope with KRAS Although KRAS gene mutation in NSCLC was found nearly 40 years ago and is frequently mutated in NSCLC, especially those occurring Caucasian patients. However despite the fact that KRAS mutation is mutually exclusionary with other driver gene mutations, strategies to treat these lung cancers have been unsatisfactory. For example, recent large-scale, SCLC 21 study failed to show a superiority of chemotherapy for KRAS mutation in NSCLC patients with KRAS mutation. This is partly because not all KRAS mutated cancer cells are fully addicted to mutated KRAS function. Considering the magnitude of the patient population, efficient strategies to treat KRAS lung cancer including the development of small molecules and immunotherapy are eagerly awaited. Development of mutation-specific and wild-type sparing TKI Osimertinib is the first third-generation EGFR-TKIs that is active for both activating EGFR mutations as well as T790M resistant mutations yet sparing wild-type EGFR function. As a result, it showed superior activity over chemotherapy in patients with advanced NSCLC harboring acquired resistance due to T790M. Following this, the Flaura study showed longer PFS compared with gefitinib/erlotinib. OS result is immature but promising. Because of low activity against wild-type EGFR, adverse events are in general less frequent. This will make it easier for this compound to combine with other modality of therapy, although the incidence of interstitial lung disease was high when combined with durvalumab in the Tatton study. In the case of ALK, alecetinib showed promising superiority in intracranial progression in the J-ALEX studies, with better tolerability. These facts clearly indicate that newer drugs that have a higher activity against mutated version but not against wild-type version further prolong patient survival. Development of combination strategies To maximize patients’ benefit, we have to understand the biology of oncogene-driven lung cancer more in detail. When EGFR mutations were initially discovered, NSCLC harboring EGFR mutations were thought to behave similarly in the patients. However, we soon knew that different EGFR mutations may result in different biological/clinical consequences. For example, exon 19 deletion (Del...
19) and L858R are sensitizing mutations, exon 20 insertion mutations are resistant against existing TKIs. Other rarer mutations, so-called uncommon mutations are not that as sensitive as Del19. Furthermore, even though with the same EGFR mutation, lung cancer never behaves same in each patient. There is a great heterogeneity in terms of progression-free survival within patients with the same EGFR mutations when treated with EGFR-TKI. This heterogeneity is now being understood as effects of co-occurring genetic alterations (co-drivers). For example, several investigators found that PFS of patients with EGFR mutation plus TP53 mutation has a shorter PFS than those without. These co-occurring alterations that negatively affect PFS include those of CDK2/4, HER2, TP53. Therefore it is clear that EGFR TKI alone will not be able to achieve long-term disease control, necessitating combination strategy. Recently, NEJ009 trial suggested that carboplatin with pemetrexed followed by pemetrexed maintenance plus gefitinib might prolong overall survival up to over 4 years. This illustrates the importance of chemotherapy as well as EGFR-TKI even for patients with driver gene alterations, probably through inhibition of some activities mediated by co-drivers. **Role of immunotherapy for NSCLC with driver gene mutations** PD-1 blockade by pembrolizumab is a standard of care for NSCLC with high PD-L1 expression except those with driver mutations. This is because PD-1/L1 antibodies could not derive benefit for the patients with EGFR/ALK alterations over docetaxel, resulting in omission of these patients in the first-line trial except in the case of atezolizumab. IMPower 150 study showed the superiority of carboplatin/paclitaxel/bevacizumab(CPB) plus atezolizumab over CPB not only in wild-type patients but in EGFR/ALK+ cohorts after first-line TKI therapy. It is not very clear this is because of combination with chemotherapy or bevacizumab or both at this point, and also the mechanism of this efficacy is not known. This study re-opened the door to immunotherapy for these patients, which was once almost closed, In this talk, I would like to envision what has to be done in the next 10 years to further improve the outcome of the patients with driver gene and ultimately to cure their disease.

**Keywords:** Targeted therapy, driver oncogene, combination therapy
Modern CT scanners are routinely being used to determine the malignancy potential of small sub-centimeter pulmonary nodules. Increasingly, this involves CT scanning and quantitative volume measurement of lung nodules over short time intervals (e.g., 3 or 6 months) to determine whether a change in nodule size consistent with malignant growth has occurred. Although it may appear that current CT scanners are more than capable of reliably performing these quantitative measurements with high quality due to their ability to obtain sub-millimeter resolution lung images, many clinical sites are not taking the steps needed to achieve consistent high quality small lung nodule measurement results. A study of volume measurement performance in a phase II clinical trial between multiple clinical sites using CT scanners which resulted in errors in volume change measurements as high as 43% [1]. In addition, a 2016 crowd-sourcing study of CT scanner image quality performance using the site’s low dose CT lung cancer screening acquisition protocol revealed that 37% of sites used insufficient slice thickness (≤ 1.25mm slice thickness is needed) and only 19% of sites used the needed slice thickness and a reconstruction kernel that avoided excessive smoothing and avoided high levels of edge enhancement [2]. Poor CT image acquisition performance has the potential to result in poor lung nodule volume measurement performance which can negatively impact patient care by contributing to unnecessary biopsies and delays in early lung cancer diagnosis. To address these issues the RSNA’s Quantitative Imaging Biomarkers Alliance (QIBA)® has developed the QIBA Small Lung Nodule Profile that provides a comprehensive set of specifications to ensure that a clinical site attains a minimum level of quantitative imaging performance necessary to achieve a specified lung nodule volume measurement accuracy. The Small Lung Nodule Profile consists of six fundamental image quality characteristics that are needed throughout the full scanner field of view to support precise volumetric measurement of small lung nodules. These characteristics are (1) Edge Enhancement, (2) Three-Dimensional Resolution, (3) Resolution Aspect Ratio, (4) CT Linearity, (5) Spatial Warping, and (6) Noise. In general, CT scanners achieve highest fundamental image quality performance at scanner iso-center with some scanners and image acquisition protocols exhibiting large losses in image quality performance as a function of distance from scanner iso-center [3]. These fundamental image quality properties can now be quickly and easily measured by a technologist at any clinical site using a new image quality measurement phantom and fully automated and cloud-based phantom analysis software. To determine the clinical impact of achieved CT image quality performance, a new set of metrics has been developed that can create simulated CT images given the image quality characteristics for a CT scanner and image acquisition protocol [4]. Quantitative measurement software can then be applied to these images resulting in expected measurement performance for a clinical task, such as the bias and precision of solid lung nodule volume change measurement for virtual lung nodules of different sizes. Having these estimates of a CT scanners performance can further be used to one day quantitatively determine the minimum time interval needed in order to be able to distinguish malignant nodule volume growth from a stable lung nodule. Regularly performing these measurements also has the potential to offer numerous advantages to lung cancer screening sites including the ability to determine if scans from two different CT scanner models will produce sufficiently similar image quality and measurement performance. In summary, a new set of phantoms and cloud-based software tools is available that enables more careful control and optimization of CT lung cancer imaging performance based on fundamental image quality properties. These new tools provide several new opportunities for clinical sites to more precisely perform CT lung cancer imaging studies and measurements. ES01 ADVANCES IN LUNG CANCER SCREENING THROUGH IMAGING
MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00

ES01.04 MULTI-PHASIC SCREENING - CAN WE ADDRESS COMPETING CAUSES OF MORBIDITY * MORTALITY SUCH AS CORONARY ARTERY DISEASE AND COPD
R. Vliegenthart
Radiology, Umcg, Groningen/NL

Lung cancer, chronic obstructive pulmonary disease (COPD) and cardiovascular disease (CVD) are highly prevalent in the Western population (annual incidences in the Netherlands: lung cancer n=12,200, COPD n=53,300, and CVD n=101,700). This results in a high burden on the healthcare system and associated costs, with annual costs of 10 billion euros in the Netherlands alone. Furthermore, lung cancer, COPD and CAD are responsible for a high burden of morbidity, with disability adjusted life year reduction of 2.9, 3.4 and 5.0, respectively. For these so-called Big-3 diseases, treatment is most often initiated at late stages due to late diagnosis after development of symptoms. Early detection and treatment will cure many patients in time, and delay or even stop disease progression. Therefore, prevention and early detection are crucial. Currently, no screening is performed for the Big-3. The impact of low-dose computed tomography (CT) lung cancer screening on lung cancer stage shift and reduction of lung cancer mortality has been demonstrated.(1,2) These results have led to recommendations to implement CT screening in high-risk individuals in the USA. Population-based studies have shown the strong relationship between CT-derived extent of CAD and COPD, and mortality, also in lung cancer screening setting.(3-8) However, there is as yet no evidence from randomized controlled trials regarding benefit of CT screening for COPD or CAD. As the high-risk population for the Big-3 is comparable (namely long-term ex-smokers), combining imaging biomarkers will likely improve CT screening efficiency. Technological developments in CT allow the calculation of attenuation of the chest on the CT image, nodule volume, coronary artery calcium score and lung density/bronchial wall thickness with low-dose CT (see Figure). Combined evaluation of early signs of the Big-3 diseases has not been extensively explored yet. Major advantages of integrated Big-3 screening can be anticipated due to shared risk factors (in particular long-term ex-smoking) and the overlap of at-risk population, simultaneous presence of B3 diseases, and the health economic yield compared to a single disease. However, at this moment there is no single CT acquisition that allows for accurate assessment of all Big-3 biomarkers. In particular, calcium scoring based on low-dose chest CT, while providing a good correlation on a population basis, is inaccurate for determining the score on an individual basis.(9) (See below)

Lung cancer remains the leading cause of cancer deaths internationally (1). There have been recent improvements in the early diagnosis of lung cancer, with the implementation of lung cancer screening programs in a number of countries and the addition of targeted therapies, which may improve progression free survival for some patients. However, mortality remains high and people living with a lung cancer diagnosis have some of the highest symptom burden experiencing across all cancer diagnoses (1,2). Patient reported outcome measures (PROs) can be defined as “any report on the status of a patient’s health condition that comes directly from the patient, without interpretation of the patient’s response by another professional” (3). PROs have been systematically included into clinical trials to track side effects and to measure the health related quality of life (HRQOL) of participants. Internationally we are seeing the use of PROs moving into daily clinical practice (4, 5). What are the benefits of using PROs in clinical practice and can they be introduced and embedded into daily practice? PROs can allow patients to highlight to their health care team their current physical and psychosocial issues. In a short clinic appointment with a health care provider the patient may not feel there is time to discuss the most important issues that are affecting them. The health care professional may not ask right questions to understand the key issues for that person at that time in the context of a short clinic appointment. What is an issue for the patient may not be what the health professional perceives is an issue, leading to barriers in providing truly patient centred care and ensuring shared decision making (6). The utilisation of PROs prior to a clinic appointment can facilitate the therapeutic conversation to ensure the main issues for the patient are addressed at that time. The use of PROs recorded directly into the electronic health record can facilitate communication within the health care team through the receipt of notifications about patient symptoms and function. This can facilitate the management of patient’s symptoms in real time, also allowing for the review longitudinal data about patients’ trends over time (7). An RCT into electronic collection of PROs during chemotherapy treatment with automated health care professional e-alerts found the intervention group had better HRQOL, fewer emergency visits and hospitalisations, as well as improved quality-adjusted survival (8). The European Organisation for Research and Treatment of Cancer (EORTC) QLQ-C30 and the Functional Assessment of Cancer Therapy (FACT-G) are two of the most commonly used general PROs. Both of these PROs have lung cancer subscales, with questions developed and validated for the lung cancer population. In New South Wales, Australia the Edmonton Symptom Assessment Scale (ESAS) and the Hospital Anxiety and Depression Scale (HADS) are being piloted for collection electronically into oncology medical information systems across the state as part of the state-wide collection of PROs in all areas of cancer health conditions. Information from these tools will be available for health professionals at the point of care and will also be linked to the NSW Cancer Registry to allow for longitudinal analysis of PROs with specific cancer treatment protocols. The International Consortium for Health Outcomes Measurement (ICHOM) have also developed a lung cancer standard set, and the EORTC Lung Cancer Quality of Life Core Domain Set (EORTC QLQ-LC13) as measures of the degree of health for people with a lung cancer diagnosis (9). With the increasing use of technology, linked e-health records and the understanding of the benefit of the use of PROs in clinical practice cancer centres should be implementing PROs as standard practice in clinical care. This will ensure health care professionals are able to identify and address physical and psychosocial issues for people living with lung cancer at the point of care. References: 1. Breathlessness is a severe symptom that is associated with suffering at end of life. Moderate to severe breathlessness is observed in 20-80% advanced cancer patients, and this symptom is considered as a poor prognostic factor. Currently, opioids (such as morphine) are widely used as first line treatment for reducing the severity of breathlessness in advanced cancer patients. In this session, we will discuss the clinical evidence, involving both efficacy and safety aspects, supporting the routine use of opioids for managing breathlessness.

Keywords: dyspnea, Opioids, breathlessness

This presentation will discuss dyspnoea in lung cancer with a focus on non-pharmacological management strategies. Lung cancer is associated with high disease burden and physical hardship. People with lung cancer experience complex symptoms, which can include dyspnoea, fatigue, cough and pain. In lung cancer, multimorbidity is also common, particularly chronic obstructive pulmonary disease (COPD) which is seen in 40-70% of patients, and itself is also associated with chronic dyspnoea. Dyspnoea is the “subjective experience of breathing discomfort that consists of qualitatively distinct sensations that vary in intensity and vary in their additional emotional and behavioral significance” [1, 2]. It is common in lung cancer, affecting up to 60% of patients. It varies in intensity and is associated with significant unpleasantness [3]. A recent systematic review found that the distress associated with lung cancer is very variable, and there does not appear to be a relationship to disease stage [3]. There are a wide variety of instruments available to measure dyspnoea. It is recommended that assessment includes intensity and sensory quality, distress or unpleasantness, and impact on health-related quality of life [1]. Dyspnoea results in an emotional response and functional consequences [4], including distress and interference with daily activities [5]. Avoidance of triggers, including avoiding physical activity, promotes a vicious cycle of inactivity and functional decline [6]. Whilst the initial focus of managing dyspnoea is to optimise non-pharmacological management of the underlying lung cancer and comorbid conditions, if dyspnoea persists, there are a range of non-pharmacological strategies that can be considered. There is high level evidence that pulmonary rehabilitation reduces dyspnoea in chronic respiratory diseases, particularly COPD and interstitial lung disease [7]. Similarly, in chronic heart failure, cardiac rehabilitation is also effective at reducing dyspnoea [7]. These outpatient-based exercise rehabilitation programs usually run for 6 to 12 weeks in duration, and include aerobic and resistance exercise training, education and behaviour change. They are associated with reduced self-reported dyspnoea, reduced exertional dyspnoea during exercise, and improved exercise tolerance [1]. The mechanisms in which exercise is thought to reduce dyspnoea in these settings is through systemic efficiency, reduced dynamic hyperinflation and reduced sensitivity to dyspnoea. There are a range of other strategies for dyspnoea which have been used in a variety of conditions. For short term relief, there is high level evidence for the use of chest wall vibration or walking aids (such as walking frames) [8]. Other strategies, with lower-level or unclear evidence, include breathing exercises (such as pursed lip breathing, breathing control and inspiratory muscle training), music, hand-held fans and acupuncture [8]. Specifically in lung cancer there is less research regarding non-

ES02.04 MOLECULAR TESTING 101 FOR NURSES
B. Eby-Sandy
University of Pennsylvania Health System, Philadelphia/PA/US

Molecular testing in NSCLC is now a standard of care for newly diagnosed non-squamous NSCLC. There are guidelines detailing the appropriate population in which tests should be offered. Several barriers exist to testing including both medical as well as administrative, making testing rates less than optimal. Several testing platforms exist, and vary internationally. Other challenges for nurses include interpreting the testing results and relaying appropriate information to patients. Also, counseling patients on the value of waiting for results of testing prior to starting therapy can be difficult, and is often performed by the oncology nurse. Utilization of a clinical tissue navigator can make this process more seamless and ensure testing is performed.

ES02.05 STRUCTURED APPROACH FOR DEVELOPING AND IMPLEMENTING AND ADVANCED PRACTICE NURSING ROLE IN LUNG CANCER
A. Seraina1, S. Peters2, M. Elcher1
1Faculty of Biology and Medicine, University of Lausanne, Institute of Higher Education and Research in Healthcare, Lausanne/CH, 2Department of Oncology, Lausanne University Hospital, Lausanne/CH

Background: Lung cancer patients experience significant physical symptoms, psychological distress and have many supportive care needs impacting their quality of life. In recognition of the complex health needs of patients with lung cancer and the European Partnership for Action Against Cancer recommendations for advanced practice nurses within lung cancer, the University Hospital of Lausanne (CHUV) (Switzerland) aimed to integrate an Advanced Practice Nurse in Lung Cancer (APNLC) within the specialized Multidisciplinary Team (MDT) of the Thoracic Cancer Center. To date, there are limited data available on the effectiveness of APNLCs for improving lung cancer patient outcomes. Introducing a new Advanced Practice Nursing (APN) role is a complex process and the full integration of this role depends on both successful role development and implementation. International guidance for APNLC roles recommends conducting research to assess the feasibility and acceptability of novel APN roles prior to formally assessing the effectiveness of these roles for patients, providers and organizations. This study aimed to 1) develop and implement an APNLC role within the context of the CHUV Thoracic Cancer Center, 2) evaluate the acceptability of the APNLC role from the perspectives of a MDT and patients cared for by the APNLC, 3) assess the feasibility of the APNLC consultations and the ability to collect patient-reported outcome measures (PROMs) during first-line treatment, 4) describe changes in self-efficacy for managing lung cancer-related symptoms, symptom intensity/burden and unmet supportive care needs of APNLC patients during first-line treatment. Methods: To develop and implement the APNLC role we employed the first 7 phases of the “The Participatory, Evidence-based, Patient-focused process for APN role development, implementation, and evaluation” (PEPPA framework). Focus groups were conducted with nurses (n=5 nurses) and physicians (n=6 physicians) to explore the acceptability of the APNLC role. Additionally, semi-structured interviews were conducted with lung cancer patients (n=4 patients) and the APNLC. The others aims were addressed using a convenience sample of newly diagnosed lung cancer patients receiving systemic therapy with/without radiotherapy. In order to assess the feasibility of the APNLC consultations and the ability to collect PROMs, an exact single-stage phase II design was applied. The study was considered as feasible if at least 55% of patients received all the scheduled APNLC-led consultations and completed PROMs assessments at the three time points (Baseline, T1 (between day 4-50) and T2 (between day 71-95)). Descriptive statistics were used to summarize the data and mixed effect models was applied to explore changes in perceived self-efficacy for managing lung cancer-related symptoms, symptom intensity/burden and unmet supportive care needs during first-line treatment. Results: Following the first seven phases of the PEPPA framework, the role was designed based on consensus of key stakeholders within the MDT. The APNLC role focused on providing psychological support, enhancing symptom self-management as well as providing therapeutic education and information about disease/treatments to patients and their carers. The APNLC role is also tasked with facilitating communication and information exchange within the MDT to improve collaboration and promote continuity of care. The designed APNLC-led intervention included four systematic, alternate face-to-face/telephone consultations with lung cancer patients during first-line treatment. Three main themes emerged describing the acceptability of the APNLC role: “role identification”, “role-specific contributions” and “providing flexible service”. Physicians and patients alike clearly recognized the APNLC role and emphasized the contribution to continuity of care, providing psycho-social support and enabling symptom self-management. Oncology nurses within the MDT perceived the APNLC role as overlapping with their own role and they expressed concern about losing part of their traditional role. Flexibility regarding care was seen as an advantage of the APNLC role, while proposed organizational challenges related to work-load. Among the 46 patients enrolled in the feasibility study, 35 met the feasibility criteria receiving the four APNLC consultations (76%, 95% CI: 0.61-0.87) and 26 completed PROMs assessments at the three time points (56%, 95% CI: 0.41-0.71). These initial findings were promising for the feasibility of APNLC consultations and the ability to collect PROMs during first-line treatment. Longitudinal analysis of patient outcomes showed a trend towards improved patient self-efficacy for managing symptoms between baseline and T1, which remained stable at T2. The intensity of predominant symptoms increased over time yet unmet information needs decreased significantly between baseline and T2 (OR = 0.15 [95% CI: 0.03-0.68] p<0.01). Discussion/Conclusions: For the first time in Switzerland, we describe the development process of an APNLC role within a multidisciplinary thoracic cancer center. Findings highlight the applicability and the utility of the PEPPA framework as a structured approach for developing and implementing new APNLC roles. In particular, in the context of the Swiss healthcare system, many APN roles are yet in early stages of development. Barriers identified during the implementation of the APNLC role were primarily related to intra-professional rather than inter-professional factors. In light of these observations of intra-professional tension, study results underscore the importance of developing a national definition of APN role and regulations guiding APN roles to support their expansion in the country and enhance acceptability of these roles. Initial results were promising in terms of feasibility suggesting that APNLC-led consultations were appropriate and perceived as beneficial for many patients. Indeed, implementation of the APNLC role in the MDT seems to contribute to the improvement and maintenance of patient’s perceived self-efficacy for managing symptoms.
and decreased unmet supportive care needs. However, to better support lung cancer patients in their symptoms self-management and decrease their symptom burden, findings of this research point to adjustments that could be made to improve the effectiveness of the APNLC role. First, we propose to adjust the dose of APNLC intervention by increasing the frequency and intensity of consultations. Second, we propose to develop an interdisciplinary approach involving joint APNLC-physicians consultations for managing complex lung cancer patients.

ES03.03 WHEN TO REPEAT PLEURAL BIOPSY
C. Labbe
Institut Universitaire de Cardiologie Et De Pneumologie de Quebec, Division of Respirology and Thoracic Surgery, Quebec/CA

Malignant pleural mesothelioma (MPM) is a relatively rare and aggressive neoplasm arising from mesothelial cells. Clinical suspicion for MPM may arise in the setting of respiratory symptoms in the context of pleural thickening or an effusion on chest imaging and a history of asbestos exposure. Cytological features in effusions may permit a diagnosis of malignancy but reported sensitivities vary widely. Pleural biopsies are often necessary if a pleural effusion remains undiagnosed after radiological imaging and pleural fluid analysis. Guidelines for potential ways to diagnose MPM and indications for each of the techniques available (closed pleural biopsy, image-guided cutting needle biopsy, thoracoscopic pleural biopsy) will be reviewed here.

ES03.04 ROLE OF CHEMOTHERAPY IN MESOTHELIOMA WITH MINIMAL BULK DISEASE
C. Lee
BC Cancer, Surrey/BC/CA

Combination chemotherapy is a standard treatment option in management of fit individuals with malignant pleural mesothelioma (MPM) (1). Along with a survival benefit, it is associated with improvements in quality of life. These advantages are in spite of the typical acute side effects experienced with platinum-based regimens. However, the severity of disease-related symptoms relative to a patient’s age and comorbid conditions often affect performance status and suitability for chemotherapy. A formal definition of minimal bulk disease has not been established, but descriptions in the literature generally correspond to tumour limited to the pleura. In the latest edition of the AJCC/UICC Staging Handbook. Also implicit in the concept of minimal bulk is pleural thickening that is not bulky, which has been referred to as being less than 10 mm, although a cutoff of 13 mm would be reasonable to adopt based on the revision of the TNM classification (2). Not included in any description of bulk is the size of pleural effusion, if present. Pleural thickening at presentation is less than 10 mm in half of all cases, but one-third have effusions considered moderate or large (3). Categorization as minimal bulk disease gives no indication as to the severity of disease-related symptoms. At diagnosis, the majority with MPM have pleural thickening on CT imaging, as well as pleural effusion, accounting for the most common presenting complaints of chest pain and shortness of breath. Constitutional symptoms such as fatigue and weight loss are indicative of rapidly progressive or more advanced disease. The immediate concern in the majority of patients is implementation of active symptom control: pharmacologic and non-pharmacologic measures for managing chest pain; and thoracoscopy with poudrage or insertion of an indwelling pleural catheter to deal with symptomatic effusions. The effectiveness of these strategies is highlighted in current practice guidelines (1,4). As much as chemotherapy may be of benefit in palliating symptoms such as pain, there is less confidence in its ability to manage pleural effusions. The application of active symptom control strategies addresses the primary pain needs of the patient, but also facilitates delivery of chemotherapy, if not increase the number of patients suitable for it. For the individual patient with MPM, establishing goals of care is essential to good decision-making. If the main aim is to improve the chance of long-term survival, the bulk of disease may not be relevant to the decision to go ahead with chemotherapy. For others, the preference may be to forego chemotherapy and its side effects, and focus on supportive and palliative measures. In those who are asymptomatic, or whose disease-related symptoms are well controlled, close observation and deferral of chemotherapy is a consideration. There are disadvantages to waiting for symptomatic progression before planning chemotherapy, as early treatment may prolong the time to symptom deterioration and may be associated with a survival benefit (5). Several factors that differ between these two groups are probably due to a proportion of those opting to wait never receiving chemotherapy because of a sudden decline in performance status or coming to a personal decision to decline treatment. Deferring chemotherapy may be more appropriate in select cases, such as asymptomatic patients with minimal bulk histology, where there is an expectation that the disease course could be relatively indolent (1). The aggressive behaviour of MPM in those with elements of...
There are increasing number of patients with early malignant pleural mesothelioma (MPM) in Japan. Some part of such early MPM cases have no apparent tumor on preoperative CT scan, i.e. radiological T0, but are ultimately staged as clinical T1 on the basis of thoracic CT scan. This situation implies that clinical T1 MPM is not always early disease. In this context, there are a simple clinical question whether or not patients without visible tumor on preoperative CT have better prognosis in comparison with those with visible tumor. HYPOTHESIS: Radiological T0 MPM is associated with better survival compared with radiological T1 disease. PATIENTS AND METHODS: Definition of radiological T0: Radiological T0 was defined as no apparent tumor with pleural thickness ≤ 5 mm on contrast-enhanced chest CT. Neither of findings from PET/CT nor thoracoscopy were considered. Evaluation of CT was performed by one radiologist (HK) who was blind to any clinical information or survival data. Patients: Patients were included in this retrospective study if they had a histologically confirmed diagnosis of non-sarcomatoid MPM, clinical T1 disease before neoadjuvant chemotherapy (NAC), had contrast-enhanced chest CT both before and after NAC, and underwent curative-intent surgery between October 2008 and December 2017 at the Hyogo College of Medicine. Three courses of platinum plus pemetrexed was employed for NAC and adjuvant chemotherapy Methods: Overall survival (OS) and progression-free survival (PFS) were calculated from the day of diagnosis. ES03.05 ROLE OF SURGERY IN TO MESOTHELIOMA S. Hasegawa1, H. Kodama2, M. Hashimoto3, A. Fukuda4, T. Nakamichi1, A. Nakamura5, A. Kuros1, T. Takuw1, S. Matsumoto6, Y. Okumura4, K. Yamakado2, T. Kijima5, N. Kondo1

1Department of Thoracic Surgery, Hyogo College of Medicine, Nishinomiya, Hyogo/JP, 2Radiology, Hyogo College of Medicine, Nishinomiya/JP, 3Thoracic Surgery, Hyogo College of Medicine, Nishinomiya/JP, 4Thoracic Surgery, Itami Municipal Hospital, Itami/JP, 5Division of Respiratory Medicine, Department of Internal Medicine, Hyogo College of Medicine, Nishinomiya/JP

Background: There is an increasing number of patients with early malignant pleural mesothelioma (MPM) in Japan. Some part of such early MPM cases have no apparent tumor on preoperative chest CT scan, i.e. radiological T0, but are ultimately staged as clinical T1 on the basis of findings at thorascopic biopsy. Currently, more than half of surgical candidates are classified as having clinical T1 disease in our hospital. This situation implies that clinical T1 MPM is not always early disease. In this context, there is a simple clinical question whether or not patients without visible tumor on preoperative CT have better prognosis in comparison with those with visible tumor. Hypothesis: Radiological T0 MPM is associated with better survival compared with radiological T1 disease. Patients and Methods: Definition of radiological T0: Radiological T0 was defined as no apparent tumor with pleural thickness ≤ 5 mm on contrast-enhanced chest CT. Neither of findings from PET/CT nor thoracoscopy were considered. Evaluation of CT was performed by one radiologist (HK) who was blind to any clinical information or survival data. Patients: Patients were included in this retrospective study if they had histologically confirmed diagnosis of non-sarcomatoid MPM, clinical T1 disease before neoadjuvant chemotherapy (NAC), had contrast-enhanced chest CT both before and after NAC, and underwent curative-intent surgery between October 2008 and December 2017 at the Hyogo College of Medicine. Three courses of platinum plus pemetrexed was employed for NAC and adjuvant chemotherapy (NAC). Overall survival (OS) and progression-free survival (PFS) were calculated from the day of pathological diagnosis. We used the Kaplan-Meier method to estimate the survival and compared the survivals between groups by Log-rank test. Analysis was based on data updated on June 27, 2018. Results: A total of 76 patients met the inclusion criteria: 65 males and 11 females; median age of 65 (16-78); 72 epithelioid and 4 biphasic. Patients were categorized into pre-NAC radiological T0 (n=23), T1 (n=29), and T2-3 (n=24) and also post-NAC radiological T0 (n=30), T1 (n=21), and T2-3 (n=25). Of 76 study patients, 27 underwent NAC followed by extrapleural pneumonectomy and postoperative hemithoracic radiation, and the remaining 49 underwent NAC followed by pleurectomy/decorticuation and adjuvant chemotherapy. Macroscopic complete resection was achieved in 71 patients (93.4%) and the remaining 5 had R2 resection. There was no 30-day mortality. Of 30 patients with post-NAC radiological T0 disease, 12 (40.0%) and 7 (23.3%) were classified as pathological T1 and T2, respectively. In contrast, of 21 patients with post-NAC radiological T1 disease, only one (4.8%) was truly pathological T1 and 15 (71.4%) were classified as pathological T3-4. The median follow-up after diagnosis for survivors was 28.9 months (range 9.6-95.6 months). For all study patients (n=76), OS and PFS were 41.9 months and 23.2 months, respectively. When analyzed on the pre-NAC CT, survival of patients with radiological T0, T1, and T2-3 were as follows: 2-year OS rate 86.3%, 66.4%, and 55.6%; 5-year OS rate 51.8%, 35.0%, and 29.7%; median survival time not reached, 37.5 months, and 27.5 months; median PFS 26.5 months, 19.1 months, and 22.8 months, respectively. Patients with post-NAC radiological T0, T1, and T2-3 had 2-year OS rate of 89.4%, 59.9%, and 54.2%, 5-year OS rate of 55.6%, 27.7%, and 25.4%, median survival time not reached, 28.2 months, and 27.5 months, and median PFS of 31.5 months, 17.3 months, and 19.1 months, respectively. When analyzed on the pre-NAC CT, no significant difference in OS or PFS was noted between T0 and T1 group. Survival analysis based on post-NAC radiological T-factor revealed that radiological T0 was associated with significant better OS (Figure 1) and PFS (Figure 2) over T1: median survival time not reached vs 28.2 months (P=0.0028, HR=0.30, 95%CI: 0.13 to 0.75); PFS 31.5 months vs 17.3 months (P=0.035, HR=0.51, 95%CI: 0.25 to 1.05). No significant difference in OS and PFS were noted between T1 and T2-3, irrespective on pre- or post-NAC CT. Comments: Since any type of curative-intent surgery for MPM is highly invasive, development of a predictor for better survival is essential. Current MPM staging system is underpowered to predict long-term survivors. In this situation, the radiological T-factor is likely adopted in version 9 IMIG staging system. The present study revealed that post-NAC radiological T0 was associated with significantly better OS and PFS over T1. It is notable that radiological T0 can be re-defined as maximum thickness of zero, and will fit into tumor thickness system. Adoption of radiological T0 may strengthen the next staging system. Conclusions: Patients with post-NAC radiological T0 MPM were associated significantly better survival in comparison with those with T1 or T2-3 disease. Multimodality treatment with curative-intent surgery is highly encouraged in patients with radiological T0 MPM.
A liquid biopsy in cancer patients generally refers to the sampling and analysis of circulating tumor cells (CTC) or circulating tumor-derived (ct) DNA for the diagnosis and management of patients (1). This contrasts with the traditional tissue biopsy, which still represents the gold-standard to assess the accuracy of liquid biopsies. Liquid biopsy has significant advantage over tissue biopsy as it is more convenient to perform with minimal risk to the patients, thus potentially allows more frequent sampling to monitor disease progression or treatment efficacy (2,3). More recently, liquid biopsy also has been proposed as primary tool for early detection and diagnosis of cancer, or in cancer genotyping to make therapeutic decisions (4). While rapid advances in microfluidic and/or high throughput sequencing technologies have demonstrated the feasibility of quantitative analysis of CTC and ctDNA in advanced stage lung cancer patients, the adoption of these technologies as clinical diagnostics should conform with the accepted principles of laboratory medicine in analytical validity, interpretation, reporting, clinical validity and utility (5). Although circulating tumor cells has been validated and approved by the FDA as a useful prognostic method for many cancer types (6), CTC in lung cancer has not become a clinically useful clinical assay in non-small cell lung cancer (NSCLC), primarily due to the small number of CTC detectable in these patients. In small cell lung cancer patients, CTC has greater number (7), yet its clinical utility still needs to be established. In contrast to CTC, the clinical adoption of ctDNA in lung cancer has occurred rapidly, especially in the detection of T790M resistant mutation during first and second-generation EGFR TKI therapies (8). Since ctDNA represents only a small fraction (<1%) of cell-free (cf) DNA in the blood, most of which are derived from leukocytes, highly sensitive methods are required to detect ctDNA. In general, two methodological approaches are used to “detect” the presence of ctDNA: PCR amplification or hybrid capture of tumor-derived target DNA fragments + next generation sequencing. With these techniques, the detection of mutant ctDNA sequences in advanced lung cancer patients with EGFR mutated adenocarcinoma has achieved 60-85% sensitivity and >95% specificity, using tissue-based diagnosis as the reference. Many pre-analytical conditions may influence the reliability of results of ctDNA analyses. Additional biological factors (e.g. tumor stage/burden, type, heterogeneity) could also influence the sensitivity of detection of specific tumor genomic aberrations. Since lysis of white blood cells will dilute the ctDNA with leukocyte-derived DNA, it is imperative to collect blood in tubes containing EDTA or leukocyte stabilizing agents (e.g. Streck tube). For the former, blood needs to be processed within 2-4 hours or sooner after collection, while with the latter, they can be kept for up to 48 hours or longer. Plasma is also preferred over serum as clotting increases the amount of non-tumor cf DNA resulting from leukocyte lysis. With the current achievable sensitivity, ctDNA should not be used in treatment naive patients as the primary method to determine the mutation status of EGFR or other actionable driver oncogenes, except when biopsy tissue is insufficient and re-biopsy is not feasible for timely molecular testing. However, despite its suboptimal sensitivity, extensive studies have established the clinical utility of ctDNA for testing T790M in patients with EGFR-mutant lung adenocarcinoma, who have progressed on first/second generation EGFR TKI therapy (9). The ctDNA assay may include DNA derived from all tumors in the body, thus has the potential of better representation of total body mutation status than tissue biopsy, which usually targets only one of many tumor nodules in metastatic setting. However, the suboptimal specificity mandates that a negative result triggers a tumor tissue re-biopsy to exclude false negative result or to identify other resistant mechanisms, including small cell carcinoma transformation. Other candidate ctDNA assays being studied for their clinical utility in lung cancer include resistant mutations to ALK inhibitors, and tumor mutation burden as predictive biomarker for immune checkpoint inhibitor therapies. Liquid biopsy has generated great excitement among oncologists as it potentially may overcome many of the “tissue is the issue” limitations in current biomarker testing paradigm. However, it is crucial that we apply the same stringency of evidence on liquid biopsy as that has been applied to tissue-based biomarker testing, including the demonstration of clinical validity and utility in clinical trial patient samples. While promising data are rapidly being generated on the roles of ctDNA assay for monitoring and adjusting treatment, or in early detection of lung cancer or residual disease, significant research is still required before they become standards in routine clinical practice. gene rearrangements involving ALK1 and ROS1 (1–2%), all of which encode protein kinases, and result in hyperactivation of downstream signaling pathways that drive cell growth, proliferation, and survival. The identification of these driver kinase genes has led to the clinical use of oral kinase inhibitors that suppress these oncogenes such as erlotinib, gefitinib, afatinib and osimertinib which target mutant EGFR; vemurafenib and dabrafenib for mutant BRAF; and crizotinib, ceritinib, allectinib for ALK and/or ROS1 gene rearrangements. Although targeted therapy agents of NSCLC are directed against tumor cells, they are still associated with toxicities affecting multiple organs. Overall, the side effects described include: skin rash, diarrhea, constipation, eye sight alterations, nausea, edema, fatigue, hypophosphatemia, hypokalemia, bradycardia, neutropenia, increased serum ALT and AST, prolonged QT-interval on EKG, among others. Some studies show that these factors are the main reason for non-adherence. It has been evident that when these side effects are managed appropriately, patients are more likely to want or be able to adhere to established treatment plans. 6,7 The effects of missed doses significantly increase the probability of developing resistance, such as the T790M mutation, which provides tumor resistance against EGFR targeted drugs, and which is the most frequent mechanism found in NSCLC.5 Therefore, treatment interruptions and non-compliance may lead to undesirable clinical outcomes: increased morbidity, mortality and also increased health care costs. Short interruptions or dose reductions, when medically necessary, may not have a negative impact on disease control.10 In order to improve compliance, which leads to overcoming resistance and reducing health-related costs, a set of strategies is needed: (1) simplifying the dosage regimen and putting in motion several complex strategies, including: combinations of thorough patient instructions and counseling; reminders, close follow-up, electronic monitoring, supervised self-monitoring, rewards for success, family therapy, couple-focused therapy, psychological therapy, crisis intervention, and manual telephone follow-up; (2) a qualified team acting in the prevention, early identification and management of adverse events; (3) patient awareness and education regarding their treatment; and (4) a health system that facilitate access to oral medications. 8,9 Table 1 - Factors affecting compliance and interventions for improvement.

In summary, the number of patients receiving oral chemotherapy is increasing. However, studies have proved that non-adherence to treatment was associated with poor responses in some diseases, and there is an urgent need to develop safe and effective systems to administer and manage these agents. The relationship between noncompliance and outcome in NCLC needs to be better studied.

ES05.02 CAN PATIENT GROUPS AND REGULATORY BODIES WORK TOGETHER TO MAKE CLINICAL RESEARCH EASIER?
A. Ferris
Lungevity Foundation, Bethesda/MD/US

Background: The lung cancer treatment landscape has rapidly evolved over the past five years, with the U.S. Food and Drug Administration (FDA) approving more than 15 new treatments for advanced-stage non-small cell lung cancer (NSCLC) -- more than in the prior 15 years combined. However, for multiple reasons, including the routine use of overly restrictive eligibility criteria and the difficulty of opening clinical trials in community oncology settings, too many advanced-stage NSCLC patients are prevented from participating in clinical trials. As a result, patients do not have early access to potentially life-saving treatments. LUNGevity Foundation is committed to making lung cancer clinical trials more patient-centric and accessible by streamlining the process of conducting studies. Approach: In 2015, LUNGevity Foundation began convening multi-stakeholder meetings, the LUNGevity Scientific and Clinical Research Roundtables (SCRTs.), in order to address this complex problem and determine innovative and timely solutions. These Roundtables bring together senior leaders of domestic and international regulatory agencies, clinicians, payers, patient advocates, patients, CROs and trial sponsors to ideate on the most pressing issues confronting the clinical trial landscape, focusing on lung cancer trials as case studies and pilots. The Roundtables provide a platform for top officials across sectors to discuss challenges and develop concrete approaches for designing and executing clinical trials that facilitate patient participation and provide earlier access to promising new treatments. Progress-to-date: Since its inception, the SCRT program has advanced progress in multiple important areas, developing multi-stakeholder working groups, hosting five in-person stakeholder meetings and three interactive webinars. These efforts have focused on the following workstreams aimed at improving clinical trials from the patient perspective: Streamlining Lung Cancer Clinical Trials:

The goal of this roundtable series is to streamline clinical trials and make them more accessible to patients. The three active workstreams include:

- Expanding eligibility criteria to allow access to patients that have been historically excluded from lung cancer trials - A manuscript was recently published in the Journal of Thoracic Oncology presenting recommendations from the multi-stakeholder Expanded Eligibility Working Group on relaxing eligibility criteria to include advanced-stage patients with brain metastasis, poor performance status, and prior malignancies. This Working Group has also identified outdated or unnecessary exclusion criteria frequently seen in lung cancer trial protocols, especially those that may no longer be relevant to current classes of drugs with new mechanisms of action. The group continues to work with regulators and industry partners to revise clinical trial protocols to ensure that such criteria are no longer included in lung cancer trials.

- Streamlining reporting of suspected unexpected serious adverse reactions (SUSARs) and adverse events - This Working Group has been cataloguing anticipated adverse drug events (ADRs) observed in clinical trials, with a goal of avoiding misunderstanding of the different types of ADRs and how they should be reported to eliminate excessive and unnecessary reporting.

- Creating a prospective real-world control arm for a histological subtype of lung cancer, such as small cell lung cancer (SCLC), where the standard-of-care hasn't changed over the past few decades and the natural history of the disease is well-characterized. The goal of trials is to reduce the number of patients need enrollment for certain trials and maximize the opportunities for patients to access novel therapies. The Working Group is collaborating with health informatics companies to develop and pilot this novel control arm for SCLC trials in the first-line setting. Patient-Reported Outcomes:

Due to more patient-centric health systems, there has been an increased use and interest in patient-reported outcomes (PROs) to include the patient’s perspective in research and clinical practice. With the passage...
of the 21st Century Cures Bill, there is a renewed focus and urgency on gathering and incorporating PROs and real-world evidence (RWE) into the drug development process. While PROs have been used for reimbursement decisions outside of the US for many years, there is still limited utilization of PROs to help inform treatment decisions. The Working Group has been focused on improving efforts to gather patient-reported outcomes (PROs) that are meaningful to patients and ensure the information is communicated to patients in a way that is useful in their decision making. The specific questions being asked in this workstream include:

- What is the prognosis for patients with lung cancer?
- How can we can analyze and communicate this data?

Findings from a patient advisory board (comprising 17 lung cancer patients and leaders from the FDA), designed to elicit feedback regarding the core elements of clinical outcome assessments (COA) that FDA previously proposed, will be presented in a manuscript (submitted to The Journal of Thoracic Oncology). The Working Group will continue to synthesize with the FDA and industry partners on PRO data collection and use. **Veterans’ Access:**

The goal of this roundtable series is to identify barriers and opportunities to ensure that veterans have access to clinical trials through a two-pronged approach—standing up more industry trials within the VA Health Care System and facilitating veteran access to trials outside of the VA health system. These roundtables engage with senior leadership from the Veterans Health Administration, practicing clinicians within the VA National Association of Veterans Research and Education Foundations (NAVREF), and industry partners. Ongoing activities include working with the National Program Director for Oncology at the VA on guidance on policies that allow veterans to be referred out to participate in trials outside the VHA, and with the VHA Office of Research & Development and NAVREF on their newly formed Clinical Trials Steering Committee to work on increasing clinical trials within the VHA. **Next topics for action:** LUNGevity Foundation is beginning new workstreams focused on efforts to 1) bring more clinical trials into the community and 2) improve expanded access programs for novel therapies. **References:**

**ES05.03 DISCREPANCIES AND SUSTAINABLE ACCESS TO INNOVATIVE THERAPIES: TRANSFORMING PATIENT EXPERIENCE IN TO PATIENT VOICE**

**J. Fox**

Medical Directorate, Ray Castle Lung Cancer Foundation, Liverpool/GB

**Background** Recent years have seen an explosion in new therapies in lung cancer. Research has given us Targeted Therapies, Immunotherapies, minimally invasive thoracic surgery and better directed radiotherapy techniques. The challenge is to ensure patients have equitable access to up to date best practice treatment and care, taking advantage of the research developments. There are many reasons for variability in such access - predominantly, new therapies on the market and healthcare systems are under enormous financial pressure; resource availability, priority setting and pressures differ between healthcare systems. Furthermore, the pace of change in lung cancer is such that it is difficult to keep up with the new developments. Health systems are inherently slow to enact change. Each healthcare system will have its own unique approach to ensuring access to innovative new therapies. In dealing with the reality of finite and scarce resources, many countries have developed formal decision making bodies, undertaking Health Technology Assessment (HTA). These processes interrogate both clinical and economic data. Ethical considerations and patient preference can also be taken in to account. Advocates can work with HTA agencies to ensure that the experience of the patient population impacted by the therapy under review, is part of the deliberations. Where assessment processes are not present, advocates can also use the patient experience to work with policymakers in ensuring that a particular disease has enough resources devoted to it. **Using Patient Experience in improving access to new therapies** Through patient experience, advocates have a voice in shaping the process whereby patients access new therapies. There is potential to input across the whole process – designing clinical trials; regulation/licensing; and access procedures. Only people living with a particular health condition can truly describe the challenges they face and the impact that a new therapy will have upon them. Quality of life scores and clinical trial data do not fully reflect patient priorities on aspects of their disease and wellbeing. Hence the reason that formal and informal processes have been developed to allow patient advocates to submit the patient perspective to decision makers. In doing so, advocates need to know the process that is required in their own healthcare system – many Regulators (eg, the FDA) and HTA bodies offer information, training and support to advocates. 1. Have the credibility to speak on behalf of their patient community - the ability to contact and survey appropriate patients. 2. Understand the experience of the patient group, receiving the therapy under review. What are the needs and experiences of this patient group? 3. Share patient experience of the therapy under review. What information and data is required to make a contribution? What other therapy options are available? Patient stories can be very powerful. Measuring the value which patients attribute to individual therapies, is an area of current interest [1], [2]. This is complex. It can be difficult to define a single set of patient values on a particular therapy. There are many individual patient variables – age, education, expectation, personal finances, social/religious/cultural factors. The focus, therefore, needs to be on inputting a broad range of outcomes, which patients regard as most relevant. **Lung Cancer Patient Specific Issues to consider** in lung cancer, we have a number of specific challenges. Globally, there is a lack of lung cancer patient advocate organisations, who have the ability to engage patients. Lung cancer patient numbers tend to be older, have poorer Performance Status and other co-morbidities. It is often difficult to reach a representative patient group. A better understanding of lung cancer biology and the targeting of therapies, means that new therapies and indications tend to be for smaller, more segmented patient groups. It can be challenging for advocacy organisations to reach these patients in significant numbers. This presentation will, therefore, expand on the areas above and encourage advocates to engage with policy makers to ensure that the lung cancer patient experience is incorporated into decision making on access to new therapies. **References**

**ES05.04 CHALLENGES AND SOLUTIONS IN ENGAGING WITH THE HEALTH TECHNOLOGY ASSESSMENT PROCESS IN CANADA**

**C. Sit**

Lung Cancer Canada, Toronto/ON/CA

Treatment advances in lung cancer have helped increase QoL and survival for lung cancer patients. However, with list prices of over $8000 Cdn per month for recent lung cancer treatments,[1,2] cost can be a barrier to access for patients. Public funding offers patients a chance at life-extending treatments that they may not have ability to access. Health Technology Assessment (HTA) bodies are called to answer the value of the new treatment within a context of responsibility to public taxpayer funds. The patient voice within this process is critical to give a “true” assessment of the disease burden which goes beyond ICER’s, QALY’s and include real world considerations of caregiver time off, and ability to go to treatments by themselves. However patient input into HTA is not standardized and varies across the world. Some HTA agencies do not accept patient input at all, some in excess of more than 1000 days) and is challenging in the era of targeted medicine, where assessment processes are not possible 2) Gaps in timing between the trial and HTA submission in a disease with a high mortality 3) Small numbers of patients with experience using the treatment under consideration – especially in the case of targeted medicines 4) Randomized double-blinded trials. Patients

**ES06 OLIGOMETASTATIC DISEASE WEDNESDAY, SEPTEMBER 26, 2018 - 10:30-12:00**

**ES06.01 CURRENT CLINICAL TRIALS IN OLIGOMETASTASES**

A. Dingemans  
Pulmonaryon, Maastricht University Medical Centre, Maastricht/NL

Long-term benefit of local ablative treatment in patients with up to 3-5 metastatic sites was seen in several, mainly retrospective, series [1]. In 2012 our group published the first prospective clinical trial in NSCLC patients with synchronous oligometastases [2]. In this single arm phase II study 40 patients with stage IV NSCLC and ≤ 5 metastases, amendable for LAT (radiotherapy or surgery), were enrolled. The 2- and 3-year survival rates were 23.3% and 17.5% respectively. In the last years the concept of oligometastatic treatment evolved. The continuing interest was pushed by the increasing number of available treatment strategies, with widespread introduction of minimal invasive surgery and stereotactic radiotherapy. Several guidelines have described oligometastatic NSCLC as a separate entity. After years of retrospective data and single arm studies reporting on oligometastatic NSCLC, at ASCO 2016 the first randomized phase II trial was presented. Progression free survival (PFS), the primary endpoint, was shown to be significantly superior when oligometastatic NSCLC patients were treated with LAT compared to follow-up or maintenance therapy after treatment with at least four cycles of platinum containing chemotherapy or three months of EGFR-TKI (EGFR mutation) or crizotinib (ALK-rearrangement). These were selected patients as oligometastatic was defined as no progression after this systemic treatment; a maximum of three remaining metastases were allowed. The median PFS were 11.9 and 3.9 months in the LAT and the control group, respectively (HR 0.35, 95% CI 0.18-0.66) [3]. The question arises whether we need additional evidence or whether the randomized phase II trial of Gomez with PFS as primary endpoint will change the current systemic practice. In the meantime another randomized phase II study was recently published, randomizing EGFR/ALK negative, NSCLC patients with up to six extracranial cancer sites (including primary) without progression after 4-6 cycles of chemotherapy to maintenance chemotherapy and LAT (radiotherapy or surgery) to all tumor sites. Primary outcome was PFS. This study was stopped after an unplanned interim analysis, performed after publication of the Gomez trial. 29 of the 36 planned patients were randomized. The median PFS was 9.7 months in the maintenance chemotherapy group and 3.5 months in the control group (hazard ratio 0.57, 95% CI 0.21-1.49, p=0.26). The phase II part of this study is ongoing (NCT03137771) and OS is the primary outcome measure. In addition to both randomized trials, at the 2017 WCLC conference data of a single arm phase II data on pemelrotumab in oligometastatic NSCLC were presented [4]. 45 patients with 4-10 metastases and two progression-free LAT to all known sites were treated with pemelrotumab. The 1-year PFS was 68%. Although the PFS difference is impressive in both randomized phase II studies, there are some concerns to implement this strategy in daily practice. Most importantly the total number of patients enrolled in the two trials combined is very limited (78) and the majority had only one metastatic site. Knowing that assessment of local progression might have an impact on the use of LAT with radiotherapy, early advocacy strategy and clear OS data are needed in order to draw firm conclusions. As patients were randomized after first line treatment baseline characteristics were not known and selection bias might have occurred. What can we expect in the next trials from different clinical trial groups that are ongoing clinical trials all use different definitions of oligometastatic NSCLC and that they require different staging procedures. One of the ongoing trials is the SARAON trial (NCT02417662), patients with oligometastatic NSCLC (defined as up to three oligometastases, FDG-PET scanning mandatory) are registered before treatment initiation and randomized (when no progression after two chemotherapy cycles), between two additional chemotherapy cycles with or without radiotherapy to all tumor sites. The number of metastasis and mediastinal lymph nodes are stratification factors. Finally, the SCOPE-1 trial (NCT02447533). Hopefully this trial will complete enrolment as it can give the final answer on whether local ablative treatment will improve OS in oligometastatic NSCLC patients. In addition Oligo-CARE is initiated, a pragmatic observational basket study to evaluate radiotherapy for oligo-metastatic cancer patients, a joint project of EORTC and ESTRO. In conclusion, since the trial of Gomez oligometastatic NSCLC “is there to stay” as so some of these patients benefit from systemic treatment combined with LAT. Most trials focus on radical radiotherapy as the LAT modality but optimally trials would also include surgery as an option. However, despite the promising results important aspects have to be addressed. In order to speak the same language we need a uniform definition of oligometastatic NSCLC. The European Organisation of Treatment of Cancer (EORTC) cancer group started an initiative to come to a consensus definition of oligometastatic disease for synchronous NSCLC. In addition, these patients have to be accurately staged (i.e. FDG-PET and brain MRI/CT), as proposed by the EORTC imaging group [5]. But most important, future trials will have to address predictive factors, as we need a selection tool to identify those patients who will have long-term benefit from LAT. References 1. **ES06.02 INTEGRATING NEW SYSTEMIC THERAPY INTO TRIALS IN OMD**

S. Popat  
Royal Marsden Hospital, London/GB

Significant progress has been made in the treatment of metastatic non-small cell lung cancer (NSCLC) in recent years. The oligometastatic state has been identified and formally adopted by UICC from IASLC recommendations by the creation of the M1b category of the 8th TNM staging system, defining patients with a solitary site of extracranial metastasis as an oligometastatic disease. Parallel to these changes, rapid technical advances in supportive care, minimally invasive surgery, and advanced technical radiotherapy have been implemented alongside a greater biological understanding of the biology of the disease. Contemporaneously, advances in drug development have transformed the face of advanced NSCLC with the routine implementation of personalized molecular oncology into routine care and marked durable responses observed, alongside the recent implementation of immune-checkpoint inhibitor therapy. With the latter, optimal scheduling with radiotherapy has been brought under the spotlight to identify, characterize, and enhance the abscopal effect for maximal clinical benefit. Whilst interactions between systemic chemotherapy and ablative dosages of radiotherapy have been established over recent years, significant uncertainty still exist in defining interactions between ablative radiotherapy and novel systemic therapies. Uncertainties include the role of radical consolidation in patients oncogene addicted disease: when to stop tyrosine kinase inhibitor (TKI) therapy and consolidate...

ES06.04 SURGICAL CONSIDERATIONS IN OMD

J. Donington

Surgery, University of Chicago, Chicago/US

Historically, surgery was reserved for palliation in patients with stage IV NSCLC, but since the 1980s there have been reports of prolonged survival following complete resection of primary tumors and metastatic lesions in select patients with low volume metastatic disease. Hellman and Wechselbaum introduced the term “oligometastasis” to describe an intermediate spread of disease, prior to widely metastatic disease and recognized it as a subset where aggressive local treatments were warranted. Surgery for metastatic NSCLC was increasing in frequency by 1990. An analysis from the National Inpatient Sample uncovered a 5.8% average annual percent increase resections of NSCLC metastases between 2000 and 2011. This increase is attributed to several factors, including more efficacious and better tolerated chemotherapies including targeted agents, which have slowed the progression of metastatic spread and altered patterns of resistance. Simultaneously, there have been significant improvements in surgical techniques, with increased minimally invasive approaches, making resection better tolerated and negating long interruption from systemic treatments. The majority of patients considered for resection of oligometastatic NSCLC fall into three categories, isolated metastasis to the brain, adrenal glands, or contralateral lung. Patients who have previously undergone resection of early stage NSCLC and subsequently develop isolated oligometastasis and good performance status should be considered for curative intent resection. Similarly patients with oligometastasis de novo should be evaluated for curative resection in addition to systemic therapy. Isolated Brain Metastasis: Some of the oldest series on surgical treatment of oligometastatic NSCLC relate to treatment of isolated brain metastasis. Up to one quarter of all patients with stage IV NSCLC harbor brain metastasis. Adenocarcinomas are associated with higher rates of brain metastasis, but 64% of patients with metastatic adenocarcinoma to the brain is the only site of involvement. Aggressive curative intent treatment of the primary and metastatic site is encouraged in those with good performance status and in whom both sites are amenable to complete resection. Curative intent treatment of primary disease is considered after a thorough search for disease at other sites. Medialional lymph node involvement portends poor prognosis and therefore invasive mediastinal staging is recommended prior to starting treatment. Brain MRI is recommended in addition to PET/CT because of increased sensitivity. Multiple brain metastasis are not an absolute contraindication to this aggressive treatment approach, but most recommend three or fewer lesions. Treatment of the brain lesion can be by resection or radiosurgery ablation. Five year survival following definitive treatment of isolated brain metastasis and primary NSCLC is 15%, and not significantly impacted by synchronous or metachronous presentation. Prognosis is improved in patients who are younger, female, have lower t-stage, and good performance status. Adjuvant whole brain radiation therapy (WBRT) following resection or radiosurgery is recommended. Randomized data on WBRT in this setting is limited, but the sole trial demonstrated a significant decrease brain recurrence. There is also no randomized data specifically addressing the use of adjuvant chemotherapy following complete resection of stage IV disease, but with strong evidence in supporting adjuvant chemotherapy for completely resected stage II and III, it is recommended. Isolated Adrenal Metastasis: In well-selected patients with isolated adrenal metastasis from NSCLC, survival following complete resection is 25%. Similar to those with isolated brain metastasis, mediastinal lymph node involvement portends poor prognosis so invasive staging is recommended. Histology and laterality appear to have no impact on survival and adjuvant chemotherapy is recommended. Synchronous and metachronous tumors have similar long-term survival rates, despite younger age distribution in patients with synchronous presentation. Operative mortality is extremely low in reported series and the majority of patients die of disease progression. MIA Disease: The appearance of bilateral NSCLC lesions with the clinical presentation of a staging challenge. In the absence of other disease it is difficult to distinguish bilateral primary tumors from stage IVa disease. Analysis of mutational status and genetic clonality difference are being investigated, but not clinically reliable at this time. Clinical multi-modality team is essential. a and the criteria described by Martini and Melamed in 1975 remains relevant. As with isolated brain and adrenal metastasis, an exhaustive search for additional metastatic disease and invasive mediastinal staging are recommended prior to considering resection. Parenchymal sparing resections are typically recommended when possible in this setting. Conclusion Most agree that favorable biology is the primary driver of prognosis in the setting of oligometastasis and the true impact of local interventions on prognosis is uncertain. But in an era where local treatments carry minimal morbidity and mortality, the lack of clarity should not translate into a denial of intervention in well-selected patients, but rather another treatment option to prolong survival. ES07 BEYOND THE DIAGNOSIS - COLLABORATIVE CARE FOR CHANGE WEDNESDAY, SEPTEMBER 26, 2018 - 13:30-15:00

ES07.01 A MOMENT IN TIME FOR THE UNPLANNED CONVERSATIONS

K. Mcguigan

Nursing, Princess Margaret Cancer Centre, Toronto/CA

Advance care planning (ACP) at its most basic level is a process of a capable person planning for future health care needs and deciding on a substitute decision maker to make health care decisions for them in the event that they become incapable. Over the past several years advance care planning has broaden in definition from a legal document driven approach to one that is individualized, supports patient autonomy and includes a relational approach to ACP. This consensus definition (Sudore et al 2017) is inclusive of engaging adults at any age or stage of illness and their families into conversations that focuses on their goals, values, and preferences for future health care to ensure that patients receive care that is consistent with these values and preferences. It may also include choosing and preparing a trusted person (s) to act on their behalf in the event that they are no longer able to speak for themselves. This definition can also help support a consistent and coherent practice. Lung cancer is the most commonly diagnosed cancer worldwide with eighty five percent of patients being diagnosed at an advanced stage of illness. Despite recent advances in lung cancer treatment it is the leading cause of death from cancer for both men and women in the world. In addition to a significant symptom burden, high mortality and morbidity, patients are faced with complex decisions regarding treatment options, future care and end of life care decisions. Initiating ACP conversations early in a patients illness trajectory and revisiting at treatment milestones in a patients illness has the potential to ensure they receive care that is consistent with their values, goals and preferences. These conversations may also alleviate the burden on family and reduce conflict with the health care team when patients’ wishes, values and goals are known and honored. There is evidence in the literature that the fear of destroying a patient and family’s sense of hope is one of the primary deterrents for health care clinicians engaging in ACP discussions. Other identified barriers to ACP in the literature are health care clinicians lack of knowledge about ACP, a lack of skills and confidence in how and
when to start these discussions, the fear of causing distress and doing harm, a lack of time and a lack of support from their health care team. A common misconception is that most people with metastatic or advanced illness will talk about ACP related issues if they feel it is important thus putting the onus on the patient rather than the health care clinician (Detering et al. 2016, Schickendanz et al 2009). Studies show that a large percentage of nurses and physicians hold the belief that advance care planning conversations should be brought up by the patient and not the care provider as this indicates a readiness to engage in the planning process (Johnson et al 2015). Patient factors to consider prior to having an ACP conversation are the patient’s readiness and motivation to discuss advance care planning, that families and trusted others can be a motivator or a barrier to ACP and that patients prefer that these conversations are initiated with the health care team that knows them the best. Patients may not initiate these conversations thinking it may be the role of the health care team has not initiated the conversation (Sudore et al 2018, Johnson et al 2015). Emerging questions and concerns amongst health care clinicians are; what communications skills are needed, what constitutes an ACP conversation, who should have these conversations, what is the best time in a patient’s illness and how do I prepare for it. One of the first things to consider before engaging patients in ACP conversations is to assess your own communication skills and readiness followed by assessing for patient’s readiness and motivation. The timing of ACP conversations is important and should be individualized, it may include family or trusted others in the discussion and it should be voluntary. Paying attention to cues from patients can lead to the unplanned conversations. Cues may be implicit or explicit and patients may not always want to be involved in decision making about treatment and care. “I want everyone to respect what’s important to me”, “I worry that what I want and don’t want will be overlooked”, “I am starting to wonder how long I may have to live” and “I don’t want to be a burden to my family”. The use of patient’s own words can help to guide the conversation. Clinician skills are important to have successful conversations that result in positive patient outcomes. Clinicians should have knowledge of ACP, be able to establish a therapeutic alliance, create a safe space for expression of emotion as ACP conversations can be difficult and emotional for the patient, family and the health care clinician, tailor the discussion to individual needs and determine what the patient and family know about the illness and what they know about ACP, an educational approach may be useful. Communication skills and tools can help to support clinicians in their practice. The use of open ended questions or phrases can to help to start the conversation. Some examples are: what is your understanding of your illness, how do you like information to be communicated to you, what brings quality to your life, what do you value most in your life, and how do you see your family and main caregivers. During the dialogue, the nurse coordinator informs them about the various aspects of the diagnosis, treatment and care. In addition, the nurse coordinator is responsible to implementing this multidisciplinary plan. One of the main challenges is maintaining the palliative treatment through a long term illness. As cancer medications might prolong life expectancy and improve patient’s quality of life – the sense of urgency of palliative care decreases along the patient’s journey, despite its utmost importance in prevention of and coping with a commonly seen future deterioration. Whereas in Israel and some European countries the “nurse-coordinator” in a palliative care unit in lung cancer management, plays a significant role in the process of adopting this approach. In my talk I will demonstrate this approach through a patient case From Sheba Medical Center in Ramat Gan, Israel.

Keywords: Early palliative care ,nurse coordinator, patients’ quality of life

ES07.04 LEVERAGING SOCIAL MEDIA TO CHANGE THE PUBLIC CONVERSATION ON LUNG CANCER STIGMA

L. Carter-Harris
IU Melvin & Bren Simon Cancer Center, Indiana University School of Nursing, Indianapolis, IN

The reality of lung cancer stigma is tangible and has a profound impact on people living with this disease. Further, stigma remains a highly significant barrier to fulfilling the clinical promise of advancements in lung cancer treatment, early detection, and reduced lung cancer burden.1-2 Lung cancer stigma can have far-reaching effects that range from reduced hope and health seeking to reduced treatment engagement. Efforts such as smoking cessation and screening, impaired patient-clinician communication, delayed access to diagnosis and treatment, negative psychosocial responses, and even more broadly, to limited public support of and actual research funding. The phenomenon of lung cancer stigma is multilevel involving that of the individual, persons in the individuals’ immediate environment, persons in the healthcare system, and society at large, which shapes public perceptions and decisions that impact lung cancer patients (e.g., public attitudes, media campaigns, policy, research funding). Stigma is multi-social in nature. It is commonly a perceived or felt stigma as well as internalized by the individual patient influencing patient behavior. The stigma of lung cancer is perpetuated by the public’s perception that this is a ‘smoker’s only’ disease. However, many people are not aware that approximately 20% of lung cancer patients diagnosed each year are never smokers.3 It is imperative that innovative and novel approaches to changing the public perception of lung cancer and its associated stigma are pursued. If you have lungs, you can get lung cancer. As opposed to the prevailing perspective of blame that highlights a lifestyle choice fueled by addiction (i.e., smoking), we need to change the public conversation around lung cancer to one that focuses on early diagnosis, treatment, research options that match the magnitude of this deadly disease, and prevention. Comprehensive tobacco control efforts over the past five decades have been lauded as one of the leading public health successes. Specifically, restrictions to smoking in public buildings and spaces, increased tobacco-related taxation, and public health national media campaigns primarily delivered through fear-based messaging have all led to diminished social acceptance of smoking as an appropriate lifestyle behavior. Collectively, this has contributed to the overall success of decreasing U.S. adult smoking rates from 43% in 1964 to the current 15.5% U.S. adult smoking rate.4 Unfortunately, the demonization of tobacco has had the unintended consequence of stigmatizing the disease of lung cancer negatively impacting those at risk for and living with the disease. Just as the stigmatization of lung cancer did not happen in isolation, addressing the social determinants is required.5 Smoking is a risk factor for lung cancer, and is inseparable from lung cancer case management, other sites are still in the early stages of adopting a social determinants approach through a patient case From Sheba Medical Center in Ramat Gan, Israel.

ES07.03 SPECIAL NEEDS AND WELLNESS IN LUNG CANCER PATIENTS - EUROPEAN PERSPECTIVE

R. Navon
Lung Cancer Unit-OncoHematology Department, Sheba Medical Center, Ramat Gan, IL

Early palliative care among patients with metastatic lung cancer can lead to improvements in various aspects such as quality of life, emotional stability and supportive environment. An integrative care, which combines the standard medical treatments of a palliative care, is considered to be palliative care. The Palliative care discipline aims to improve patients’ quality of life and support their families, as they face a life-threatening illness. A key ingredient of this approach is the ability to identify and to map patients’ needs and to address them in a holistic and systematic way. Each individual patient may have different needs, which include symptoms, symptom patient and family coping, information, social support, etc. This type of care requires the involvement of multidisciplinary team including Oncologist, Radiation unit, palliative team, Psychologist, social worker, spiritual guidance, community services such as home care unit or family physician, inpatient departments and day care treatment units. The need for multi-team effort makes the task of coordination and integration significantly challenging. In order to achieve this goal, the role of the nurse coordinator is both to the actual coordinator of the various disciplines involved, as well as to the one responsible to implementing this multidisciplinary plan. One of the main challenges is maintaining the palliative treatment through a long term illness. As cancer medications might prolong life expectancy and improve patient’s quality of life – the sense of urgency of palliative care decreases along the patient’s journey, despite its utmost importance in prevention of and coping with a commonly seen future deterioration. Whereas in Israel and some European countries the “nurse-coordinator” in a palliative care unit in lung cancer management, plays a significant role in the process of adopting this approach. In my talk I will demonstrate this approach through a patient case From Sheba Medical Center in Ramat Gan, Israel.

Keywords: Early palliative care ,nurse coordinator, patients’ quality of life
Malignant pleural mesothelioma (MPM) is an aggressive, rare cancer due to exposure to and inhalation of asbestos (Odergel et al. 2017). Incidence is higher in certain occupational groups including asbestos mining and disposal and construction industries (Rake et al. 2009). Rates vary within and across countries. The UK has approximately 2,700 new diagnosis a year, one of the highest internationally. Rates of MPM show no signs of reducing and global incidence and burden is likely to be underestimated due to poor data capture in some countries. Whilst asbestos use has drastically reduced in developed countries, significant amounts of asbestos are still used in India, China, Russia, and some developing countries (Frank & Joshi 2016). The lifetime period for MPM varies from 30 and 50 years with an average of 40. Occasionally exposure to diagnosis can be 10 years or less, but this is uncommon. MPM is an incurable cancer but there are new treatments offering promise in terms of length of life and palliation of symptoms. New radical surgical procedures are being performed and novel drug treatments provide better patient outcomes. In addition there are new procedures for the consequences of MPM such as trapped lung and malignant pleural effusion (MPE). Although showing no signs of the global burden reducing, and the increase of new treatment and procedures, there is little research exploring the experience of living with mesothelioma from the perspective of the person with the disease and their family. This presentation will shine a light on existing research, and provides us with an understanding of the experiences of living with MPM. It will draw on the wider literature as well as recent and current studies being conducted by the author and colleagues. International literature will be included but many references will be to the UK context. The journey of the person with MPM will provide the structure for the presentation. Starting with the long road to diagnosis, the experiences of coming to terms with and understanding the diagnosis will be considered. This will be followed by research on people’s experiences of treatment and trials and care related to end of life. An underpinning theme will be understanding the burden reducing, and the increase of new treatment and procedures, and the shock of being delivered a terminal diagnosis. Although challenging, for some actually getting a diagnosis confirmed has the benefit of the end of uncertainty. Understanding and coming to terms with a MPM diagnosis is fraught and perplexing. Not only is the diagnosis life limiting, it was due to exposure to asbestos many years ago. The extent to which people remember and expected consequences of this exposure will impact upon ability to accept the diagnosis. It is not uncommon for people to have never heard of MPM and people can struggle to understand the nature of the tumour and their prognosis. Many people see cancer as a solid tumour or lump, so a diffuse cancer such as MPM is difficult for people to understand. Balancing the needs of patients and family members can be difficult especially if they conflict in terms of the nature of information and the time in which it is required. Prognostic factors are a good example as patients and family carers may differ when and if they want such information. For those with a MPE, there is an urgency to have that treated. Unless the MPE and related symptoms are addressed, people are unable to assimilate information about the underlying diagnosis of MPM. This highlights the importance of timing related to information delivery. As new treatments become available, this will increase the information burden for patients. There are also challenges regarding decision making and tolerating the burden of treatments and interventions (Hughes & Arber 2008). There may be a time pressure for people to resolve this for family members before the person with MPM dies (Hughes & Arber 2008). Finally research findings regarding end of life are considered, including the access to timely palliative care, pressures on family members in coping with MPM as an industrial disease requiring post-mortem and family involvement (Clayson et al. 2005).

Psychosocial impacts emerge across the pathway as patient’s and carers deal with stress, shock, changes to identity, relationships and the demands of managing uncertainty. Throughout the pathway, research indicates the need for people with MPM to balance out the bleak with the positive (Taylor 2018). Understanding this can help health professionals better meet the needs of patients and family. Much of the research on MPM experience highlights the enormity and range of information people have to take on board. Some of this has an immediate pressure as it is linked to treatment or trial decisions. In conclusion, the contribution of ‘Relationship-centred care’ (RCC) will be considered. This expands on and enhances the notion of person-centred care. The proposition is that RCC will help address the complex and challenging nature of improving the MPM patient and carer experiences (Taylor et al. 2018). The experience of patient and family carers experiences of MPM is relatively unexplored. We need more evidence to help us understand what is important to them and how care priorities can best be met. At the impact of increased asbestos use in some developing countries and the ongoing study of asbestos-related diseases, research to illuminate patients perspectives and experiences in those nations will be required.

Keywords: patient experience, Mesothelioma, quality of life
from thymic carcinoma as well as other mediastinal tumours such as carcinoids, diffuse large B-cell lymphomas and germ cell tumours. Accurate staging is also important. Using the 8th TNM system, this has greater prognostic significance than histological subtype. Assessment of completeness of resection is also vital, and may require discussion with the surgeon. However, histological subtyping may be more important in relation to Cancer. Thus, having recurrence. In relation to targeted therapies, there is no evidence for use of EGFR-related drugs, although there are isolated cases showing response to sorafenib and sunitib, which may be related to c-KIT and PDGFR status. However there are no routine diagnostic procedures at the present time. One putative marker is mesothelin, where strong expression has been associated with improved overall survival. In relation to immunotherapy, PD-L1 positivity within tumour cells is associated with high stage and more aggressive histologic subtypes and trials are ongoing. It seems likely that pathologists will be required to undertake these assessments in the near future.

Other Thoracic Malignancies

Throughout the mediastinum, pleura and lung, a multitude of other malignant tumours may occur. Although rare, the pathologist needs to be aware of these. Even within this group, knowledge of the molecular characteristics is important, with several mesothelioma tumours and lymphoproliferative diseases as well as rare epithelial malignancies having characteristic genetic abnormalities that aid in diagnosis and may provide targeted therapeutic options (Table 1). Some abnormalities may also point towards considering genetic screening of relatives (e.g. pleuropulmonary blastoma and Dicer1 mutations).

I. Wistuba

Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston/US

The primary induction of lung cancer is difficult to study in humans because patients often present very late in the course of their disease. Genetically engineered mouse models (GEMMs) have therefore emerged as crucial bridging tools underlying pathogenic mechanisms and clinical translation. Importantly, they reveal insights on the events and processes underlying tumor initiation and progression, studies which are not possible when employing transplantation or chemically-induced model systems. The recent advent of next-generation sequencing technologies has provided us with an in-depth characterization of the cancer genome of lung adenocarcinoma (LUAD) (1), squamous cell carcinoma (LUSC) (2) and small cell lung cancer (SCLC) (3). While these studies have highlighted the genetic complexities of lung cancers, attention is now focused on elucidating “driver” mutations that confer a growth advantage, from “passenger” mutations that have little impact on malignant transformation. Investigating the loss or gain-of-function of individual genes, alone or in combination, can be directly addressed using GEMM systems. The “gold-standard” lung cancer models are based on Cre-loxP recombination technology that enable the formation of autochthonous tumors from a limited number of somatic cells in a spatial and temporal fashion. Critically, tumors arise spontaneously in the lung, in the setting of an intact immune microenvironment. GEMMs are designed to harbor genetic mutations frequently identified in human lung cancer. Cre-inducible alleles are engineered to disrupt tumor suppressor genes (LoxP sites flanking key exons): that are removed upon Cre recombinase expression (and activate oncogenes (LoxP-flanked stop codons (lox-stop-box) that result in gene expression upon recombination). Cre-recombinase is delivered to the lung via inhalation or intratracheal injection of a recombinant adenovirus (Ad5) expressing Cre-recombinase under the control of a ubiquitous cytomegalovirus (CMV) promoter. Expression of Cre-recombinase directs the recombination of floxed alleles in a variety of epithelial cell types in the adult mouse lung (4.5). Utilizing this approach enabled investigators to interrogate the functional consequences of genetic alterations in human lung cancer through the generation of models of LUAD, SCLC and more recently lung LUSC (6). The recent advent of CRISPR-Cas9 gene-editing technology now enables us to interrogate the functional interaction between multiple genetic alterations in a high-throughput setting (7). Furthermore, the generation of cell type-specific Ad5-Cre viruses, that restrict Cre expression, and thus recombination, to alveolar type II (ATII) (Ad5-SPC-Cre), club (Ad5-CC10-Cre), neuroendocrine (Ad5-CDGRP-Cre) and basal (Ad5-K5-Cre, Ad5-K14-Cre) cells, have provided models of the cellular origins of different subtypes of lung cancer (9,10). Critically, unpatient-derived xenograft (PDX) models, one additional advantage of GEMMs is the ability to interrogate the interplay between tumor cells and immune cells present in the tumor microenvironment. Such studies are crucial given the success of immune checkpoint inhibitors in lung cancer patients. This presentation will outline lung cancer GEMMs commonly used in the field and how these models can be utilized to identify cancer initiating cells, understand the molecular pathways underlying tumorigenesis, the immune microenvironment of lung cancer, and importantly to identify vulnerabilities that can be exploited for the design of improved treatment modalities for patients. Establishment of preclinical lung cancer models that closely match patient tumor biology is imperative for developing therapeutic strategies with the most translational relevance. Non small cell lung cancer (NSCLC) cell lines or xenografts grown under 2D conditions or as cell line-derived xenografts (CDXs) are the most widely used models. They have been complemented with murine models engineered to develop lung cancer after introduction of specific genetic alterations (GEMMs). Lung cancer cell lines are readily amenable to mechanistic studies and economic high-throughput drug screening. However, for many NSCLC cell lines, the spectrum of mutations and copy number alterations have drifted considerably relative to patient tumors 1. This finding, in conjunction with long-term adaption to heterologous in vitro growth conditions, raise concerns about the extent to which cell line biology and potential drug responses can deviate from clinical tumors. GEMMs are powerful tools for studying specific oncogenic mechanisms in isolation in vivo, but these models lack the intratumoral heterogeneity of patient tumors, which is thought to play a major role in the development of drug resistance. Furthermore, ideally, GEMMs should be constructed using the appropriate cell of origin, which is challenging, as there are differences in the compositions of human and murine airways, and the cellular origins for most forms of lung cancer have not been established. NSCLC patient-derived xenografts (PDXs) overcome some of these limitations of the other models. They show much less genetic drift than cell lines, and their mRNA expression and the phospho-tyrosyl proteome more closely match patient tumors 1. We have established a large collection of NSCLC PDXs from surgically resected tumors and endobronchial ultrasound-guided (EBUS) and CT-guided biopsies. Tumor specimens were initially implanted in the subcutaneous flanks of NGS mice (NOD SCID gamma, non-obese diabetic severe combined immunodeficiency, gamma). The PDXs have been viably cryopreserved and cryo-sectioned and were re-implanted in NOD SCID mice. Most of our collection comprises the major histologic subtypes of NSCLC (52 adenocarcinomas (LUAD) and 62 squamous cell carcinomas (LUSC)). They, along with the primary patient tumors, are being molecularly profiled at multiple levels so that they can be optimally used for personalized medicine studies and novel integrated approaches to understand NSCLC pathogenesis, prognosis, and treatment. These levels include copy number variations, exome mutations, DNA methylation, mRNA expression, and protein expression at the protein level, the PDX models recapitulate the mutation spectrum, copy number variations, and gene expression of matched patient histologies. They also recapitulate sensitivity and resistance to known targeted therapeutics (e.g. EGFR inhibitors), and thus, can be used to dissect mechanisms underlying differential drug responses. Such studies are ongoing, including investigation of potentially new biomarker-targeted therapeutic combinations. We have also found that not all patient tumor fragments engraft successfully, and that successful engraftment correlates with poor patient outcomes of the patient 1. We are using this relative inefficacy of a new molecular fingerprint to predict clinical outcome, as well as understand the bases that distinguish less and more aggressive tumor behavior. In parallel, we have developed methods to grow organoids from primary patient-derived tumors and PDX models in 3D culture using Matrigel (PDO and XDO, respectively). For LUAD, both the PDO and XDO success rate of establishing bona fide organoid models is ~20%. Our stringent criteria include a minimum capacity of 10 passages and a split ratio of at least 1:3. We have been more successful to establish organoids with a success rate of 17%, and only from PDOs. So far, using these methods, we have established 4 models of each histology, which we have confirmed
form tumors when transplanted into mice. Molecular profiling indicates that the organoids maintain the same mutation spectrum and copy number variations of their parental tumor tissue. These models offer distinct advantages over PDXs and cell lines. As compared to standard 2D cultures, they recapitulate the appropriate tissue histology, and thus, possibly clinically relevant growth control mechanisms, even while growing ex vivo. This notion is further supported by the ex vivo protocols supporting gene expression patterns, which allows the organoids to be segregated into their respective tumor histologies when using signatures derived from patient or PDX material. Given the low cost, rapid growth rate, and ease in vitro manipulation, these models are ideally suited for rapid discovery and testing of new therapeutic strategies that can be matched to specific patient molecular profiles. In summary, generation of molecularly profiled PDX and organoid models offer great opportunity for translational and personalized medicine in NSCLC.

MTE03 CLINICAL TRIAL DESIGN WITH NOVEL LUNG CANCER THERAPY (TICKETED SESSION)
MONDAY, SEPTEMBER 24, 2018 - 07:00-08:00

MTE03.01 INCLUSION/EXCLUSION UPDATES (CNS METS, MULTIPLE PRIOR CANCERS, ORGAN DYSFUNCTION)
P. Ellis
Medical Oncology, Juravinski Cancer Centre, Hamilton/ON/CA

Introduction Randomized clinical trials (RCTs) represent the gold standard trial design for the evaluation of treatment interventions. Advancing knowledge in oncology has relied heavily on RCTs focusing on important outcomes such as overall survival (OS) and more recently progression free survival (PFS). Many examples exist, even in recent times, where the use of alternate study designs, such as cohort and case control series, have concluded benefit for a therapy that was subsequently disproven by RCTs. Nevertheless, an increasing number of therapies are being approved by licensing authorities such as the FDA based on intermediate outcomes such as objective response rate (ORR) from phase II clinical trials. Pragmatic versus explanatory trials RCTs can be either explanatory or pragmatic. Explanatory trials evaluate a treatment intervention under ideal conditions. They tend to have more restrictive inclusion and exclusion criteria to minimize the potential for confounding due to coexistent health problems. Pragmatic trials, on the other hand, evaluate treatment interventions in real life practice conditions. Inclusion and exclusion criteria are generally less restrictive and the results are considered more generalizable to the broad population of people with the underlying condition. RCTs in oncology are often explanatory in design. Inclusion criteria generally limit eligibility to the highest functioning patients. They often specify the type of diagnostic material needed and require samples to be available for correlative studies. Trials are generally very restrictive in regard to prior therapy that patients may have received and most trials require normal, or near normal organ function for eligibility. Exclusion criteria contain lengthy lists of criteria that make patients ineligible. Many trials exclude patients with brain metastases unless they have been treated and stable for some time. There are often lengthy lists of coexistent health problems, such as cardiac disorders, that commonly coexist in patients with lung cancer, that make an individual ineligible. The end result is that the generalizability of many RCTs is limited and healthcare providers need to extrapolate trial findings to a large proportion of their patients who might not have met inclusion and exclusion criteria for the trial studies. Despite this, the evidence of efficacy, Why should we rethink our current approach Historically, most advances from RCTs in lung cancer have represented small incremental gains in OS or PFS. Under these conditions, dependence on explanatory trials with multiple inclusion and exclusion criteria may have been appropriate to minimize the confounding effects from intercurrent problems. However, many changes have taken place in therapeutic options for lung cancer patients over the last decade. Our understanding of underlying molecular abnormalities important in lung cancer development and growth has increased greatly. Multiple agents targeting underlying molecular abnormalities have demonstrated ORR almost twice that of conventional chemotherapeutic agents, with similarly impressive improvements in PFS. Additionally, many newer agents have been developed that cross the blood brain barrier and have demonstrated significant anti-tumor activity in patients with CNS metastases as well. Given the improved tolerability of these agents and increased expectation of benefit from therapy, less stringent inclusion and exclusion criteria should be considered. Trials of targeted therapies should include a broader spectrum of patients including those with lower performance status and untreated CNS disease. Criteria focusing on organ function should be limited to known toxicity concerns for the therapy under evaluation. The emergence of treatments targeting activation of the immune system also represents a significant therapeutic advance. Some trials evaluating immune checkpoint inhibitors have been very restrictive for patients with CNS metastases. Nevertheless, responses are seen in patients with CNS metastases, questioning the need for such restrictive exclusion criteria. Patients with underlying autoimmune disorders are excluded from the majority of trials of immunotherapy agents. Some emerging data exists though suggesting that these agents may be safely given to patients with underlying autoimmune diseases. These findings highlight the need to modify inclusion and exclusion criteria for trials of immunotherapy agents to gain information of safety and efficacy in these populations of patients and to increase the generalizability of trial findings. Conclusions The advancement of knowledge in oncology remains dependent on well conducted RCTs. However, we need to question the rigidity of a number of common inclusion and exclusion criteria in an attempt to improve the pragmatic aspect of many trials and increase the generalizability of current RCTs.

MTE03.02 NOVEL TRIAL DESIGN FOR PRECISION MEDICINE
F. Blackhall
Manchester University and the Christie Hospital NHS Foundation Trust, Manchester/GB

Trial design for precision medicines has shifted to increasing use of platform protocols, ‘liquid’ biopsy and the practice of co-clinical trials using patient or circulating tumour cell derived (PDX/CDX) models. Epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors were the first class of precision medicine approved for advanced non-small cell lung cancer (NSCLC) but initially for unsellected patients following the traditional convention of phase I evaluation in heavily pretreated populations, phase II evaluation also in pretreated ‘all comers’, and then in large, randomised, phase III, double blind, placebo controlled studies versus best supportive care. The linkage between sensitising EGFR mutations and their prediction for efficacy came later. It now seems remarkable that these agents made it through to standard of care is questionable whether they would have been approved for all comers in the current health economic climate. The ‘EGFR story’ catalysed the current goal to integrate drug-target linkage early in drug development. This was achieved for the first in class ALK inhibitor, crizotinib, initially developed as a MET inhibitor but on discovery of ALK gene fusion and its potency for ALK a strategy to enrich for patients with tumours positive for ALK gene fusion by fluorescent in situ hybridisation (FISH) ensued. The phase I trial (PROFILE 1001) led to accelerated approval within 4 years on the basis of response rate, setting the paradigm of ‘enrichment’ studies for precision medicine development. (2) In parallel, platform studies using ‘umbrella’ or ‘basket’ protocol designs emerged to screen prospectively for multiple targets simultaneously and enrol the patient to a study arm designed for the target/biomarker(s).

Keywords: precision medicine trials

MTE04 COMPARISON OF VARIOUS RISK MODELS (TICKETED SESSION) MONDAY, SEPTEMBER 24, 2018 - 07:00-08:00

MTE04.02 WHERE SHOULD HEALTH PROGRAMS SET THRESHOLD FOR TAILORED SCREENING? J. Mulshine Graduate College, Rush University, Chicago/IL/US

Since the publication of the U.S. Preventive Services Task Force recommendation statement on lung cancer screening much discussion has focused on what is the critical information required to make an informed decision regarding the benefit of undergoing thoracic CT screening (1). Ever more sophisticated modeling approaches are being developed to better characterize the risk: benefit consequences of screening. This session will explore the current state of this complex issue. Yet as screening implementation builds momentum, more information is emerging about the information gleaned from thoracic CT obtained in a population of heavily tobacco-exposed individuals that may profoundly effect the screening health benefit discussion. A comprehensive analysis of diseases, injuries and risk factors across the United States from 1990 to 2016 was recently reported by a jointly sponsored consortium from the National Institutes of Health and The Bill and Melinda Gates Foundation, as a guide to investment for research, care and public health policy in the United States (2). According to that report, lung cancer including both the trachea and the bronchi was and remains the second leading cause of years of life lost in 2016. Even though, there was a 15% reduction in IHD mortality since 1990, ischemic heart disease still results in over 2.84 times more deaths than lung cancer. However, for both of these diseases, the age-standardized death rate is fortunately declining. In contrast for the third leading cause of death, chronic obstructive pulmonary disease (COPD), over that same 26 year interval, the total number of deaths has increased by 86.9%. Collectively, these three diseases, IHD, lung cancer and COPD account for over 44% of the mortality from the top 25 causes of years of life lost in 2016. As we consider risk developing risk models for lung cancer screening, it is used to develop strategies to better define risk. The most likely determinants of that individual’s life expectancy are the three most lethal diseases, IHD, lung cancer and COPD. Ever since we began to develop screening, we have known that large numbers of individuals can be included in the coughing up blood (hemoptysis) lung cancer screening CT, who will also be found that have asymptomatic but significant lung masses as a result of the National Lung Screening Trial entry criteria. Many researchers have shown that these guidelines may not be optimal for achieving the maximal lung cancer mortality reduction attainable through screening. Also, there is variability from country to country in lung cancer risk depending upon demographics, ethnic and racial mix, smoking incidence patterns and types of tobacco products. Individual risk prediction models that have been validated in the country and population group in which they will be used will assist in optimizing effectiveness and efficiency. Where to set the risk threshold will be a function of cost-effectiveness and will be the subject of this presentation. What are the components of a risk model and how do the various risk models compare, and which ones are available to use? This talk will review the risk models published to date. Also, several groups have considered several or even all of the factors. As we have just reviewing some advantages to certain models. The complexities of these model comparisons will be elucidated. Country to country variability will also be discussed. Models also differ in the number of variables they include. There are advantages to the parsimonious as they may be easier to use and may do less well in better defining risk. Given that different racial and ethnic groups have different risk profiles it should be important to characterize this risk and have one useable model that incorporates it rather than separate models for different groups. Another issue is how to fine operate of models into facilitating entry into screening programs. What are the strengths and limitations of electronic medical records for this process? CMS requires an “informed decision making” visit with a health-care provider prior to lung cancer screening. What ideally should this include and how should risk be discussed? As the field of oncology moves to a “precision medicine” approach lung cancer screening can be at the forefront of this effort. The goal of an effective and efficient strategy will hopefully translate into the most numbers of lives saved for the screenings done. It is a challenge our community can meet.

Keywords: lung cancer risk; CT screening; risk-based screening

MTE04.01 COMPARISONS OF RISK MODELS C. Berg Division of Cancer Epidemiology and Genetics, Us National Cancer Institute, Rockville/MD/US

Lung cancer unfortunately remains the leading cause of cancer death in the world. Lowering lung cancer mortality in the near term while efforts continue to halt the tobacco use epidemic would result from early detection with low-dose helical CT screening in countries with the health care resources to support this complex endeavor. Current guidelines from groups like the United States Preventive Services Task Force (USPSTF), the Centers for Medicare and Medicaid Services (CMS) and the Canadian Task Force on Preventive Health Care follow criteria for entry to screening that mimic the National Lung Screening Trial entry criteria. Many researchers have shown that these guidelines may not be optimal for achieving the maximal lung cancer mortality reduction attainable through
employed, before the development of symptoms and avoid the disabling burden of largely incurable advanced disease. Guidelines have already been established regarding the extent of lung and peribronchial tissue to be removed in thoracic CT scans as promoted by cardiac professional societies (8). In parallel developments, the pulmonary community is also finding compelling evidence for cardiovascular disease when evaluating for COPD (9). Finding from thoracic CT-detected diseases is frequently being reported on the radiologists’ report for lung cancer screening. Considerable progress has been made in developing predictive risk models for lung cancer in the screening setting (10, 11). However, from a patient’s perspective, a lung cancer-related risk assessment does not include the vast majority of risk-for-death information that is relevant to a heavy smoker that could be available on their screening CT in regard to the first and third leading cause of death (IHD or COPD) (2-9). Therefore when considering developing future risk outcomes tools for an individual deciding on whether or not to undergo CT screening for lung cancer, we perhaps need a more inclusive evaluation of health outcomes that consider the major knowable consequences of extensive tobacco exposure. The most recent Surgeon General’s Report released in 2014 and summarizing 50 years of studying tobacco health consequences, reaffirmed the causal inference of tobacco smoke to a lengthy list of diseases including most prominently, cancers, cardiovascular disease and chronic obstructive pulmonary disease (12). In discussions about other major chronic diseases such as diabetes or hypertension, people are educated about the multi-organ involvement of these diseases, so they have the information to better protect their health. The three leading causes of loss of life (IHD, lung cancer and COPD) in the United States cumulatively account for over 13,500 years of life per year. However, from a heavily tobacco-exposed individual’s perspective, lung cancer only accounts for 26% of this mortality burden. A thoracic CT scan can provide actionable risk information for all three leading tobacco-related causes of death. The most recent draft research plan for the United States National Cancer Institute explicitly evaluates lung cancer screening outcomes for impact on all-cause mortality. It is a critical time to consider more comprehensive tools to transparently inform about the relevant health information available with the use of thoracic CT imaging in heavily tobacco-exposed individuals.

MTE06 SYMPTOM MANAGEMENT IN MESOTHELIOMA (TICKETED SESSION) MONDAY, SEPTEMBER 24, 2018 - 07:00-08:00

MTE06.02 HOW TO REGISTER TOXICITY AND GUIDE PATIENTS L.达尔森

Mesothelioma UK. University Hospitals of Leicester NHS Trust. Leicester/GB

There are 125 million people exposed to asbestos in the workplace and it causes over 100,000 deaths annually (IOSH 2018). The UK has the highest incidence of Malignant Mesothelioma in the world with 2697 cases in 2015 (CRUK 2018). Approved treatment in the UK has not changed for over a decade with Pemetrexed being the only standard treatment widely available. However the last 2 years has seen an increase in clinical trial opportunities using both targeted and immunotherapy drugs. To help promote equitable access, Mesothelioma UK publishes a regular clinical trials update listing all trials that are open to recruitment (Mesothelioma UK 2018). These new treatment options have brought with them new challenges in terms of patient expectation, accessibility of treatment and side effects. McCambridge et al (2018) describe 2017 as a year characterised by several important advances in the field although only a minority are considered practice changing. This results in patients feeling anxious about the ongoing limited treatment options and frustrated by difficulties experienced in trying to access new treatment modalities. This presentation will briefly review current treatment options in the UK and how patients and health care professionals are kept informed about treatment and trial opportunities. Approaches to managing treatment expectation are explored and finally how health care professionals and patients are educated about side effects from new treatment modalities in and out of clinical trials. MTE07 MANAGEMENT OF PLEURAL RECURRENCE (TICKETED SESSION) MONDAY, SEPTEMBER 24, 2018 - 07:00-08:00

MTE07.01 FROM RADIATION ONCOLOGY PERSPECTIVE A. Rimmer

Radiation Oncology, Memorial Sloan Kettering Cancer Center, New York/US

Radiation therapy (RT) plays an important role in the multimodality management of thymic malignancies and is an effective local treatment modality with the goal of reducing the risk of local recurrence. It can be employed in the neoadjuvant setting for downstaging of mediastinal metastases and as adjuvant RT based on emerging data and general oncologic principles. It is important to evaluate the role of RT for pleural recurrence in the context of surgery and systemic treatment options as part of a multimodality approach and carefully coordinate the three modalities for optimal outcomes. Studies on the specific role of RT in pleural recurrences are sparse. However, there are several recent large database and population-based studies that indicate which patient subsets may benefit the most from RT. The indication and clinical setting for RT (perioperative versus definitive RT) depends on surgical resectability and operability of the patient. The adjuvant setting is the most extensively studied setting for RT in thymic malignancies. The greatest benefit of adjuvant RT appears to be in patients with newly diagnosed locally advanced stage III and IV thymomas, including patients with pleural dissemination. For thymic carcinomas the impact of adjuvant RT appears more significant. For incompletely resected thymic tumors there is a stronger rationale for adjuvant RT based on emerging data and general oncologic principles. The principles of adjuvant RT may be applied to surgically resected pleural recurrences as well. However, the role of definitive RT for pleural recurrences is an excellent treatment option. A subset of patients is technically or medically inoperable, due to invasion of critical structures such as the heart, great vessels, spine, esophagus etc. or comorbidities. In general, thymic malignancies are radiosensitive, allowing for long-term local control in medically inoperable, due to invasion of critical organs at risk. This may vary from treatment of a small tumor bed of a single pleural metastasis to hemithoracic pleural RT following an extrapleural pneumonectomy or lung-sparing pleurectomy/decoration in select cases. For inoperable or unresectable pleural recurrence, radiation therapy techniques is available to aid the radiation oncologist in optimally targeting the tumor bed, while maximally reducing the radiation dose to surrounding organs at risk. The radiation technique should be tailored uniquely to the needs of each individual patient’s presentation. Techniques include 3D conformal radiation therapy, intensity-modulated radiation therapy, proton therapy and intraoperative radiation therapy using high dose rate brachytherapy or low dose rate seed implantation. The extent of the radiation treatment field will depend on the intraoperative findings, pathologic result to date, proximity to and criticality of critical organs at risk. This may vary from treatment of a small tumor bed of a single pleural metastasis to hemithoracic pleural RT following an extrapleural pneumonectomy or lung-sparing pleurectomy/decoration in select cases. For inoperable or unresectable pleural recurrence, radiation therapy is an excellent treatment option. A subset of patients is technically or medically inoperable, due to invasion of critical structures such as the heart, great vessels, spine, esophagus etc. or comorbidities. In general, thymic malignancies are radiosensitive, allowing for long-term local control in medically inoperable, due to invasion of critical organs at risk. This may vary from treatment of a small tumor bed of a single pleural metastasis to hemithoracic pleural RT following an extrapleural pneumonectomy or lung-sparing pleurectomy/decoration in select cases. For inoperable or unresectable pleural recurrence, radiation therapy is an excellent treatment option. A subset of patients is technically or medically inoperable, due to invasion of critical structures such as the heart, great vessels, spine, esophagus etc. or comorbidities. In general, thymic malignancies are radiosensitive, allowing for long-term local control of multiple pleural metastases, including thymic tumors. Lastly, palliative RT should be considered whenever surgical management or definitive radiotherapy treatment options are not feasible. Conventional palliative RT is an important modality to improve quality of life by alleviating pain, treating SVC syndrome,
The pleural space represents the most common location for recurrence following resection of thymic epithelial tumors (TET). The rationale to include surgical resection in the management plan for these patients is based on small case series and reports, many from the European continent that demonstrate long periods of survival following pleural metastasectomy. Two large, retrospective series of patients with pleural disease have been recently published, both of which reflect pooled data from multiple institutions: one from Europe and the other from Japan. Despite this, little prospective data address this issue. In addition, the management strategy for pleural disease in patients with TET is extrapolated from the management of primary TET in the mediastinum, where surgical resection plays an important role. Prognostic factors after surgical resection for pleural disease mirror those that are most consistently reported for primary mediastinal TET. Most case series of patients undergoing resection for pleural disease (either recurrence or initial presentation) suggest that the ability to completely resect the disease is an important prognostic factor. The surgeon wishes to perform the least amount of resection possible while still rendering the patient grossly disease free. Metastasectomy may range from the resection of a single pleural lesion to an extensive parietal pleurectomy with or without pulmonary resection(s) for visceral pleural involvement of metastatic deposits. On occasion, the surgeon may explore the chest of a patient with the intent of performing metastasectomy, but instead encounters diffuse innumerable visceral and parietal pleural metastatic deposits. In this case, EPP may be the optimal option to render the patient grossly disease free. Patients should always be prepared for this development whenever operating on a patient for metastatic TET, so that an educed decision can be made to proceed with EPP at the time of exploration, if necessary. EPP, however, may not be a good option for patients with thymic carcinoma that has metastasized to the pleural space given the magnitude of this disease burden in hopes of increasing the likelihood of complete resection. Once again, this strategy appears to be safe and associated with encouraging rates of complete resection and survival, but definitive data confirming a benefit are lacking. In summary, the surgical resection of pleural recurrence of TET is associated with prolonged survival in selected patients, as reported in many case series. However, given the lack of controlled studies, it is unclear if prolonged survival is a direct result of the surgical approach or simply selection of patients with more forgiving tumor biology. Despite this, a rational approach may be to invoke a surgical approach as the initial strategy in patients with thymoma whose disease appears to be resectable. Once surgical options have been exhausted, or the disease is clearly unresectable, systemic therapy and/or radiotherapy can be utilized to achieve further disease control. References: 1. oncology team needs adequate knowledge and skills in the delivery of a tobacco dependence treatment intervention. Although many healthcare providers may know about the devastating health effects of smoking and tobacco use, including lung cancer, few received the necessary training to deliver an evidence-based intervention. Many educational resources are available as listed in Table 1. Basic content of educational programs to support delivery of a smoking cessation intervention includes information about health risks of smoking and exposure to secondhand smoke, nicotine dependence and withdrawal, health benefits of quitting, evidence-based methods for supporting tobacco dependence treatment including behavioral interventions (i.e., social support and skills training), identification of triggers for relapse and how to manage withdrawal symptoms and cravings, and knowledge of FDA-approved pharmacotherapy, including side effects and toxicity. With the advent of the electronic medical record (EMR), tobacco use is often included as core information at patient intake with reminders to providers increasing the rates of advice and assessment. The EMR may be tailored to include easy-to-use prepopulated “Smart sets” for intervention with information about approved medications and referral options as well as downloadable materials for patients and families. The EMR can push alerts to clinicians to prompt treatment. Inpatients who are identified as smokers can be offered nicotine replacement therapy (NRT) to alleviate withdrawal symptoms, regardless of their desire to quit long-term. Changes in the healthcare environment also can support implementation of these recommendations. These include adopting smoke-free policies in healthcare settings, beyond the inpatient hospital, and supporting quit efforts of healthcare providers. Although smoking is declining among healthcare providers, this may be an issue in some settings and in some geographic areas. Smoking of the healthcare provider has been associated with decreased interventions and confidence in providing a patient with patient. Promoting the smoking cessation support services provides an opportunity to support the quit efforts of healthcare providers as well. Providers’ support of patient quit efforts is essential regardless of the smoking status of the individual clinician. Table 1. Resources to support implementation of tobacco dependence treatment in oncology clinical settings

**MTE09 MANAGEMENT OF ADVANCED WILD-TYPE LUNG CANCER IN SPECIAL SITUATIONS (TICKETED SESSION)**

**MTE09.01 EVIDENCE BASED MANAGEMENT OF THE PATIENT OVER 80**

E. Quoix

Pneumology, University Hospital, Strasbourg/FR

Lung cancer is the first cause of death by cancer in the entire world. In the US the estimated number of new lung cancer cases in 2018 is 234030 with an estimated number of deaths of 154050 (25% of all cancer deaths) (1). Due to the conjunction of two factors (increased incidence of cancer with age and increase of life expectancy), median age at diagnosis is now 70 years in the US. The probability of developing a lung cancer is 6.1% after 70 years of age in males and 4.8% in females to be compared with respectively 1.9% and 1.4% between 60 and 69 years (1). Seventy years is also the cutoff most frequently used to define eligibility for clinical trials of systemic treatments (2) (3) (4). Although, octogenarians represent a non negligible part of the patients, lung cancer is most frequently diagnosed among people aged 65–74 years (33.4% of the cases) whereas
26.8% are diagnosed between 75 and 84 years and 9.4% after 84 years (https://seer.cancer.gov/statfacts/html/lungb.html). Non-small cell lung cancer (NSCLC) represent 85% of all cases whatever the age of diagnosis and, between 2007 and 2013, 57% of them were diagnosed at a metastatic stage (1). Thus systemic treatment to be applied in older patients is of paramount importance. Patients without targetable mutations and with a PD-L1 expression <50% should be considered for chemotherapy whereas those with a PD-L1 expression >50% should be considered for immunotherapy by Pembrolizumab as first line therapy (5). Recommendations for fit patients with no targetable mutations are to give a platin-based doublet (4 to 6 cycles) followed by a maintenance therapy in patients with no progressive disease at the end of the induction cycles. In non-squamous cell carcinoma, bevacizumab may be added in the absence of contra-indication (5). Regarding chemotherapy for older adults, we have some specific trials (Table 1). The first point of these studies is that elderly patients do benefit of chemotherapy. Second point is that a non platin-based doublet does not provide any survival benefit compared to single agent therapy and third, carboplatin-based doublet (especially monthly carboplatin + weekly paclitaxel) provides an important survival benefit over single agent alone for elderly patients with PS 0-2 (6). In this study subgroup analysis showed that the survival benefit of a doublet compared to single agent therapy was also observed in the octogenarians. We have no data regarding maintenance therapy in elderly patients. The benefit/risk ratio is not in favor of bevacizumab after 70 years (6). The case of immunotherapy in elderly patients is of importance as the increased incidence of cancers in this population may be due to immune dysfunction (7). However, we do not have studies dedicated to elderly patients and data are obtained from subgroup analyses of studies with no upper limit of age (with the risk of selection biases). Pembrolizumab was compared to chemotherapy in patients with PD-L1 expression >50% and resulted in a survival benefit (8). Moreover in a recently published trial, addition of Pembrolizumab to chemotherapy as first-line therapy resulted also in a survival benefit compared to chemotherapy alone (9). Although there were some patients aged 80 years and more in these trials, specific studies are lacking and should be implemented. With reference to second line treatment, there are also no specific trials for elderly patients although erlotinib was due as second line therapy in one randomized trial (10) with similar results as observed in the octogenarians. Pembrolizumab was compared to chemotherapy in patients with PD-L1 expression >50% and resulted in a survival benefit (8). Moreover in a recently published trial, addition of Pembrolizumab to chemotherapy as first-line therapy resulted also in a survival benefit compared to chemotherapy alone (9). Although there were some patients aged 80 years and more in these trials, specific studies are lacking and should be implemented. With reference to second line treatment, there are also no specific trials for elderly patients although erlotinib was due as second line therapy in one randomized trial (10) with similar results as observed in the octogenarians.

MT09 MANAGEMENT OF ADVANCED WILD-TYPE LUNG CANCER IN SPECIAL SITUATIONS (TICKETED SESSION)
MONDAY, SEPTEMBER 24, 2018 - 07:00-08:00

MT09.02 MANAGEMENT OF THE PS 2 PATIENT

J. Schiller
Inova Schar Cancer Institute, Falls Church/VA/US

Patients with poor performance status (PS) of 2 represent a heterogeneous group of patients and a large proportion of the non-small cell lung cancer patient population (about 30–40 percent). Assessment is complicated by the influence of comorbidities versus disease burden on performance status and treatment outcome. The treatment of PS 2 patients was of particular interest in the late 20th/early 21st century. Studies evaluating that impact of performance status on outcome have shown that a poor performance status is also a poor prognostic indicator. ECOG 15818 showed that patients with a performance status of 0, 1, or 2 and median survivals of 36 weeks, 26 weeks, and 10 weeks, respectively. The toxic death rate was 3 percent, 2 percent, and 10 percent respectively (1). Despite their poor prognosis, studies have shown that PS 2 patients do benefit from chemotherapy. Gridelli et al randomized patients 70 years or older with a PS of 0-1 to best supportive care versus a single vinorelbine (2). A statistically significant improvement in overall survival was observed (relative hazard ratio of death for vinorelbine-treated patients was 0.65). Other studies compared single agent versus doublet therapy in PS2 patients. Obasaju et al (3) randomized patients to single agent gemcitabine versus gemcitabine plus carboplatin in a US oncology trial in PS2 non-small cell lung cancer patients. Median survival was 5.2 months in the single agent arm versus 6.9 months in the doublet arm; overall response rates were 11.5% versus 36%, respectively. Another trial (4) (Reynolds, JCO, 2009) also randomized PS2 patients to gemcitabine versus carboplatin and gemcitabine and also found an improvement in response rate, progression free survival, and overall survival, although only the difference in response rate was statistically significant. Dr. Lilenbaum reported the results of CALGB9730, a study of single agent pemetrexed versus carboplatin and pemetrexed. Patients with PS 2 who were treated with carboplatin and pemetaxel had a 4.7 month survival versus 2.2 months in PS2 patients treated with pemetrexed alone. In 2013, Zúñik and colleagues presented the results of a phase 3 comparison of single agent pemetrexed versus combination pemetrexed plus carboplatin chemotherapy in patients with performance status 0–2
and no prior chemotherapy. The response rates were 10.3% for single agent pemetrexed versus 23.8% for the combination of carboplatin and pemetrexed. In the attempt to treat stable disease, the median PFS was 2.8 months for single agent pemetrexed and 5.8 months for the combination. Median overall survival was 5.3 months for pemetrexed and 9.3 months for the combination; one-year survival rates were 21.9% and 40.1%, respectively. Doublet therapy has also been accepted as standard of care compared in PS2 patients. ECOG 1599 was a phase 2 randomized trial for PS2 patients, in which patients were randomized to dose attenuated carboplatin plus paclitaxel or gemcitabine plus cisplatin. Disease control rates (RR and SD), time-to-progression (TTP), progression free survival (PFS) and survival results are similar for the two regimens. PCb yielded more grade 3–4 neutropenia, neuropathy and grade 1 arthralgia/myalgia. GC caused more grade 3 thrombocytopenia, fatigue, nausea and grade 1 nephropathy. 6) There is less data as to how these patients respond to immunotherapy, since the phase 1b trials have been excluded in many clinical studies. However, several nivolumab studies have included patients with a performance status of 2. CheckMate 171 was a European, single arm, phase II study in previously treated patients with metastatic squamous cell carcinoma of the lung, which included patients 70 years and older or with poor performance status. 7) A total of 809 patients were enrolled, 98 of whom had a performance status of 2. Baseline characteristics and prior therapy in the PS2 subgroup were consistent with those in the overall ambulation, with the exception that the PS2 subgroup had fewer complete or partial responses as best response to most recent therapy. The safety profile of nivolumab was also comparable between the overall patient population and those with a performance status of 2, with 46% grade 3 or 4 (TRAEs) and 5% TRAEs leading to discontinuation. Overall survival was low were in the PS2 patients (median 5.4 months compared to a median of 9.9 months in the overall patient population). 14 percent of all patients had a complete or partial response compared to 11 percent of PS2 patient. CheckMate 153 was a phase ⅓ study which evaluated the safety of nivolumab monotherapy in patients with previously treated metastatic non-small cell lung cancer in the US and Canada. 1375 patients were enrolled. 123 of whom had a performance status of 2. The frequency of grade 3 or 4 adverse events was 12% in patients with a performance status of zero or one compared to 10% in patients with a PS of 2. Grade 5 events were less than 1% in the PS 0-1 patients and was 2% in the PS 2 patients. Six-month and 1 year overall survival rates in the PS2 subgroup was lower than in the PS0-1 subgroup (10.5 months vs. 15.9 months, respectively) and one year overall survival rates of 44 percent versus 17 percent. Significant improvements in symptoms burden were observed in the PS2 patients at most time points, with improvement in quality of life starting at week 2 and onward. 8) CheckMate 169 was an expanded access program involving nivolumab in previously treated patients with advanced non-small lung cancer in 161 patients. Baseline characteristics were generally the same in the PS2 patient population as the overall patient population. The safety profile was also comparable, with rates of any grade or grade 3-4 TRAEs, and TRAEs leading to discontinuation were also similar. Median survival was 5.9 months in the PS2 patients and 9.1 months in the overall patient population. 9) Taken together, these studies show that patients with advanced non-small cell lung cancer and a poor performance status have a poor prognosis than those with a PS of 0 or 1. The data regarding TRAEs is more variable, with some studies suggesting they are comparable to those observed in PS 0 or 1 patients, while others report a higher incidence of TRAEs in PS 2 patients. Despite this, however, PS2 patients derive a benefit from chemotherapy when compared to no therapy, and doublet therapy vs single agent. Randomized trials with immunotherapy are lacking; however, retrospective data suggests that the toxicity data is comparable to those observed in PS 0 or 1 patients, while others report a higher incidence of TRAEs in PS 2 patients. Despite this, however, PS2 patients derive a benefit from chemotherapy when compared to no therapy, and doublet therapy vs single agent.

**MTE11.02 BIOLOGY OF SMALL CELL LUNG CANCER (TICKETTED SESSION)**
**TUESDAY, SEPTEMBER 25, 2018 - 07:00-08:00**

**MTE11.02 BIOLOGICAL SUBSETS OF SCLC**

**C. Rudin**
Memorial Sloan Kettering Cancer Center, New York/NY/US

Small cell lung cancer (SCLC) is an exceptionally lethal cancer for which new therapeutic approaches are needed. Over the past few years several research teams have applied global profiling approaches to characterize the SCLC genome, epigenome, transcriptome, and proteome. Despite the seemingly homogeneous microscopic appearance of SCLC, these studies have consistently suggested the presence of biologically distinct subsets of disease. Parallel studies across libraries of patient-derived xenografts and in a diversity of genetically engineered mouse models of SCLC have
validated these subset distinctions. Some models suggest that these subsets reflect parallel programs of oncogenesis, perhaps emerging from distinct cell lineages. Conversely, other data suggest that these subsets are largely distinct, with little overlap among disease subsets, or at least that transition from one phenotypic subset to another is possible. Most exciting from a treatment perspective, several research groups have reported unique therapeutic vulnerabilities among these subsets. Detection of these vulnerabilities among patients is actively tested in SCLC patients, and emerging correlative data further confirm the predicted differential sensitivities among SCLC subsets. Together, these studies advocate for a very different approach to clinical translation of immune inhibitors that has taken to date. In all SCLC, the same, a more successful approach may be to consider focused trials among biomarker-selected subsets of disease, exploiting the distinct dependencies and vulnerabilities of biologically relevant subsets. This presentation will highlight some of the recent preclinical studies that have defined determinants of these subsets, together with recent clinical work emphasizing their importance to the field, and to our patients.

Keywords: subsets, omics, small cell lung cancer

MTE12.01 IS IO AN OPTION FOR PATIENTS WITH CONTRAINDICATIONS (AUTO-IMMUNE DISEASE, PULMONARY FIBROSIS, HIV, HEPATITIS, TRANSPLANT ETC)

A. Robinson
Oncology, Queens University, Kingston/ON/CA

This session will focus on an approach to making informed decisions for patients who are limited from the pivotal clinical trials of immunotherapy. The non-comprehensive presentation will focus on some distinct clinical entities (HIV, Hepatitis B&C, Tuberculosis), select auto-immune diseases (AIDs), and organ transplant patients, and illustrate an approach to use clinically. Information from reports of similar patients treated with immunotherapies is informative[1, 2], however caution is required in interpreting these reports as both selection and reporting bias may occur. There are six key questions that need to be considered prior to starting therapy – accepting that many of these answers have a high degree of uncertainty. Decisions are based on case collaboration with disease experts; evidence from published and presented studies and reports; and biologic plausibility/pathogenesis. 1: What is the benefit and toxicity of this therapy compared to it's alternatives in the absence of contraindications? 2: How may the underlying condition impact the benefit and toxicity? An understanding of the condition and co-management with other specialists is desirable. Is there a potential for benefit or harm from activating T-cells? The potential impact is estimated from: critically reading cohort studies/case series/case reports; discussions with specialist colleagues for understanding disease pathogenesis; and understanding where the patient is in the spectrum of their comorbid disease. Consider possible effects on the organ at risk, but also other organs (i.e. extra-colonic manifestations of ulcerative colitis; extra-articular manifestations of rheumatic disease etc.), and whether there is any impact on toxicities unrelated to underlying condition. For auto-immune disease, the cohort studies of Leonardi et al and meta-analysis of Abdel-Wahab are informative. Leonardi et al included 56 patients with NSCLC and a history of auto-immune disease treated at several large treatment institutions over 3 years. Most patients were asymptomatic from their AID at baseline. Abdel-Wahab et al included 123 patients, but did not restrict to lung cancer, and included patients treated with both CTLA-4 and PD-1 inhibitors. For Leonardi et al, 5 of 10 patients who were symptomatic had a disease flare or worsening, while 8/46 who were not symptomatic at baseline had a flare. The vast majority of these patients were treated in second or above line (84%). The Abdel-Wahab paper revealed 75% of patients had a disease exacerbation or immune-related adverse event even or both, however 46% of patients were symptomatic from their AID at baseline. Case reports and small series are available for solid organ transplant, while prospective cohorts and retrospective cohorts are available for some chronic infections. Given the significant biases inherent in these case series and reviews, a prudent approach to most auto-immune diseases is to assume that disease may worsen/recur, and to monitor and intervene early. Also assume that there are some patients who will not worsen, either because of a lack of functioning immune system/burning out of initial disease/for other reasons. Disease specific recommendations and considerations (Multiple Sclerosis, Guillain-Barre, Crohn’s/UC, and inflammatory arthritides) will be discussed in the session. 3: How may concomitant medications impact the benefit and toxicity, when/how to these medications if possible. This impact is estimated from cohort studies, case reports, biological rationale, and discussion with specialist colleagues regarding alternative therapies with potentially less impact on T-cell function. While cohort studies have been varied in showing an impact of immuno-suppressive medications on immune therapy response, the data remain extremely sparse and biologic rationale is used for decision making. A general approach would be to use the lowest dose feasible with the most targeted approach feasible for the underlying disease. It is plausible that gut-specific therapy for IBD (i.e. vedolizumab), will have less effect on Tumor T cells than systemic steroids, anti-TNF agents, etc. There is very little collective published experience in this area. 4: If this patient requires immune suppression for toxicity, are there special considerations or risks? Information from clinical trials and population studies help determine the likelihood of immune suppression. Expertise from specialist colleagues may be required to understand how to mitigate the effect of immunosuppression before or during immunosuppression. This is particularly true for infectious diseases that may have exacerbations with prolonged courses of immunosuppression (hepatitis B, TB etc). Suppressive or eradicative anti-infectious medications may improve safety of subsequent immunosuppression and may be considered. 5: Does the patient have the reserve to tolerate the expected or possible toxicities of the immunotherapy? Physician judgement/experience and a knowledge of how clinical trials toxicities translate to the ‘real’ world are needed. Patients with certain immune or non-immune underlying conditions that result in a decreased patient/organ reserve may be less likely to tolerate toxicities. For instance, an asymptomatic pneumonitis (Grade 1 toxicity) in a relatively fit patient may translate to a grade 4/5 toxicity in a patient who at baseline is oxygen dependent with near-end stage pulmonary disease. 6: If I proceed with IO therapy, how do I monitor to intervene early if complications arise? Other than ‘routine’ monitoring; How do I monitor for the infectious disease; transplant rejection; or auto-immune flare? Most of the published experiences with toxicity suggests that reversibility of toxicity may occur with early intervention. Thus monitoring is required and will be disease specific. Ideally, a monitoring plan agreed upon by both the oncologist and the disease specialist will be explicit. Patient education is crucial, as many of these diseases will present clinically and not through testing. REFERENCES 1. Ostios-Garcia, L., et al. MTE12.02 HOW CAN WE MINIMIZE TOXICITY FOR OUR HIGH RISK PATIENTS?

M. Nematiollahi
William Osler Health Center, Brampton/CA

This session will focus on strategies and innovative approaches to minimize cancer immuno-therapy toxicities. Immune checkpoint inhibitors (ICI) are a new class of anti-neoplastic agents termed immuno-therapy, and are now standard of practice for lung cancer population including elderly with comorbidities. These agents have significantly impacted patient outcomes by offering durable responses. However, the effective and safe delivery of these agents require expertise in understanding the unique characteristics of the ICI (Immune Checkpoint Inhibitors) that differ from cytotoxic chemotherapy. Certain immunotherapy protocols may have up to 50% rate of developing severe irAEs. The number of indications of ICI treatment is rapidly evolving and broadening thus being proactive in developing a specialized clinic for these patients would not only centralize care and optimize efficacy but minimize toxicities in high risk population. Currently there is a large unmet need for an education class for patients prior to starting immunotherapy. Many centers have chemotherapy teaching class which are attended by all patients prior to starting chemotherapy, however the information regarding toxicities does not apply to ICI and could lead to under reporting of irAEs particularly in high risk population with comorbidities and elderly. At William Osler Health Center, under supervision of Dr. Parneet Cheema an immune-oncology clinic has been established. Objective: The objective of this initiative is to generate a standardized, reproducible, and safe implementation immunotherapy program that could be easily recreated at any community cancer center. This presentation will discuss the clinic design, immunotherapy teaching class, logistics and standardized ICI delivery, care monitoring, and follow-up.

MEET THE EXPERT SESSIONS

INVITED SPEAKER 
MEET THE EXPERT SESSIONS

A recent observation study on the management of lung nodules 8 mm to 20 mm by community pulmonologists in the US showed a high benign biopsy rate of 62% and benign surgical resection rate of 35%. 

Furthermore, the surgical resection rates were similar irrespective of the pre-test probability of malignancy risk. 

The study suggested there is a lack of adherence to nodule management guidelines. However, there are a number of lung nodule management guidelines and lung nodule malignancy risk prediction tools. 

Some are based on 2D diameter size measurement while others used volumetric measurement or a combination of both. New nodules with a prior negative CT have a higher probability of malignancy even at a smaller size. 

Comparing to baseline screen, the malignancy risk of new nodules is higher for nodules <8mm. Computer assisted diagnosti (CAD) tools facilitates volume measurement and reduce inter-observer variability but they may not be generally available. Volumetric measurement is particularly useful for comparison of serial scans for evidence of growth. Growth independent nodule characteristics such as right upper lobe and central distribution may further improve volume based new nodule malignancy prediction. Nodule size and growth are the most important parameters for malignancy. To measure size accurately especially to determine malignancy risk, it is necessary to address standardization of technical requirements related to the scanners and image acquisition protocols.

The action thresholds for early recall CT imaging study, PET/CT or biopsy vary in different guidelines with major differences for non-solid nodules making it difficult for clinicians to remember or apply. Therefore, a lack of adherence might be related to the scanners and image acquisition protocols.

MEET THE EXPERT SESSIONS

Thoracoscope is, by its original meaning, defined as an endoscope through an intrathoracic lumen, just like a bronchoscope for the bronchial lumen. But today this endoscope has been widely accepted as a surgical instrument to perform various kinds of intrathoracic procedures which had been otherwise done with open thoracotomy. Video-assisted thoracoscopic surgery (VATS) has been expected to reduce the surgical burden, and already applied for the complex approach for lung cancer. It is now a part of our routine procedures. However, despite the minimally invasiveness of the procedure, VATS may become a risky surgery in several special situations. Not only the surgeons, but also pulmonologist, mediastinal oncologist, or radiation oncologist should know the nature of the surgery, and the situations in which VATS should be rather avoided. In this MTE sessions, I would like to present the special situations in which the VATS procedures are at too high risk, and therefore, and are not considered to be performed. HIGH-RISK SURGERY

When done the surgery become at high risk? In what situation, we should think the surgery is at high risk? Generally, there must be two kinds of situations each alone or both combined, which make the surgery at high risk. One is the patient at high risk for surgery. Two is the VATS lung resections at technically high risk.

LUNG RESECTIONS AT TECHNICALLY HIGH RISK 2-1. DIFFICULT ONE-LUNG VENTILATION. One-lung ventilation, collapsing the entire lung of the operative side, is an indispensable part of the stable VATS procedure. Thoracic surgeons are usually filled with expanded lung, and only very limited space is left when the lungs are aerated. To make VATS procedures possible, deflation (collapse) of the lung on affected side is indispensable, which provides the space for observation and working of thoracic instruments. Therefore, for patients who cannot tolerate one-lung ventilation because of the limited pulmonary reserve or previous history of lung resection, VATS is generally not indicated. For these patients, we consider routine open thoracotomy with intermittent collapse of the side of lung next to the lesion. 2-2. THE VATS PROCEDURE IS RIGHT, but the resection is not feasible. Tight adhesions might exist within the thoracic cavity, especially for patients with the history of pleurisy or surgery. As seen previously, the working pleural space is an indispensable element of a VATS procedure. Surgeons are concerned about such history in case VATS resection is indicated.

There are several types of adhesions which make VATS procedure difficult. Examples for these conditions are as follows: 1) Previous pleurisy. If intrathoracic adhesion, mostly due to the previous pleurisy, is extensive, it is impossible to have an enough working space. In fact, lung under thoracoscopy procedure is done, but it is usually done with significant amount of blood loss. There might be even a higher risk of damaging the visceral pleura and lung parenchyma, which may cause prolonged air leakage especially in the elderly with bullous lung. Therefore, except for a collapsed lung, the extrapleural adhesions should be respected as a contraindication and a case which should be converted to the open thoracotomy.

2) Adhesions at pulmonary hilum ("Frozen hilum"). In some cases with past history of infection such as tuberculosis, the hilar nodes are tightly adhesive to the bronchovascular structures. This is extremely difficult situation even for routine lobectomy. VATS resection for such cases are hardly considered. 3) Previous thoracotomy. Major lung resection after previous lung resection involving the hilum (for example, a completion right lower lobectomy after previous wedge lobectomy) has been otherwise done with open thoracotomy. Also, for these operations, VATS resection is rarely indicated. 2-3. COMPLEX PROCEDURES. Among various procedures in thoracic surgery, complex procedures are thought to be done safely by open thoracotomy, and not by VATS. This might include the following; such as bronchovascular plasty, combined resection with neighboring structures, pneumonectomy, and pleuropneumonectomy. 2-4. OTHER SITUATIONS WHICH MAKE VATS PROCEDURE AT HIGH RISK 1) Complex anatomical variations. In some cases, the bronchial or vascular structures are too close to the trocar port or access thoracotomy, but also, they might be crushed during being extracted, which may result in tumor dissemination. 3) Special locations. In the intrapulmonary and mediastinal lesions, there are special locations where the thoracoscopic instrumentation is quite difficult: Lesions located at mediastinal aspect of the lung, and those close to hilum. Mediastinal mass (swollen lymph nodes) adjacent to...
the vital structures such as great vessels is also least suitable for this technique because of danger of massive bleeding.

MT16 WHAT IS CHANGING IN THE MANAGEMENT OF PULMONARY NEUROENDOCRINE TUMOURS? (TICKETED SESSION)
TUESDAY, SEPTEMBER 25, 2018 - 07:00-08:00

MT16.01 PROPER TREATMENT OF LCNEC; CHEMOTHERAPY OR TARGETED TREATMENT
S. Thongprasert
Oncology, Bangkok Chiangmai Hospital, Chiang Mai/TH

Neuroendocrine Tumors of the Lung consisted of two subtypes which is small cell lung cancer (SCLC) and large cell neuroendocrine carcinoma (LCNEC). Both subtypes represent around 15% of all Lung Cancer. The incidence of LCNEC was quite low as compare to SCLC. However both are aggressive and poor prognosis. The treatment of LCNEC was usually followed the SCLC. In early stages (I-II-III), surgery is recommened but does not seem to be sufficient. Platinum-based adjuvant chemotherapy may be useful while the role of neoadjuvant chemotherapy is still not well defined. In patients with advanced stage LCNEC, the chemotherapy regimens used in SCLC which is cisplatin plus etoposide remain the standard of treatment, but results are not satisfactory. Due to their peculiar clinical and biological features and the lack of literature data, there is an emerging need for a consensus on the best treatment strategy for LCNEC and for the identification of new therapeutic options. In this review, we will discuss the key aspects of LCNEC management and the possibility of using the gene sequencing to clarify the selection of chemotherapy regimen.

TUESDAY, SEPTEMBER 25, 2018 - 07:00-08:00

MT16.02 THE MANAGEMENT OF SMALL CELL LUNG CANCER FOLLOWING FIRST LINE TREATMENT FAILURE
G. Goss
Division of Medical Oncology, Department of Medicine, University of Ottawa, Ottawa/ON/CA

SCLC remains a clinical challenge that has not benefited from the same medical advances in recent years as non-small cell lung cancer (NSCLC). Beyond first line chemotherapy, there are few approved therapies for recurrent small cell lung cancer (SCLC). A multitude of agents have been tested over the past decades, yet little improvement has been made in survival rates. This talk will review previous efforts in treating SCLC upon progression after first-line therapy, the current science that is changing our understanding of the biology of SCLC and will discuss the evidence for new agents in this indication, by reviewing recent and current clinical trials. The addition of platinum agents to first-line chemotherapy regimens in the 1980’s improved overall response (OR) and complete response (CR) rates, and thus platinum doublet chemotherapy, most commonly in combination with etoposide, is the current standard of care.1 SCLC is initially very chemosensitive, OR rates to platinum-etoposide chemotherapy in the first line setting for limited disease (LD) are between 60-90% with CR rates of 40-70%, and one third of patients will survive 5 years and be considered cured. The prognosis is far less optimistic for the two thirds of patients with SCLC who are diagnosed with extensive-stage (ES) disease. OR rates for ES SCLC are 40-70%, and CR rates are 10-20%.4,5 The median progression-free survival (PFS) in the first-line setting is in the order of 15 months for LD6 and 6 months for ES.4 Unfortunately, the high response rate seen in the first line setting is not maintained when patients are retreated. Patients can be classified into three groups based on their response to initial chemotherapy; sensitive tumors response > 90 days, refractory within 90 days of completing primary therapy and refractory (non-responders and progression on treatment).2 Therapeutic options therefore include re-challenge for those patients with sensitive disease or a change of regimen. Topotecan has been approved by the FDA since 1996 for the second-line treatment of SCLC following first-line relapse.7 There are additionally several guideline-recommended therapies that are not FDA/EMA approved, such as cyclophosphamide/doxorubicin/vincristine (CAV), irinotecan (Cape), paclitaxel, gemcitabine, temozolamide and nivolumab with ipilimumab.8 Response rates to second line therapy are 27% at best and less than 15% in chemo-refractory cases, with a median time to progression of only 13 weeks.10 Despite decades of testing with multiple agents, there have been no new drug approvals in over 20 years and improved therapy is urgently needed.20 With the advent of targeted therapies over the past decades, there has been no such large trial of early phase clinical trials in SCLC. However, these agents have yet to demonstrate success in phase II-III evaluation. The lack of progress in improving survival rates for SCLC led to its inclusion in the U.S. Congress’ Recalcitrant Cancer Research Act in 2012. Subsequent comprehensive molecular characterization of the disease has led to a better understanding of known molecular vulnerabilities and has pointed to new areas requiring therapeutic interrogation. Examples include developmental regulatory pathway abnormalities, DNA damage repair abberations, and the manipulation of the immune response. Fundamental to further therapeutic progress remains the challenge of understanding the mechanisms that underlie the rapid emergence of chemo-resistance in SCLC. Recent reports of early phase clinical trials with immune checkpoint inhibitors documenting important response and survival rates provide tangible hope for the approval of new therapeutic options. However, immune strategies should exclude the empiric testing of new monotherapies and combinations in the absence of strong pre-clinical science. This will necessitate the development of next generation pre-clinical models, that are biologically representative of the human immune system and disease. Finally, improved translational research will inform more rational clinical trial design, and concentrate resources towards the most promising therapeutic avenues. References: 1. MT17 LIVING WITH AND BEYOND Lung Cancer: An Education for Advocates (TICKETED SESSION)
TUESDAY, SEPTEMBER 25, 2018 - 07:00-08:00

MT17.01 LIVING WITH AND BEYOND LUNG CANCER: AN EDUCATION FOR ADVOCATES
A. McNamara, W. Boercke, R. Rigney
1Information Development, Irish Cancer Society, Dublin/Ireland. 2Social Service, Cancercare, Syosset/US. 3Lung Cancer Alliance, Washington/DC/US

Who is this session for? This session is aimed at lung cancer advocates, including members of healthcare teams and advocacy organisations. The session will be an interactive discussion on living with and beyond lung cancer. Key topics include an introduction to survival rates for lung cancer survivors, interventions and a global discussion on how advocates can address the needs of lung cancer survivors in their country. The session will be jointly presented by both authors. Background: Lung cancer has been the most common cancer in over 20 years with an estimated 1.8 million new cases in 2012 (IARC, 2018). Sadly lung cancer is the leading cause of cancer deaths worldwide. Every year, lung cancer causes more than 1.6 million deaths; more than breast, colon and prostate cancers combined (IASLC, 2015).
MEET THE EXPERT SESSIONS
INVITED SPEAKER

However there are lung cancer survivors. According to the Concord study (2015) 5-year net survival from lung cancer is typically low, in the range of 10–20% for most geographical areas. This study is the most comprehensive international comparison of cancer survival to date, covering countries that are home to two-thirds of the world’s population and shows extremely wide differences in survival between countries. Anyone who has been diagnosed with cancer is a survivor – from the time of diagnosis to the end of life. Caregivers and family members are also cancer survivors (National Coalition for Cancer Survivorship, 1986). For the purpose of this session, we will focus on lung cancer patients who are post treatment. Unmet needs: The impact of a cancer diagnosis can evoke a range of emotions, anything from fear, anxiety, anger or denial. There is no right or wrong way to feel and patients often describe it as being on ‘an emotional rollercoaster.’ A study performed by Zabora et al. in 2001 examined the prevalence of psychological distress by cancer site and found considerable variation. Of the patients surveyed, 43% of lung cancer patients experienced elevated levels of distress in comparison to 32% of breast cancer patients, 31% of bowel cancer patients and 30% of prostate cancer patients. Numerous studies have since replicated these results. And being off treatment does not imply less distress for lung cancer survivors (Eichler, 2018). Lung cancer survivors’ health related quality of life is generally low; therefore, management is crucial during the posttreatment period. The experience of having unmet supportive care needs is most strongly associated with intrusive cancer-related thoughts, limitations in physical functioning, distress associated with physical symptoms, and health-care satisfaction (Sanders et al., 2010).

Issues for post treatment survivors: The concept of quality of life has been a concern for many health-care professionals (Brennan, 2004). Surviving cancer does not always result in a return to ‘normal life’. The impact of a diagnosis can affect the overall quality of life of a survivor, including physically, psychologically and socially (Ivers, M. et al., 2009). For the purpose of this presentation, we will focus on post-treatment survivors and outline cancer-related lung cancer survivorship have expressed, including: Expectations Avoiding Triggers Anxiety Volume Guilt The Meaning of My Lung Cancer Experience Who/What Am I Social Disconnections Vulnerability Interventions: Psychosocial interventions with cancer patients usually focus on adaption and adjustment to diagnosis and treatment, helping the patient to engage in behaviours that are more conducive to better health (Neuz & Neuz, 2007). We will outline a variety of interventions that are successfully used to support lung cancer patients, including: CBT Focusing on Current Facts Staying in The Moment Talk Therapy Managing and Creating New Expectations Lowering the Anxiety Volume Re/Building Self-Esteem Socialization Exercises Global variations: There are wide variations in survival rates globally and this in turn impacts the work priorities of advocates. Both authors will present on lung cancer survival in their own country, demonstrating different unmet needs and priorities. The audience will then be invited to discuss key survivorship concerns within their organisations and given an opportunity to share their own survivorship initiatives and projects.

Keywords: Global variations, survivorship, interventions

Plasma genotyping has rapidly evolved from an investigational technology into a standard-of-care tool with the potential to direct therapy in metastatic non-small cell lung cancer (NSCLC). Tissue genotyping has historically been considered the gold standard for genotyping in NSCLC both at initial diagnosis and acquired resistance to therapy. However, plasma genotyping is increasingly useful as a rapid alternative to tissue genotyping in certain clinical contexts. This technology is particularly applicable in patients with insufficient tissue available for genotyping at initial diagnosis as well as at the development of acquired resistance. The optimal use and interpretation of plasma genotyping requires understanding of cell-free DNA (cfDNA) biology, assay characteristics and the application of testing in different clinical scenarios. In newly diagnosed metastatic NSCLC, plasma genotyping is useful for the detection of targetable genomic alterations or non-targetable driver alterations (eg. Kras) that are mutually exclusive with targetable alterations. The potential utility of plasma genotyping in newly diagnosed patients is particularly pronounced in patients with insufficient tissue from their diagnostic biopsies for genotyping, those with inaccessible or difficult to biopsy lesions and patients in which rapid initiation of treatment is needed due to clinical deterioration. The high positive predictive value of most modern plasma genotyping platforms for the detection of targetable genomic alterations means that positive results can be used to rapidly guide initial targeted therapy in metastatic NSCLC patients. However, the modest sensitivity of these assays requires that negative results be confirmed by tissue genotyping with repeat biopsy, if necessary. In patients with acquired resistance to targeted therapy, plasma genotyping can be utilized to detect resistance mutations at the time of progression. Furthermore, plasma genotyping may detect resistance mutations missed by standard tissue genotyping in this context due to tumor heterogeneity. Plasma T790M testing in patients with acquired resistance to first- and second-generation EGFR kinase inhibitors has been utilized extensively for selecting patients for treatment with second-line osimertinib. However, the utility of this technology in acquired resistance to EGFR therapy is likely to decrease as more patients are treated with front-line osimertinib without a targeted therapy option at development of acquired resistance. The recent explosion of multiple treatments for ALK acquired resistance has opened a new opportunity to apply plasma genotyping technology for the selection of second-line targeted therapy in these patients. While cfDNA technology has aided in the detection of actionable mutations, there remain challenges at present related to modest assay sensitivity, standardization of both analytic and clinical validation across testing platforms and adapting this technology to the ever-changing treatment landscape of metastatic NSCLC. In addition, DNA captured in plasma may be from multiple sources other than tumor, including germline, fetal, post-organ transplantation and clonal hematopoiesis of indeterminate potential (CHIP). These mixed sources have been routinely detected in commercial-based assays and can affect the interpretability of assay results. Despite potential limitations, cfDNA platforms offer immense promise in serving as an accurate molecular proxy for tumor biology. There is considerable potential for plasma genotyping in the detection of early-stage disease and for patients at risk for disease recurrence post curative intent therapy. In addition, there may be future utility with these assays in the detection of tumor mutational burden (TMB) and other predictive biomarkers of immunotherapy. Future prospective efforts that mandate plasma interrogation both as a static and dynamic biomarker will enable a firmer understanding of how best to utilize this unique technology.

H. Wakelee

Medicine (Oncology), Stanford Cancer Institute/Stanford University, Stanford/CA/US

Given the rarity of thymic epithelial tumors (thymoma and thymic carcinoma) accumulation of clinical trial data to guide management has been challenging, yet the chemo-sensitivity of these malignancies is clearly established. As with most solid tumors it is important to fully assess for any chance of locally aggressive disease with surgery of radiation for a curative intent. Thymic malignancies are often very radiation sensitive as well and I am quick to refer to radiation oncology for localized disease progression or any symptomatic areas. The high rates of paraneoplastic syndromes and autoimmunity adds to the complexity of management of this disease, especially thymoma. I am grateful for the support of neurology colleagues and immunology colleagues to help with myasthenia gravis and immunotherapy/rheumatology management of these complex patients. Once the disease has spread extensively in the pleural or metastases have developed, systemic therapy will be essential. I will start to with a platinum based regimen initially. For young and fit patients the three drug CAP regimen of cyclophosphamide, doxorubicin and cisplatin has a very high response rate. Given the cumulative cardiotoxicity of the anthracycline in the regimen, I usually stop at 4 and no more than 6 cycles. Most patients are then able to enjoy a chemotherapy holiday for several months, and even up to a year or longer. I will consider cisplatin/etoposide if anthracyclines are contraindicated, and especially if any concurrent radiation is under consideration. Carboplatin/paclitaxel was also studied prospectively and remains the most studied regimen for thymic carcinoma. The response rates with all of these regimens are approximately 50%, somewhat higher with the platinum/anthracycline combinations, though given larger numbers in trials the precise response rates are difficult to state with certainty. None of these regimens include a maintenance component, yet the PFS can be 1-2 years. I will also consider giving platinum/pemetrexed as a first line regimen given the improved tolerability, despite limited data. This is less active in thymoma patients, though activity in a limited number of thymic carcinoma patients has been noted despite the usual squamous histology. Once a patient has progressed on first line treatment one may choose between a number of single chemotherapeutic agents with activity including 5-FU and derivatives, gemcitabine, pemetrexed, taxanes and others. I choose between these based on toxicity profiles and prior regimens for the patient and do not have a single standard approach. For younger and fit patients, especially if they have a history of smoking burden, I will consider combination regimens. There is also growing evidence for activity of agents with mechanisms of action that differ from those of traditional cytotoxic drugs. One of the first of these was octreotide with or without prednisone. I have used this regimen rarely and in the setting of a positive octreotide scan, or a patient with autoimmune diarrhea where the octreotide was effective in controlling symptoms of disease. More recently I have begun to use the mTOR inhibitor everolimus in my thymic malignancy patients based on a 51 patient trial with the compound. At 10 mg/day oral dosing the disease control rate was 88%, and the partial response rate was 54% for the thymoma subgroup. There was a complete response in a thymic carcinoma patient and partial responses observed in a minority of both thymoma and thymic carcinoma patients. Median PFS exceeded a year in the thymoma patients. However, significant toxicity was seen with serious drug related adverse event in 14 of the 51 patients including 3 events of fatal pneumonitis. In my practice I have found that most patients do require a dose reduction to 7.5 or 5 mg daily. Pneumonitis remains a risk with this agent, but can be managed if discovered early. More specifically for thymic carcinoma emerging data with sunitinib has been very encouraging. In a trial that included 23 evaluable thymic carcinoma patients without any evidence of autoimmunity, enrolled 41 patients. The overall response rate was 22.5% including a complete response, however 15% of patients had severe autoimmune toxicity, which involved grade 4 myocarditis in 2 of the patients and myositis (elevated CPK) in an additional 3 patients. Taken together I am still very considering PD-(L)1 inhibitors in thymic carcinoma patients as the risk/benefit ratio (23% response and 15% severe autoimmune toxicity) is much closer than we have with many other therapeutic options. The risks in patients with thymoma or any underlying paraneoplastic autoimmunity limits our utility of these drugs at this time. Thymic malignancy patients have multiple treatment options and many can have long periods of disease control with the traditional cytotoxic options available and a growing number of targeted therapeutics. MTE23.01 SURGICAL CONSIDERATIONS FOLLOWING INDUCTION THERAPY FOR STAGE IIIA DISEASE

E. Valierrerez
Thoracic Surgery, Swedish Cancer Institute, Seattle/WA/US

Considerations following Induction Therapy for Stage IIIa Disease Surgery after induction therapy can at times be very challenging. From my own observations, this may particularly be an issue when the patient had not involved involvement at presentation (e.g. demonstrated a good response to the induction treatment (induction chemoradiation (CRT) or induction chemotherapy (C) alone) where fibrosis of the responding lymph nodes may make the hilar vascular mobilization more difficult. Induction immunotherapy as well in limited reported series) The following lines will describe some tips on how to minimize the risks of such resections. Preoperatively: One should always take advantage of the induction therapy period (12 weeks or more) to achieve absolute smoking cessation in these patients. After induction therapy, one should obtain a fresh set of PFTs including a DCO measurement as both radiation and some of the induction chemotherapy agents may have caused significant pneumonitis with resulting altered lung function. If there is a possibility that a pneumonectomy will be required, prepare yourself. (QVO, stress echo). Radiation esophagitis may have brought some nutritional issues, consider an alimentary "boost" when a significant weight loss has occurred during the induction phase of therapy. If there may be a risk that the SVC will be clamped, repaired or replaced, discontinue the post-cath preoperative. Finally, make sure to review all imaging, particularly the pre-induction therapy CT: the MTD is a good format for such review in our institution. Surgery Personally, I approach these cases via open thoracotomy, though some have reported successful resections on MIS platforms. All patients get an epidural catheter preop. If the SVC, anticipate issues with the SVC with a UCS or the intercostal muscle flap. POSTOP AND DC Remember to keep the patient dry. For pneumonectomies, we give a steroid bolus before entry, get infra diaphragmatic IV access preop. Emphasize w/ anesthesia, in the preoperative area, the absolute need to keep these patients dry: an irradiated mediastinum cannot handle excess fluid. At entry, I prepare/ handle the intercostal muscles without dividng it. (I now keep the omentum for later if needed to manage a complication, and spare the sartorius anterior at all cases). If accessible, I usually clear zone 7 first, with frozen section read. (The frozen section information/ feedback during this type of surgery can be very useful when one gets into a tough surgical corner…) If one is attempting a lobectomy and anticipates possible difficulties in the hilum, one should consider obtaining early circumferential control of the main veins and main PA (if possible), and do so intraparacardially if needed. Similarly, early division of the azygos vein on the right, the right PA in the patients. External resources such as quitlines or referrals to external tobacco cessation programs require action and increased motivation on the part of the patient, while incorporating resources in the workflow of the screening program deliver the resources to the patient as a standard part of practice. Furthermore, the lung cancer screening program may be able to interact with the patient over time (through annual follow up at least) and may be an optimal way to deliver cessation resources to these patients. This session will explore different programmatic strategies to deliver cessation resources to patients in the construct of a LDCT Lung Cancer screening program. The coordinator of our screening program is a Advance Practice Registered Nurse (APRN) who sought out training and certification as a certified Tobacco Treatment Specialist (TTS). Referrals to the screening program are initially contacted by phone for a screening, scheduling the call, which also includes the initial intake counseling these patients regarding tobacco cessation. An initial intake phone call determines appropriateness for screening and also can include elements of the 5A framework: ASK, ADVISE, ASSESS, ASSIST, ARRANGE. Then on the day of the scan, the APRN coordinator meets with the patient face-to-face at the point of the scan, and has already established rapport by telephone prior to the visit. The day of the scan, the patient recieves in person counseling as part of their visit, and a cessation strategy or “Quit Plan” is made which may include medications such as nicotine patches and/or gum. After the scan, telephone follow up is conducted to both discuss cessation and discuss scan results with a plan for follow up. Additionally, patients can be enrolled in a state Quitline program as a standard part of the workflow which provides them with ongoing support. Another option for patients following the screening program is to refer them to group counseling sessions. The American Lung Association’s Freedom From Smoking is one such structured program. Patients may not independently seek these programs out, but as a lung screening program, developing ties to programs in the community with integrated referrals to group counseling programs can be another way to further the delivery of resources to these patients. As patients return for repeat scans to follow up indeterminate nodules, or return the following year for routine scans, or for cessation support that has been delivered, and if they quit, abstinence support is provided. Quitlines, group counseling, and nicotine replacement therapy have been shown to be cost effective strategies to help people who smoke to increase chances of quitting. A lung screening program may identify 2% of its participants with lung cancer, but the majority (or in our case 71%) are smoking, and integrated cessation resources help those patients to reduce or quit smoking, the benefit of the lung screening program is greatly amplified, and patients can reduce risk for future cancers as well as cardiovascular and non-oncologic respiratory diseases.

MTE24.02 SMALL LUNG TUMOURS: HIGH RISK LESIONS AND CONTRAINDICATIONS TO STEREOTACTIC ABLATIVE BODY RADIOTHERAPY (SABR)

D. Ball

Radiation Oncology, Peter MacCallum Cancer Centre, Melbourne/AU

The development of SABR has revolutionised the non-surgical treatment of small, node negative lung tumors, both primary and metastatic. SABR is better tolerated, painless, inexpensive outpatient procedure that delivers promising results. However, there is now randomized evidence that it not only results in better local control than conventionally fractionated radiotherapy in patients with inoperable peripheral stage I non-small cell lung cancer, but increases survival as well. The impressive local control rates of over 80% have tempted some investigators to expand the indications for high dose hypofractionated SABR beyond small peripheral tumors. Perhaps the most controversial extended indication is the use of SABR for “central” lung tumors. There is no agreed definition of what constitutes a central tumor, although in the absence of consensus, the “no-fly zone” described by Timmerman is widely used even though it was based on a very small number of events.1 Phase II trials have been interpreted as indicating that SABR of central tumors has acceptable toxicity (RTOG 0813), even though there was a 3% mortality likely resulting from treatment; or conversely as unsafe, with the Nordic HILUS trial reporting around 10% mortality after SABR of tumors close to the main or a lobar bronchus. The European Lung Tumor trial should throw more light on the safety of treating central tumors with a “risk-adapted” approach using a more fractionated schedule of 60 Gy in 8 fractions.2 Many patients referred for SABR have poor respiratory or cardiac function making them unsuitable for surgical resection. Does this make them unsuitable for high dose SABR as well? The available evidence suggests not, but extreme caution should be taken in patients who have underlying interstitial lung disease.3 The relationship between SABR and cardiac injury, especially in the era of combined immunotherapy and SABR, remains under investigation. This high risk group of patients are currently eligible for the Stablamates trial, which is comparing systemic therapy with resection with SABR. Of note, the TROG 0813 includes 27 patients with COX < 80% predicted. A patient’s suitability for SABR will also depend on the dose constraints on nearby organs at risk. The chest wall is less concerning than previously, but is it the dose to the neurovascular bundle, rib or the whole musculoskeletal structure that most accurately predicts risk of chest wall pain? The brachial plexus tolerates hypofractionation poorly, and as with other scenarios where there is doubt about the safety of SABR, it is well to recognise that less effective but safer fully fractionated schedules are available. Other considerations, not in terms of risk, but of practical delivery of the treatment include synchronous multiple tumors, large tumors (>5 cm), and visibility for image guidance: What defined too small? Image degraded by implanted fiducials? 1. Timmerman R, McGrory R, Marnitzis T, et al. Lung cancer is the most common cancer around the world and it affects many older adults (1). With older age, the risk of treatment complications may rise. However, there is a lack of evidence on how to best treat older adults with cancer as this population has been severely under-represented in clinical trials. As patients age, their health and function can vary significantly, resulting in an increasingly heterogeneous population. Lung cancer is the most common cancer around the world and its effects are seen in older adults (1). With older age, the risk of treatment complications may rise. However, there is a lack of evidence on how to best treat older adults with cancer as this population has been severely under-represented in clinical trials. As patients age, their health and function can vary significantly, resulting in an increasingly heterogeneous population (3,4,5). Comprehensive geriatric assessment (CGA) (consisting of the domains comorbidity, medication use, functional status, cognition, psychosocial wellbeing, social support, mobility/fall risk) should be conducted to help clinicians with the treatment selection and care during the treatment. Implementing a comprehensive geriatric assessment in the oncology setting can help the oncology team with 1) detecting additional health conditions; 2) the assessment data can be used to predict life expectancy; 3) the assessment data can be used to predict chemotherapy toxicity; 4) the assessment data can result in changing treatment plans; and 5) the assessment data can be used to potentially reducing toxicity (3,4,5). The randomized trial of Dr. Corre and his team showed that treatment selection for older adults with Non Small Cell Lung cancer (NSCLC) based on the CGA was associated with decreased treatment toxicity (6). This assessment should be followed up with a care plan to address the health and functional status issues identified. In this session we will review how to enhance the clinical care for your older adult with lung cancer. The learning objectives for this session are: 1) to review the currently available evidence with regard to comprehensive geriatric assessment and management for your older adult with lung cancer patients including the Corre study. 2. To review how you can improve the clinical care of your older adult with lung cancer (how the current version of CGA including which tools, domains, who does what as well as the top 10 clinical pearls). Endobronchial biopsy (EBBx): This is the most frequently performed bronchoscopic procedure for diagnosis of lung cancer. It is relatively safe with a high diagnostic yield (76%-97%). As airway bleeding is one of the commonly encountered problems, the learning points include:
1) Hot (electrocautery enabled) biopsy from vascular lesions 2) Avoid biopsy from cavity 3) Avoid biopsy from an excavating ulcer with vascular supply 4) Avoid biopsy from tracheal tumor or tumor at the tracheal carina. Importantly, biopsy with electrocautery enabled forceps does not affect the tissue quality or the diagnostic yield. Transbronchial lung biopsy (TBLB): In certain situations TBLB is needed for diagnosing diffuse infiltrative lung disease in the setting of lung cancer including but not limited to lymphangitis, drug-induced interstitial lung disease, radiation pneumonitis and secondary infection. As pneumothorax, airway bleeding and crush artefacts are the commonly encountered problems, the important learning point is: 1) Do not use cup forceps for doing TBLB. Alligator forceps is preferred. It is likely that the cup forceps cuts through the blood vessels, whereas the alligator forceps crushes the blood vessels, thus leading to higher bleeding with the former method. In addition, the cup forceps has a smaller diameter (4 mm) compared with the alligator forceps (7 mm) in the open position; thus, it possibly reaches the lung segments more distally compared with the alligator forceps, leading to more pneumothoraces. Bronchoscopic staging procedures: EBUS-TBNA is an accurate, safe and cost-effective tool for lung cancer staging. It has been shown to have a pooled sensitivity and specificity of 93% and 100% respectively. The subgroup of patients who were selected on the basis of CT or PET positive results had higher pooled sensitivity than those without any selection (94% vs. 76%; p<0.05). EBUS-TBNA and EUS-FNA have been shown to have similar yield but lower complication rates as compared to mediastinoscopy in the initial mediastinal staging of non-small cell lung cancer. These endosonographic procedures are also safe and highly specific (99%) for mediastinal restaging of lung cancer. The important learning points are: 1) Use of EBUS-TBNA results in significantly shorter time to treatment decision compared to conventional techniques 2) Do not use conventional TBNA for staging of lung cancer. EBUS-TBNA is preferred for both diagnosis and staging 3) Upfront mediastinoscopy for lung cancer staging in untreated patients and for restaging in patients after neoadjuvant chemotherapy (or neoadjuvant chemoradiation) is not needed as endoscopic procedures (EBUS-TBNA, EUS-FNA or their combination) are preferred for both of these. Medical thoracoscopy: Medical thoracoscopy is a very useful procedure for both diagnosis of malignant pleural effusions as well as performing pleurodesis. Most patients present late at our center with extensive pleural adhesions and fibrosis. In such cases, flexi-rigid thoracoscopy has a lower yield in such cases (73% vs. 98%). The important learning point is: 1) Do not use flexi-rigid thoracoscopy for diagnosis of malignant pleural effusions. Rigid bronchoscopic procedures: These are often undertaken as part of intervention for airway obstruction/stenosis. The important learning points are: 1) Avoid complex intervention procedures using flexible bronchoscope - prefer doing them using a rigid bronchoscope 2) Avoid placing stents when the distal airways are involved 3) When in doubt, place a silicon stent. Silicon stents are easy to extract, work even in malignant disorders, can always be replaced by metallic stents. Sometimes, what appears malignant may not be so and in tuberculosis endemic countries, endobronchial tuberculosis is a great mimicker of malignancy 4) Never place uncovered metallic stent for malignant disorders 5) Do not place metallic Y-stents using flexible bronchoscopy as this can be associated with criss-crossing of guidewires, loss of airway control (and immediate conversion to rigid bronchoscopy) and need for fluoroscopic guidance 6) Do not place silicone stents using flexible bronchoscopy. In summary, each bronchoscopic procedure has inherent risks and potential for unintended complications. Therefore,
The pathologist is an integral member of the thymic malignancies tumor board team as he/she provides information on diagnosis, tumor stage, completeness of resection, and potential performance of biomarkers which is necessary for the team to conclude on the optimal treatment for each individual patient. Information that will be expected from the pathologist depends on whether a preoperative biopsy, a resection specimen or a specimen from a recurrence/metastasis is discussed (Table 1). For preoperative biopsies it is important to establish a histologic diagnosis including thymoma, thymic carcinoma, thymic neuroendocrine tumor, or benign thymus gland. Morphologic mimickers of thymic epithelial tumors (TET) such as lymphoma or germ cell tumors also need to be considered. Thymoma are not further subtyped on biopsy due to the potential heterogeneity of these tumors. Moreover, the subtype of a thymoma in general does not play a role for treatment decisions. In contrast, the subtype of a thymic carcinoma might be of value at the time of biopsy as some subtypes behave in a very aggressive manner and might be treated differently from a squamous cell carcinoma, the most common subtype of thymic carcinomas. For instance NUT carcinoma commonly have already metastasized at time of diagnosis. Similarly, SMARCA4-deficient tumors (even though not included in the current WHO) are highly aggressive tumors. Lymphoepithelioma-like carcinoma can also behave more aggressively. Although these subtypes of thymic carcinoma are quite rare, they should be kept in mind and the threshold of ordering ancillary tests such as immunohistochemistry and immunohistochemistry for NUT and/or SMARCA4 or an ETV6-NTRK3 in situ hybridization should be low. As some TET are unresectable, suggestions for biomarker testing or initial management might be reconsidered. If a resection specimen of a TET is discussed stage and resection status are critical as they are the most important diagnostic parameters and guide additional treatment recommendations. The new IASLC/ITMIG TNM staging system introduced 8th edition of the UICC/AJCC TNM should be used. Currently, in many centers, both, Masaoka-Koga stage (4) and TNM stage (5) are reported simultaneously as some treatment protocols are still based on the Masaoka-Koga staging system. The histologic classification also plays a role especially if the TET was not previously biopsied (which is the most common scenario in thymoma). In resection specimens the histologic classification should include the distinction between thymoma, thymic carcinoma and thymic neuroendocrine tumor vs benign thymus gland and, thymic follicular hyperplasia, true thymic hyperplasia) vs mimickers of TET. In resection specimens the thymic tumours should be further subtype, which is usually performed according to the 2015 WHO classification. (6) If the patient underwent neoadjuvant therapy, a comment on treatment effect and the disease status post resection might be made (7). Although uncommon, biopsies or resections of recurrences or metastases of TET are performed and are discussed during tumor board. Based on the type of specimen (biopsy vs resection specimen) similar issues as described above will be discussed. In addition, especially in resection specimens, the WHO subtype of the TET should be mentioned as it might differ from the original specimen. In conclusion, the pathologist will contribute important information in regards to histologic diagnosis, stage, completeness of resection and biomarker testing of TET to the tumor board discussion which will be crucial for further treatment decision.

Koga K, Matsuno Y, Noguchi M, Kusukawa K, Masaoka K, Yamao K, et al. A review of 79 thymomas: thymic carcinoma and thymic neuroendocrine tumor vs benign thymus gland. In: thymic gland is left behind. However, thymectomy alone is an option in stage I tumours and in non-myasthenic patients. If the tumour is widely invasive (stage III/IV), en bloc removal of all affected structures, including lung parenchyma (usually through limited resection), pericardium, great vessels, nerves and pleural implants, should be carried out. Resection of venous vascular structures (innominate vein(s) and superior vena cava) includes partial resection with suturing or complete resection and vessel reconstruction using vascular prosthesis. Areas of uncertain resection margins are marked with clips to allow a precise postoperative radiotherapy delivery. Phrenic nerve preservation does not affect survival, but increases the risk of local recurrence, and should be balanced with the achievement of a complete resection, especially in patients with severe and uncompensated myasthenia gravis. Frozen sections to assess tumour involvement of resection margins are not always recommended, since the risk of false-negative results is high. Minimally invasive surgery is an option for presumed stage I and possibly stage II tumours in the hands of appropriately trained thoracic surgeons. This includes transcervical, extended transcervical, and VATS-assisted surgery (VATS) and robotic approaches (right or left, right and left, right and cervical, left and cervical, subxiphoid and left and right, cervical and subxiphoid); furthermore, robotic surgery may allow a better visualisation of the thoracic cavity when compared to VATS. The choice of minimally invasive surgery should not jeopardise or change the principles that are deemed appropriate for an open approach, especially the achievement of complete resection that may ultimately require switching to an open procedure. Minimally invasive surgery is not recommended for stage IIIs tumours, because the lack of long-term follow-up, Lymphadenectomy has historically rarely performed after resection of thymic tumours. The new IASLC/ITMIG TNM staging system of thymic tumours, however, leads to the recommendation that locoregional lymphadenectomy should be carried out during resection of all types of thymic tumours. A proposed nodal map is available from ITMIG. Routine removal of anterior mediastinal nodes and anterior cervical nodes is also recommended. Systematic sampling of other intrathoracic sites is encouraged (i.e.
paratracheal, aortopulmonary window and subarcinal areas, depending on tumour location) in stage III/IV tumours. Systematic lymphadenectomy (neck, axilla, iliac fossa) is recommended in the multimodal treatment to the high rate of lymphatic spread (20% versus 3% in thymomas) If complete resection is deemed not to be achievable upfront on the basis of imaging studies, as it is frequently the case in Masaoka-Koga stage III/IV tumours, any biopsy should be accompanied by induction chemotherapy as part of a curative-intent sequential strategy that integrates subsequent surgery or radiotherapy. Patients not eligible for local treatment should receive palliative chemotherapy only. Recurrences of thymic epithelial tumours are not uncommon (10%-15% of all-stage resected tumours) and should be managed according to the same strategy as newly diagnosed tumours. Complete resection of recurrent lesions represents a major predictor of favourable outcome, and surgery is then recommended in case of resectable lesions.

GR01.03 SURGICAL ONCOLOGY
D. Waller
Barts Thorax Centre, St Bartholomew’s Hospital, London/GB

In this section we will address the controversial areas of surgical management in more advanced stages of thymoma. Using case-based discussion we will debate the following clinical scenarios: Stage III Thymic tumours (with invasion of great vessels) Is there a role for primary surgical debulking leaving an intention R2 resection? There is little survival evidence to support intentional debulking but such procedures may reduce the dose and extent of radiotherapy subsequently required and therefore the associated morbidity [1]. However, there is a lack of supportive evidence for debulking surgery in thymic carcinoma. [2, 3] Should primary treatment be chemoradiotherapy followed by consolidation surgery? Induction therapy is feasible in locally advanced thymic tumours and has been reported to achieve around a 50% partial response. A complete pathological response has not been seen but such treatment can facilitate a high rate (over75%) of R0 resection.[4] Stage IVa Thymic tumours – pleural/pericardial deposits is there a role for radical surgery? The International Thyimc Malignancies Interest Group have recommended that in locally-advanced Stage IVa patients with pleural involvement, major pleural resections, including pleurectomy/ decortication or extrapleural pneumonectomy are indicated, provided a complete resection of the pleural deposits is anticipated, usually in a multidisciplinary setting [5] Should this be extrapleural pneumonectomy or thymectomy and extended pleurectomy/decortication? As in other disease, extrapleural pneumonectomy (EPP) is associated with a high 30 day mortality of up to 17% (6). Providing a complete resection can be achieved there is no difference between EPP and extended pleurectomy decortication (EPPD) (7) and median survival may exceed 4 years. The occurrence of occult nodal metastases must be recognized and radical radiotherapy must include lymph node dissection. Stage migration due to lymph node metastases, WHO-classification type C, and T3/4-status are associated with inferior survival but extended surgery has been found to be the only independent significant prognosticator in multivariate analysis [8, 9]. [6] Post-surgical incisional disease? Radical resection should be facilitated by extended approaches which are well tolerated and adequate exposure is necessary to ensure a complete resection Recurrent thymic tumour – after previous resection is there evidence that extending local control prolongs overall survival over systemic therapy alone? Survival is acceptable and superior to non surgical treatment if complete resection of recurrence is achieved. There is no evidence to support debulking of recurrent thymoma [10]. A significant prognostic is associated with multiple versus single relapses, Masaoka stage III primary tumour versus Masaoka stage I-II primary tumour, distant versus loco-regional relapses and B3 histotype versus other. On multivariate analysis, completeness of resection, number of metastases, Masaoka stage of primary tumour and site of relapse were identified as the only independent predictors of survival [10] Conclusions The relative rarity of thymic tumours has contributed to the lack of high grade evidence from randomized controlled trials of large numbers of patients. Most supportive evidence for radical surgery in advanced thymic malignancies has therefore been provided by relatively small selected case series. However, the formation of larger collaborative groups with cumulative databases has provided more robust support for extended surgical procedures that many have avoided previously. The superiority of resection as part of multimodality treatment over non-surgical treatment alone seems to be justified provided high quality surgical standards are maintained. [11] References 1. Thymic malignancies represent a heterogeneous group of cancers, which are classified according to the World Health Organization (WHO) histologic classification system, tumours originating from other anatomic locations. The management of thymic epithelial tumours is mostly based on non-randomized studies, retrospective data, and recommendations rely on expert opinion; this is related to the rarity of the disease, precluding large clinical trials to be developed. Systemic treatment may be delivered in a curative-intent approach, for patients presenting with locally-advanced tumour at time of diagnosis, with invasion of intra-thoracic neighboring structures, and/or dissemination to the pleura and the pericardium, precluding upfront complete resection to be achieved. In such cases, chemotherapy has been used both to reduce the tumor burden – possibly allowing subsequent surgery and/or radiotherapy- and to achieve prolonged disease control. In this setting, the duration of chemotherapy must be extended.

There are two types of chemotherapy: Neoadjuvant and adjuvant chemotherapy. Neoadjuvant chemotherapy is administered before surgery or radiotherapy, to reduce the tumor burden and allow a complete resection. Adjuvant chemotherapy is administered after surgery or radiotherapy, to prevent recurrence and improve survival.

Thymic malignancies are classified according to the World Health Organization (WHO) classification system, which is based on histopathologic features, grading, and staging. The classification system includes a number of subtypes, with different clinical behavior and response to treatment.

Thymic carcinoma (TC) is a rare, aggressive tumor that is highly sensitive to chemotherapy. It is associated with a high incidence of loco-regional recurrence and a poor overall survival.

Thymoma (TM) is a less aggressive tumor compared to thymic carcinoma. It is characterized by a high rate of lymphatic spread and a tendency to recur in the thoracic cavity. The management of thymoma is primarily surgical, with the goal of achieving a complete resection. However, the rate of local recurrence is high, and the overall survival is generally poor.

Chemotherapy is an important treatment option for thymic malignancies, with different regimens being recommended based on the specific subtype and stage of the tumor. For thymic carcinoma, combination chemotherapy with cyclophosphamide, Adriamycin, and vincristine (CAV) is the standard regimen. For thymoma, the most common regimen is combination chemotherapy with cyclophosphamide, doxorubicin, and vincristine (CAV).

Radiotherapy can also be used in the management of thymic malignancies, especially for patients with loco-regional recurrence or with unresectable disease. The use of radiation therapy is guided by the specific subtype and stage of the tumor, with different radiation regimens being recommended.

When surgery is not feasible, chemotherapy is often the only available treatment option. The choice of chemotherapy regimen depends on the specific subtype and stage of the tumor, as well as on the patient’s overall health status. In some cases, immunotherapy or targeted therapies may be considered.

The prognosis for thymic malignancies is generally poor, with a median overall survival of around 3 years. Factors that influence the prognosis include the subtype and stage of the tumor, the presence of extracapsular extension, and the response to treatment. The multimodality approach is essential for improving the survival outcomes of patients with thymic malignancies.
GR02 MANAGEMENT OF N2 NSCLC - A CASE BASED DISCUSSION
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

GR02.01 CASE 1: SINGLE ZONE N2 (NO PNEUMONECTOMY) NECESSARY
A. Wrona
Department of Oncology and Radiotherapy, Medical University of Gdańsk, Gdańsk/PL

Lung cancers invading ipsilateral mediastinal lymph nodes (stage IIIA/N2) account for 30–50% of the locally advanced NSCLC cases [1]. The optimal treatment strategy for potentially resectable stage IIIA/N2 remains challenging and controversial. Interpretation of literature data is complicated by inconsistent evaluation of N2 disease (pathological confirmation vs. imaging-based), heterogeneity of N2 disease spectrum (ranging from single-station microscopic to bulky, multilevel nodal involvement) and pooled analysis of N2 patients with other stage IIIA/B patients. Results of primary surgery or radiotherapy used as single-modality are disappointing [2]. To improve outcomes combinations of chemotherapy+/-radiotherapy and surgery are being explored. Treatment strategies for patients presenting with non-bulky N2 disease include: (1) induction chemotherapy followed by surgery and postoperative radiotherapy if indicated; (2) induction chemotherapy followed by surgery and postoperative chemotherapy if indicated; (3) definitive chemoradiotherapy. Preoperative chemotherapy offers the possibility of tumor downstaging, may increase operability and assists in early re-evaluation on the N2 status. Latest randomized clinical trials showed a significant survival benefit of preoperative chemotherapy (hazard ratio [HR] 0.87, 95% CI 0.78–0.96, p<0.007) [2]. It was consistent with an absolute survival improvement of 5% at 5 years, from 40 to 45%. The tumor downstaging effect is dependent on chemotherapy regimen and number of administered cycles. Cisplatin as compared to carboplatin is found to be more effective in inducing tumor response, therefore most pronounced adverse effect of carboplatin may be avoided after preoperative cycles of chemotherapy [3]. Adding radiotherapy to preoperative chemotherapy can increase pathological complete response (pCR) and mediastinal downstaging. Preoperative chemoradiotherapy, as compared to neoadjuvant chemotherapy alone is associated with comparable perioperative complication rates, a higher rate of positive surgical margins and a higher rate of loco-regional recurrence [4]. However, based on the negative results of the Intergroup 0139 trial, designed to address the role of surgery after neoadjuvant chemoradiotherapy, level 1 evidence exists for definitive chemoradiotherapy as first-line treatment in resectable NSCLC [5]. Additionally, two published meta-analyses, the use of preoperative chemoradiotherapy did not translate into better overall and progression-free survival of resectable stage IIIA/N2 NSCLC [4, 6, 7]. Furthermore, delivering doses of ≥45 Gy in combination with chemotherapy is predictive of postoperative complications, in case of a high risk of positive surgical margins the use of preoperative radiotherapy in combination with chemotherapy, in expert hands, should be considered for carefully selected, fit patients. After induction chemoradiotherapy, lobectomy is the preferred surgical approach, as pneumonectomy, especially right-sided, may carry the risk of unacceptable perioperative mortality [14-26%] [5]. To conclude, neoadjuvant chemoradiotherapy or chemoradiotherapy alone followed by surgery seem both acceptable in selected stage IIIA/N2 NSCLC clinical scenarios. Those approaches present an alternative to definitive chemoradiotherapy strategy for clinically fit patients with potentially resectable N2 NSCLC. In the context of the available data a real-life single zone N2 NSCLC case will be presented and discussed. The importance of careful patient selection has been enrolled, demonstrating the feasibility of a national MTB for thymic malignancies, that, besides ensuring patients an equal access to highly specialized management, provides with a comprehensive tool to monitor dedicated actions to improve the management of patients, and enroll patients in clinical trials. Similar thoracic oncology-dedicated networks are now being implemented in France and in other European countries, such as Spain and Italy (the TYME collaborative group). Within the European Reference Network EURACAN, the rare thoracic tumor domain – referred to as G8 domain - handles a network of 20+ healthcare providers; the objectives of EURACAN include the updating and the assessment of current guidelines, the development of educational programs, dissemination and communication with patients groups, and the establishment of research projects, from the diagnostic workup of the disease to the therapeutic strategies. Achieving the highest quality of patient care is the main objective of EURACAN, and the RYTHMIC model provides some practical tools to be implemented at the European level, including Clinical Oncology Patient Management tools. The European network also provides an infrastructure for collaboration with diagnosis and pharmaceutical companies; one example may be the opening of dedicated cohorts in basket studies assessing new drugs, for which the network allows a better identification of patients and facilitates the recruitment in the trials.

PC01.01 PRO INTRAPLEURAL CHEMOTHERAPY IS IT THE FUTURE?
I. Opitz
Thoracic Surgery, University Hospital of Zurich, Zurich/CH

Considerable progress was achieved in the field of mesothelioma (MPM) research and treatment over the last decades. However, high local recurrence rates – even after aggressive treatment - remain an unresolved problem. Based on anatomic constraints, it is impossible to leave adequate safety margins - usually required for oncological surgery - when resecting mesothelioma, therefore leading to only macroscopic – but not microscopic - complete resection (MCR). The remaining microscopically small tumor residuals are most probably the origin of later recurrence. Intracavitary local treatment modalities target this hypothesis. Substances can be applied locally in desired high doses, while side effects can be reduced by decreased systemic absorption. Several intracavitary approaches have been evaluated to try to reduce local recurrence and were mostly applied after MCR, either lung sparing (extended) pleurectomy / decortication ((e)P/D) or extrapleural pneumonectomy (EPP). Intracavitary chemotherapy has been successfully applied in peritoneal carcinomatosis and the knowledge gained to reduce systemic side effects and simultaneously increase the local concentration of the drug is to combine cisplatin with a fibrin glue. Cisplatin-fibrin can be sprayed on the resection surface of the chest wall and the lung after surgery. A safe maximally tolerated dose and the methodology to reduce associated complications have been established. Another technique to reduce systemic side effects and increase penetration depth of the chemotherapeutic agent into the tissue and therefore a maximized cytotoxic effect on tumor cells. Looking at current guidelines, intracavitary treatments have not yet entered routine treatment regimens for mesothelioma patients. The recommendation of the American Society of Clinical Oncology Clinical Practice Guideline (ASCO) summarizes: Intracavitary therapies (chemotherapy or photodynamic therapy) may be administered safely in experienced centers of excellence, preferably in the context of a clinical trial. Their role in improving outcome is indeterminate (Type of recommendation: evidence based; Evidence quality: low; Strength of recommendation: weak). Hyperthermic intraoperative chemotherapy (HIoC) with cisplatin has demonstrated safety and some efficacy in two phase I or II prospective clinical trials in patients undergoing EPP and P/D immediately after surgery. A safe maximally tolerated dose and the methodology to reduce associated complications have been established. In a phase I dose escalation trial (INFLuenCe-Meso) safety was confirmed, and currently further tested in a phase II clinical trial (NCT01644994). Additionally to intracavitary applied chemotherapeutics which are mainly platinum based other substances were tested. Tada et al recently published the results of a phase I clinical trial using zoledronic acid. This intrapleuraly applied drug is a third generation bisphosphonate and was used in patients with inoperable MPM. Prior to this, the efficacy was equally demonstrated in preclinical studies.

PC01 CONTROVERSES IN MESOTHELIOMA
MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

PC01.03 PRO IO IN MESOTHELIOMA SHOULD ONLY BE GIVEN ON CLINICAL TRIALS
P. Bradbury
Princess Margaret Cancer Centre and University of Toronto, Toronto/ON/CA

It is 15 years since the pivotal study of pemetrexed and cisplatin versus cisplatin in inoperable pleural mesothelioma was reported, demonstrating a median overall survival (OS) improvement for the combination (pemetrexed/cisplatin 12.1 months vs. cisplatin 9.3 months) [1]. Since that time the only trial to demonstrate a further improvement in OS has been with the addition of bevacizumab to standard chemotherapy (median OS 18.8 months vs. 16.1 hazard ratio [HR] 0.77 [0.62–0.95], p = 0.0167) [2]. IO is showing promise in mesothelioma. The PD-1 inhibitors, pembrolizumab and nivolumab as single agents have response rates ranging from 18–29% (Table), with prolonged duration of responses reported. In combination, nivolumab and ipilimumab has a disease control rate (DCR) at 12 weeks of 50%, and the combination of durvalumab and tremelimumab had response rate of 28%. In combination with chemotherapy durvalumab, pemetrexed and cisplatin had a 65% 6 month progression free survival and 55% response rate (Table). While these results are encouraging, the majority of reported trials are small, single arm, with response or disease control rates as the primary endpoints. The only randomized control trial to have been completed so far, evaluated tremelimumab as a single agent in patients with previously treated mesothelioma following encouraging results from two single arm single institution studies of tremelimumab (9). Unfortunately, the primary endpoint of OS was not met (tremelimumab vs. placebo median OS 7.7 vs. 7.3 months [0.92 [95% CI 0.76–1.12], p = 0.41) It is notable that the DCR on the placebo arm (defined as CR, PR or SD of at least 12 weeks) was 21.7% (16.0–28.3) highlighting some patients have indolent disease and the need for randomized trials comparing at least 12 weeks) was 21·7% (16·0–28·3) highlighting some patients have indolent disease and the need for randomized trials comparing at least 12 weeks.

Keywords: Mesothelioma, Checkpoint inhibitors

Malignant pleural mesothelioma (MPM) is a relatively rare malignancy that is considered to be incurable despite advances in surgery, radiation, and chemotherapy. For patients with disease progression after primary platinum/pemetrexed-based therapy, there are limited options for treatment and no approved second-line agents. Recent data from several studies have demonstrated clinically meaningful, and sometimes remarkable activity of checkpoint inhibitors in patients with MPM that has failed first-line therapy. Although the data sets are relatively small, response and survival rates are consistent across studies and appear to be better than those seen in historical controls. Undoubtedly, larger trials with randomized cohorts would provide more robust data. However, access to clinical trials for rare diseases such as MPM is limited in many parts of the world. Therefore, the use of checkpoint inhibitor therapy is a reasonable and medically appropriate option for patients with MPM, especially when a clinical trial is unavailable.

**Keywords:** Mesothelioma, Checkpoint Inhibitor
Thoracic radiotherapy for LS-SCLC: QD is just as good as BID?

Most of the advances in outcome of small cell lung cancer (SCLC) in the past few decades can be attributed to improvements in radiotherapy, including better imaging and target selection, better treatment planning, better integration with chemotherapy and better systemic therapy, rather than to acceleration of single-fraction irradiation. Thoracic radiotherapy plays an important role in the treatment of limited disease SCLC (LS-SCLC). Best results are obtained with twice daily (BID) radiotherapy, starting early and given concurrently with chemotherapy [1]. In addition, it was shown that a shorter time from start of chemotherapy to completion of radiotherapy was associated with longer survival [2]. Two meta-analyses demonstrated that use of thoracic radiotherapy led to improved local control and an absolute survival benefit at 3 years of 5% [3,4]. Turrisi et al. [5] demonstrated in the Intergroup 0096 study that 45 Gy given BID in 30 fractions in 3 weeks was superior compared to the same dose delivered once-daily (QD) in 25 fractions over a 5 week period. Overall survival at 5 years was improved (26% vs 16%), but at the expense of more Grade 3-4 oesophagitis (16%) [6]. In spite of the Grade 3-4 side effects, BID radiotherapy is still used in a only a minority of SCLC patients [7]. In The Netherlands, early concurrent BID radiotherapy is given in about a quarter of the patients [7]. The radiotherapy dose in the QD arm of the Intergroup trial [5] was relatively low and some argued that a higher QD radiotherapy dose might be equivalent to or even better than the 45 Gy BID scheme. In the ongoing CALGB 30610 / RTOG 0538 study (NCT00632853) a dose of 70 Gy once-daily in 35 fractions in 7 weeks is compared with the 45Gy BD scheme. In this trial, radiotherapy starts with the first course of chemotherapy and includes elective nodal irradiation. Accrual is expected to continue for several years. In the recently published CONVERT trial (ISRCTR919243762), patients were randomized between 45 Gy BID in 3 weeks and 66 Gy in 33 fractions in 6.6 weeks starting with the second course of chemotherapy [8]. Treatment did not include elective nodal irradiation. The study was designed to investigate whether the higher QD regimen would lead to improved survival. Median overall survival was 30 months for the BID and 25 months for the QD arm. There were no statistically significant differences in overall survival or in metastatic progression. Survival in the control arm (BID) was 12% higher than expected when designing the study, possibly due to improvements in radiotherapy techniques. Based on the study, it can be concluded that a higher dose given QD does not lead to improved survival or better local control. There were no significant differences in acute toxicity, except for more Grade 4 or higher neutropenia in the BID arm (49% vs 38%). The risk of Grade 3-4 oesophagitis was 19% with no significant differences between the two study arms. Based on the results of this trial, 45 Gy given BID in 3 weeks should remain the reference standard. This regimen leads to the best results in the shortest time with the fewest number of fractions. The CONVERT study also indicates that where delivery of a BED scheme is not feasible, a higher dose once-daily scheme does not compromise clinical outcomes. However, it is surprising to note that the significantly higher biologically equivalent radiotherapy dose of the QD scheme in the CONVERT study did not translate into better outcome. Does the early distant dissemination of the disease preclude further improvements in local control and survival by local treatment? Or is the influence of the repopulation may greater than calculated in our radiobiological models? The possible benefit of shortened treatment time was evaluated in a phase II study from Norway in which 45 Gy BID in 3 weeks was compared with 42 Gy in 15 fractions in 3 weeks given QD. There was no significant difference in progression free survival at 1 year, the primary end point of this study in which 157 patients were enrolled (49% vs 45%). Although overall response rates were similar (88% and 92%), more complete responses were seen in the BID arm (33% vs 13%). In addition, although not statistically significant, overall survival was 25 months for BID vs 19 months for the QD arm. In the BID scheme, treatment is completed in 3 weeks and a BED10 of 52 Gy is delivered, whereas the same BED10 is reached after about 22 fractions of 2 Gy delivered once-daily. The delivered BED10 for the last third of the treatment does not seem to contribute to outcome. This suggest that repopulation starts very early and that tumor doubling times may be much shorter than generally assumed and a shorter QD scheme may be preferable if treatment is not delivered BID. The optimal thoracic radiotherapy dose for treating limited stage small cell lung cancer remains to be defined. Given the radiosensitivity of small cell lung cancer cells in preclinical studies in the 1980's it was postulated that twice daily radiotherapy would result in improved efficacy. Since then, clinic evidence experience included the landmark Intergroup 0096 trial, which demonstrated improved overall survival for patients assigned to twice daily radiotherapy (45 Gy) compared with once daily radiotherapy to the same total dose. Despite being one of the few randomized trials showing that changing the radiotherapy regimen impacts overall survival, the twice-daily regimen was slow to be adopted in clinical practice and many NCI cooperative group studies continued to use once-daily radiotherapy. Reluctance to routinely use the twice-daily regimen likely relate to concerns with acute toxicity, logistic issues, and use of a modest radiotherapy dose of only 45 Gy on the standard arm. In addition, a contemporaneous study from NCCTG did not show an advantage to twice-daily radiotherapy, although a planned treatment break was included such that radiotherapy was not accelerated. Alternative strategies of improving the efficiency of radiotherapy have been tested. The development of high dose once-daily regimens with a 70 Gy regimen utilized in several phase II trials from the Cancer and Leukemia Group B. These trials are somewhat difficult to interpret, as radiotherapy was not initiated until the 3rd cycle of chemotherapy and novel induction chemotherapy regimens were included. The RT0G has also studied a concomitant boost regimen, though overall survival was lower than expected in the phase II experience. Results from the CONVERT trial, comparing 45 Gy twice-daily and 66 Gy once-daily radiotherapy, were recently elective. The trial was powered to show superiority of high dose daily radiotherapy and failed to do so, and thus the authors concluded that 45 Gy twice-daily remain the standard of care. The CALGB 30610 trial, which uses 70 Gy in the once-daily arm, is near completion and will provide further data regarding the therapeutic ratio of these regimens. For the time being it should be kept in mind that the long held assumption that increasing radiotherapy dose with conventional fractionation will result in improved outcomes may not be justified – particularly in current chemotherapeutic regimens of local radiotherapy. For example, increasing the radiotherapy dose from 50.4 Gy to 64.8 Gy, with cisplatin and 5-FU, did not improve outcomes for patients with esophageal cancer on the phase 3 Intergroup 0123 trial. Perhaps even more surprising are the results of RT0G 0617, where even in the era of advanced radiotherapy treatment planning raising the radiotherapy dose resulted in worse outcomes.

PC03.01 POST-OPERATIVE RADIATION THERAPY OR NOT: PRO

C. Falkson

Oncology, Queen’s University and Ccse4 at Khsc, Kingston/ON/CA

Thymic epithelial tumors are rare tumors which has been an obstacle to performing prospective randomized studies. There is definite evidence that these tumors are radio-responsive but the exact role of radiation remains unclear. An additional confounding factor is that until the proposed standardization of classification (ITMIG) and staging (JART) by the International Thymic Malignancy Interest Group (ITMIG) there has been significant inconsistency of interpretation of both histology and staging leading to inconsistency in recommendation for post-operative radiation. Radiation fields, techniques and doses have also been very variable. Literature informing about post-operative radiation is largely reliant on single institution data and mostly retrospective work which introduces inherent bias. More recently consortiums (such as JART and ChART) were formed to try and combine data. Unfortunately most of these databases were primarily surgical based and indications for radiation and radiotherapy techniques are not well defined. The largest data base of thymic tumors is the one established by ITMIG which has facilitated international collaboration and establishing of large retrospective and prospective databases. In this debate we will review the literature supporting the role of radiation in the post-operative setting after thymectomy. Recent studies from different institutions have produced very different results for post-operative radiotherapy and we will compare these to try to determine why the results are so divergent.}

PC04.03 BID RADIATION - DISCUSSION PRO AND CON

PC04.04 BID RADIATION - CONCLUSION
outcomes with postoperative radiation will depend on appropriate patient selection. We will try to define the patient population that might benefit from treatment. We will also try to answer the question of routine postoperative treatment in more advanced stage disease, or only if resection is incomplete? We will explore how histology impacts on the decision to offer post-operative radiation? We will also try to define what fields should be appropriate, what techniques would be optimal and what doses should be delivered. The thymus resides in the mediastinum adjacent a heart, lungs and great vessels. Despite improved conformal techniques of radiation these organs still receive radiation and the potential damage from the radiation is not well quantified. International collaboration with standardization of definitions and complete radiation data is ultimately the only way we will achieve knowledge to advise the exact role of post operative radiation.

Keywords: Thymic epithelial tumors, post-operative radiation thymoma thoracotomy is added in addition to full sternotomy by changing the patient’s position from the prone to the decubitus position. Hemi-chest shell ventilation is another in median sternotomy when combined resection of the involved organs is required. In this approach, sternum is split from the sternal notch to the level of 4th intercostal space, and there, lateral thoracotomy is added. This approach enables the procedures of lung resection. Japanese Association for Thoracic Surgery (JATS) has conducted nation-wide survey of the general thoracic surgery in Japan annually since 1986. According to JATS survey, the number of VATS in surgery for thymic epithelial tumors has increased gradually since late 1990’s. In 2013, surgical resection of thymic epithelial tumor was done in 2230 cases in Japan. Approach through VATS or thoracotomy with VATS procedure was selected in 843 patients, indicating that the proportion of VATS rose up to 38% during 20 years. The remaining 1387 patients are presumed to experience median sternotomy, indicating that median sternotomy was used in 62% of operations of thymic epithelial tumors. In thymoma, median sternotomy was chosen in 1139 (60%) out of 1904 cases. On the other hand, in thymic carcinoma or neuroendocrine tumors, median sternotomy was used in 248 (76%) out of the cases. Invasive or aggressive tumors are resected using median sternotomy. Japanese Association for Research of the Thymus (JART) conducted Japanese nation-wide database study in 2013, and collected the clinical data of 2835 patients undergoing surgical treatment between 1991 and 2010. Because VATS thymectomy was introduced in the middle 1990’s in Japan, the patients treated from 2001 to 2010 were focused in this review. 1978 cases were treated during those 10 years among the JART database. 33 patients experienced median sternotomy, indicating that median sternotomy was used in 19 patients, which corresponds to only 4.7% of the entire cases. The proportion of median sternotomy according to TNM-based clinical stage was 74% in stage I, 87% in stage II, 91% in stage IIIA, and 91% in IIIB, suggesting that VATS is likely to be indicated to less invasive tumors. Although a study using JART retrospective database revealed that the long-term outcome of VATS for thymic epithelial tumors is compatible with that of open procedure, recurrence after VATS resection for thymoma larger than 5cm was reported, suggesting limited indication of VATS thymectomy. Thus, further experience of VATS or VATS procedure is required to determine the definitive indication of thoracoscopic approach, and open surgery using median sternotomy has still its role as one of the standard procedures.

Keywords: Thymoma, Thymic carcinoma, VATS
Thymic carcinoma is a more aggressive neoplasm than its more common counterpart thymoma, with a higher incidence of recurrence and worse overall survival when matched by stage and complete resection status. Large retrospective database studies provide support for adjuvant radiation for completely resected thymic carcinoma. The European Society of Thoracic Surgeons (ESTS) database, the International Thymic Malignancy Interest Group (ITMIG) and the Chinese Alliance Thymus (JART) database report on 155 patients with stage II and III thymic carcinoma, including 1042 cases pooled from the ITMIG and European Society of Thoracic Surgeons (ESTS) retrospective databases, 764 cases had available chemotherapy information. Sixty-one percent (n=463) of patients received neoadjuvant or adjuvant chemotherapy, with 22% receiving chemotherapy in the neoadjuvant setting, 31% in the adjuvant setting, and 8% in both the neoadjuvant and adjuvant setting. Chemotherapy was more frequently given to patients with Masaoka stage III-IV disease. The most common adjuvant treatment strategies included adjuvant chemotherapy and radiation (26%) and adjuvant radiation alone (22%), although 10% of patients received both neoadjuvant chemotherapy and adjuvant radiation. In a univariate analysis, chemotherapy was associated with an improved overall survival but was not associated with recurrence-free survival. Because of the limited sample size, it was unclear whether adjuvant chemotherapy strategy improved overall survival such as delivery of chemotherapy in the neoadjuvant or adjuvant setting. However, chemotherapy was not a significant factor for clinical outcomes in a multivariate analysis. There are other smaller database studies investigating adjuvant chemotherapy for thymic carcinoma. Due to both the retrospective nature of the studies and small sample sizes, it is difficult to evaluate the independent impact of adjuvant chemotherapy on clinical outcomes, as chemotherapy was often given in conjunction with radiation. Across these studies, there is no clear indication of benefit of adjuvant chemotherapy for resected thymic carcinoma. In the Japanese Association for Research on the Thymus (JART) database report on 155 patients with stage II and III thymic carcinoma, adjuvant chemotherapy was not a significant factor for disease-free survival in a multivariate analysis of adjuvant radiation, stage, and resection status. In the Chinese Alliance for Research of Thymoma Database (ChART) report on 329 patients with thymic carcinoma, there was no difference in overall survival between patients who received adjuvant chemotherapy and those who did not in the overall cohort and in Masaoka-Koga stage subsets and resection status categories. However, of the 148 patients who received adjuvant chemotherapy, 127 received a Platinum-based regimen and in 80 cases, in stage III or in those cases become resectable after induction chemo, independently by stage e type of resection, especially if not received before. The upcoming IASLC/ITMIG staging system, which redefines Masaoka-Koga stage IIIa contingent some situations to stage I and II (as mediastinal pleural or pericardial involvement) could potentially influence adjuvant chemo in stage III thymic carcinoma. Stage III will be distinguished into T3, potentially resectable upfront, and T4, which may require neoadjuvant radiation and 6. Adjuvant chemotherapy may be reconsidered on the basis of drug combinations effective in the palliative setting; platinum-based doublet plus etoposide or taxanes, or multiple drug regimens including anthracyclines are the most used, no data favoring one regimen over the others. Response rates among 60 to 100% in main phase II trials are reported. Neoadjuvant primary chemotherapy, adjuvant or plus chemoradiotherapy, remains the standard of cancer care in stage III thymic carcinoma. In one of the largest known datasets of thymic carcinoma, adjuvant chemotherapy was not a significant factor for clinical outcomes in a multivariate analysis. Finally, in a meta-analysis of 973 patients with thymic carcinoma, the rate of adjuvant chemotherapy was 21.2–61.5% among those who received adjuvant chemotherapy, and 28% and 56% also receiving adjuvant chemotherapy, respectively. Chemotherapy was not associated with overall survival in both univariate and multivariate analyses. Several retrospective database studies have shown no clear benefit of adjuvant chemotherapy for patients with resected thymic carcinoma, although these datasets have their limitations. Many additional questions remain about adjuvant chemotherapy including the indications for recommending adjuvant chemotherapy; the details of the chemotherapy such as the regimen and number of cycles; and the timing of initiation of chemotherapy after surgery and how it should be integrated with perioperative radiation. In summary, there is lack of data to support the routine use of adjuvant chemotherapy after complete resection of thymic carcinoma and further study is required. References: 1. PC04 TARGETED THERAPY FOR NSCLC
MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

PC04.01 OPTIMAL SEQUENCING OF EGFR TKI THERAPY (GEFITINIB/ERLOTINIB/AFATINIB FIRST VERSUS OSIMERTINIB FIRST)
J.C. Yang
Department of Oncology, National Taiwan University Hospital, Graduate Institute of Oncology & Cancer Research Center, National Taiwan University, Taipei/TW

Patients with advanced non-small cell lung cancer harboring epidermal growth factor receptor (EGFR) mutations should be treated with EGFR tyrosine kinase inhibitors (TKIs) as first-line therapy based on several large randomized phase III studies comparing first/second generation EGFR TKI vs. chemotherapy. The standard of care of using gefitinib/erlotinib/afatinib as first-line treatment has been challenged recently from a few progress made from recent reports. First challenge is the selection of first-generation gefitinib/erlotinib or second-generation afatinib. Second challenge is the treatment selection for patients with EGFR L858R and del 19 mutation. A couple of randomized studies comparing afatinib versus gefitinib (LUX-Lung-7) or dacomitinib versus gefitinib (ARCHER1050) demonstrated progression survival improvement for 2nd generation EGFR TKI versus 1st generation EGFR TKI in patients with common EGFR mutations. In addition ARCHER1050 showed a statistical difference in overall survival (OS) for dacomitinib. The advantage of 2nd generation EGFR TKI as first-line treatment are the coverage of HER2 inhibition, and probably deeper response due to irreversible inhibition of EGFR pathways. The higher duration of response should be balanced with higher side effect due to potent wild type EGFR inhibition in normal cells that caused severe side effects. The second improvement of first-line therapy was shown in two Japanese studies randomized erlotinib/afatinib versus placebo that also showed dacomitinib seemed to improve PFS substantially in both phase II and phase III studies. However, OS difference has not been observed, for reason not clearly understood. A 3rd approach using first generation EGFR TKI upfront was the success of combination of gefitinib and pemetrexed and carboplatin

Keywords: EGFR mutation, First-line therapy, Osimertinib, G-/E-/Aefitinib First-Lung Cancer
over gefitinib in a Japanese study resulted in PFS and OS improvement. These three approach need to be further studied for universal application. However, the PFS of these three approaches need to be closer to or higher than first line osimertinib (approximately 19 months) achieved by the phase III randomized study FLAURA or phase II AURA expansion cohorts. Since the salvage strategy of osimertinib failure is still under intensive investigation due to the heterogeneous resistance that can be caused by osimertinib prolonged use, the use of osimertinib as first line treatment should be considered only as an option rather than standard, pending the above mentioned PFS and OS improvement in these novel strategies to be compared and published in the future. We will be studied). In conclusion, we had made substantial advanced for the treatment of EGFR mutation positive NSCLC patients. Yet the best sequence of treatment should be further studied since long term control close to cure is always our ultimate goal for treatment of these patients.

City of Hope Comprehensive Cancer Center, Duarte/CA/US

Lung cancer is a heterogeneous genomic disease defined by molecular pathways that mediate onco genesis which are often driven by genetic alterations and targeted therapies are available to modulate these pathways and improve patient outcomes. Non-small cell lung cancer (NSCLC) has been at the forefront of expanding knowledge of genomic alterations to inform therapeutic options that improve cancer patient outcomes. Signaling through the epidermal growth factor receptor (EGFR) can modulate multiple intracellular pathways, including mitogen-activated protein kinase (MAPK), phosphatidylinositol 3-kinase (PI3K)/AKT, and signal transducer and activator of transcription proteins (STATs). Activating mutations in the epidermal growth factor receptor (EGFR) gene have been associated with improved progression free survival when patients are treated with EGFR tyrosine kinase inhibitor (TKI) therapy. Progress has been made in identifying these mutations and providing targeted therapy to improve outcomes for patients. Despite these advancements, tumors develop resistance and patients still succumb to the lung cancer, so overcoming the resistance became a priority. With the identification of third-generation EGFR TKIs, such as osimertinib, clinical benefit was maintained after tumor progression on first-generation EGFR TKIs, and questions regarding the optimal sequencing of EGFR TKIs emerged. Mutations in the TK domain of the EGFR gene demonstrate increase sensitivity to EGFR TKI in NSCLC. Gefitinib was the first EGFR TKI to demonstrate PFS benefit over chemotherapy as front line treatment of patients with EGFR mutant NSCLC. This was the first study to definitively identify mutation status as an important predictive marker for EGFR-TKI therapy and support molecular selection for patients with metastatic NSCLC. Multiple subsequent trials with gefitinib, erlotinib and atezanib confirmed enhanced PFS for front line EGFR TKI therapy. Developing appropriate therapies for EGFR-TKI-resistant disease requires a detailed understanding of mechanisms of resistance. Secondary mutations have been described that may arise that render initially sensitive tumors that harbor EGFR mutations, resistant to EGFR therapy. Multiple mechanisms of resistance have been identified, but approximately 50-60% of EGFR mutant NSCLC develops a T790M resistance mutation. Osimertinib was developed to overcome T790M resistance and block mutant EGFR while sparing wild type EGFR. Treatment following the development of T790M resistance led to improved objective response rates (ORR) and PFS for patients with EGFR mutant NSCLC. Early evidence suggested that osimertinib could be effective as first-line treatment, and had the potential benefit to prevent the most common cause of resistance. In the phase III FLAURA trial, 556 patients were randomized to osimertinib or standard, first generation EGFR TKI (erlotinib or gefitinib). The primary endpoint was progression free survival (PFS), and demonstrated an improvement for osimertinib at 18.9 months (95% CI, 15.2-21.4) compared to standard EGFR TKI at 10.2 months (95% CI, 9.6-11.1) with a hazard ratio (HR) 0.45 (95% CI, 0.37-0.57) and p < 0.001. The PFS for patients with central nervous system metastases remained higher for osimertinib at 15.2 months (95% CI, 12.2-18.4) compared to standard EGFR TKI at 9.6 months (95% CI, 7.0-12.4) with a hazard ratio (HR) 0.47 (95% CI, 0.30-0.74) and p < 0.001. The improvement of PFS in patients with brain metastases augments the clinical benefit to patients who may avoid or defer radiation treatments to the brain. Overall survival (OS) was immature with a trend toward improvement with osimertinib. ORR was similar in both arms, 80% (95% CI, 75-85) for osimertinib and 76% (95% CI, 70-81) for standard EGFR TKI therapy (95% CI, 70-81). These results have led to the US Food and Drug Administration approval of osimertinib as front line therapy for patients with advanced EGFR mutant NSCLC. Providing a drug with less toxicity and increased efficacy as a first-line option improves quality of life and outcomes for patients. New mechanisms of resistance will develop and must be overcome, but third-generation EGFR TKI therapy is now the new standard of care for front line therapy in metastatic EGFR mutation positive NSCLC. **PC04 TARGETED THERAPY FOR NSCLC**

**MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45**

**PC04.03 ADJUVANT TARGETED THERAPY FOR PTS WITH GENOMIC ALTERATIONS - YES**

S. Lu  
Shanghai Lung Cancer Center, Shanghai Chest Hospital, Shanghai Jiao Tong University, Shanghai/CN

**1. Introduction:** In recent years, the discovery of targetable gene alterations such as epidermal growth factor receptor (EGFR) mutations and anaplastic lymphoma kinase (ALK) rearrangements has revolutionized the therapeutic approach to advanced NSCLC. The outstanding activity shown by EGFR- and ALK- tyrosine kinase inhibitors (TKIs) in advanced NSCLC patients with EGFR mutations or ALK rearrangements, respectively, leads to the logical question of what role these agents may have if used in the adjuvant setting.  

**2. Rationale for adjuvant targeted therapy**  
At the present time there is no evidence suggesting a worse prognosis for EGFR-mutated NSCLC in early stage disease [1]. Similarly, retrospective studies exploring the impact of ALK rearrangements in early stage NSCLC suggested that ALK status lacks a prognostic role, as no significant difference in DFS was found between ALK-rearranged and ALK-negative patients [2-3]. Nevertheless, EGFR mutations and ALK rearrangements are both highly predictive of response to selected targeted therapy in advanced NSCLC.  

**3. Prospective trials**

4. Conclusions and future directions

A critical issue is how to select the patients who may need adjuvant targeted therapy. Measurement of residual disease by circulating tumor cells and/or DNA could help identify the high-risk population. However, for these patients it should be clarified whether targeted therapy should be used sequentially after platinum-based chemotherapy or as stand-alone treatment; therefore, better understanding of the biology at recurrence and novel testing strategies for residual disease are crucial in order to help select those patients who could benefit the most from adjuvant targeted therapy.

PC05 OPTIMIZING CLINICAL TRIAL DESIGN IN NSCLC
TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

PC05.01 DEBATE 1: WHICH IS MOST IMPORTANT EFFICACY ENDPOINT IN FIRST LINE TRIALS IN ADVANCED NSCLC PFS OR OS - POINT OF VIEW: PFS
M. O’Brien
Royal Marsden Hospital, Sutton/GB

This is an old chestnut. The debate has gone on for years and for first line trials in advanced NSCLC it is always OS that wins. So why do I think I will win this time? Well maybe it is because (I was given the task and I like a challenge) we are in a new era of medicine and we are in such a hurry to get new drugs to our patients to prolong our lives and cure them. A PFS (DFS) endpoint in a clinical trial is all about the activity of that drug or intervention. It is reported at a point when crossover to other treatments has not happened. It is the standard endpoint for treatments for advanced breast cancer and other disease where there are many treatment options and in general patients will live to get all those treatments options. An OS endpoint in advanced lung cancer in the past has generally been a PFS – both of them short ie. less than one year. An OS endpoint suggests that a treatment has truly modified the natural history of a disease and therefore this new treatment should be given as early as possible. In this era of new treatments it is gratifying to see an improved PFS has predicted an improved OS e.g. Keynote 024 and it is a gratifying to see that the trial did not report until PFS and OS were available at the same time as in coprimary endpoints. So in these trials of very active treatment PFS reported one year earlier than OS could have cut down the expense of the trial and got the drug to patients earlier. Looking at drugs that target the EGFR mutation gefitinib, erlotinib and Afatinib – all positive for PFS and all negative for OS because of crossover. If OS had been the only endpoint, all these drugs would still not be on our pharmacy shelves. So I believe if you have a great treatment that should activity very early on then PFS should be the endpoint. However if the benefit is small but still significant then OS must be the endpoint. But surely at this point in time we only want very active treatments that give us big differences in PFS as we know that these will be the treatments that can change lives.

Keywords: PFS OS debate

PC05 OPTIMIZING CLINICAL TRIAL DESIGN IN NSCLC
TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

PC05.04 DEBATE 2: PATIENT REPORTED OUTCOMES SHOULD BE THE MOST IMPORTANT ENDPOINT IN TRIALS IN THE PALLIATIVE SETTING - YES
M. Pérol
Department of Medical Oncology, Centre Leon Berard, Lyon/FR

The aim of an anticancer treatment in palliative setting, i.e. when there is no curative intent, is to improve the quality and the quality of life. The evaluation of a treatment effect is mainly based on randomized clinical trials which are meant to provide a correct assessment of the effect size. Therefore, the selection of the primary endpoint is critical not only for the sample size calculation but mainly to judge the relevance and the meaning of the treatment results which define the treatment utility from both the patient perspective and the healthcare system in terms of cost-effectiveness. Two categories of endpoints are used in clinical trials: some are patient-centered, clinical endpoints including overall survival (OS), health-related quality of life (HRQoL) assessment and tolerance profile whereas other are tumor-centered as progression-free survival (PFS), response rate, disease control rate. OS is a universally accepted measure of the treatment benefit in oncology, directly reflecting the quantity of life gained and is still the preferred endpoint of Phase III clinical trials. However, OS as a primary endpoint has some limitations: it usually requires a longer follow-up and a large sample size leading to an increase in the cost of trials. Moreover, especially in cancer with an improved prognosis as for lung cancer depending on an oncogenic driver, OS can be confounded by the effect of crossover and subsequent treatments with small effect sizes between sequences. These reasons make increasing difficult to demonstrate an OS benefit especially for first-line therapy. These limitations have led to consider tumor-centered endpoints, mainly PFS, as surrogate endpoints for an OS benefit in clinical trials. PFS provides results earlier and is not influenced by subsequent treatments. However, selecting PFS as primary endpoint assumes that there is a statistical validation of PFS as a surrogate endpoint for OS, which is not the case in advanced NSCLC, especially in palliative setting: many trials have demonstrated a PFS benefit without improvement of OS. Furthermore, there is a lack of consensus for PFS definition or tumor progression (i.e. taking or not into consideration symptomatic progressions), blinding or independent review is required to provide more robust evidence of a PFS benefit and its assessment is dependent on the status of the evaluation. In this context, HRQoL may constitute an alternative endpoint, which ensures earlier assessment of direct clinical benefit for the patient and takes into account the impact of potential treatment-related toxicities; HRQoL is therefore more recognized as a component endpoint for assessment of the benefit coming from cancer therapy by the American Society of Clinical Oncology and the European Society of Medical Oncology and for drug approval by Regulatory Agencies. It appears obvious that in the time to symptom deterioration, or improvements in symptoms and in HRQoL might be more meaningful to the patient with an advanced lung cancer than the RECIST criteria or PFS, not necessarily reflecting a clinically meaningful benefit. HRQoL is a multidimensional concept representing the patient’s perception of the effect of the treatment on physical, psychological, and social aspects of life. QoL measurement in clinical trials is based upon patient reported outcome (PROs) which are reports of the status of a patient’s health condition coming directly from the patient, without any interpretation by a clinician. Many validated self-completion QoL questionnaires for cancer patients are available in order to consider the multidomain aspect of QoL; the EORTC QLQ-C30 with its specific module for lung cancer (LC-13), the FACT-L are the most frequently used for assessment of patients HRQoL, physical functioning, or tumor related symptoms in lung cancer. HRQoL evaluated with PROs has been shown to be an independent prognostic factor in advanced lung cancer. However, the complexity and heterogeneity of QoL data reports and numerous methodological issues for QoL analyses make the PROs difficult to understand for clinicians and limit their utility to help for therapeutic decisions. Indeed, HRQoL is challenging to assess and raises many methodological issues, including missing data and patient drop-out rate, multiplicity, longitudinal analysis and lack of standardization making impossible to perform across trials comparisons. These issues as well as the usual deferred publication of QoL results after tumor-centered endpoints communication have led the scientific community and the clinicians to give little attention to PROs. Nevertheless, there is a greater awareness that a similar degree of scientific rigor should be applied to the PRO strategy to make it a key component of treatment effect, likely more sensitive to assess therapy’s effect on the disease and the patient than conventional measures. Different approaches have been underscored to improve the use of PROs in clinical trials. Recent extensions of the CONSORT have suggested recommendations for PROs analysis and report in clinical trials, with the need to define PROs as a primary or secondary endpoint with a specific statistical defined hypothesis, including approaches to deal with missing data; it is then possible to consider HRQoL as a co-primary endpoint. New statistical methods have also been suggested for longitudinal analyses of PROs as linear mixed model for repeated measures or time until definitive deterioration for symptoms or QoL score deterioration. Other approaches suggest focusing on three well-defined concepts: symptomatic adverse events, physical function, and disease-related symptoms which are easier to assess and are key components of a treatment effect. Information after the treatment and during subsequent treatment should also be collected to take into consideration the impact of a delayed disease progression on QoL or those of subsequent treatment-related toxicities. As tremendous advances have been made in the field of lung cancer treatment, especially in advanced disease with its transformation into a chronic disease for some patients, the treatment focus has shifted to improve or preserve the patients QoL. It is therefore mandatory to develop new and validated endpoints that better indicate a clinical benefit rather than small variations in tumor size. PROs should not be viewed anymore as a surrogate endpoint, but regarded as an important patient-centered endpoint, needing an optimization of trials design and methods to analyze HRQoL.

Keywords: Patient-reported outcome, clinical trials, lung cancer
Background: Although thousands of patients annually receive treatment for advanced non-small cell lung cancer (NSCLC), little is known about the patients’ views on the decision to receive that treatment. Even with encouraging new treatments, survival rates continue to be low in NSCLC. With potential treatment toxicities and with modest response rates, there are many risks for regret by both patients and their supporters. The highly symptomatic nature of NSCLC, coupled with pressures to decide rapidly on therapy, creates challenges that affect quality decision making. In a recent review of 59 studies dealing with regret (Becerra Perez et al, Med Decis Making; 2016;36:777-790), no study focused on lung cancer, even with 66% of the studies in oncology settings, none reported reduced regret over time during the study, and only 2 studies reported delayed regret several months after the decision. In this review, risk factors for regret seemed to be able to be affected by clinicians, according to the opinion of the authors of this systematic review. In a large survey (Morse et al. J Psychosocial Oncol. 2014;32:112-123) results including more than 3500 patients with cancer. More than 90% of these individuals rated “making decisions about care” as being important to them, out of 26 issues. The patients with lung cancer, ranked decision making as the third most important issue of the 26 surveyed.

In a recent article in the New England Journal of Medicine (Groopman and Hartzband 2017;377:1507-1509), the authors state that the risk of regret is in almost every medical decision a patient makes and the impact of regret is underestimates in patient decision making. They observe that regret and its impacts are not sufficiently considered by physicians as part of the decision-making process. A profile of the extent of regret, and factors contributing to that regret, is lacking for those undergoing systemic therapy for lung cancer, and for their supporters. Patients early and predicting patients at high risk for regret during treatment could assist in early intervention, which may decrease eventual regret.

Methods: We sought to investigate prospectively the incidence, extent, and associated factors concerning regret in patients receiving systemic treatment for advanced NSCLC. We added a phase III trial which included 164 patients. All patients were monitored using the LCSS PRO assessment questionnaire. Patients were randomized 1:1 to either usual care or to enhanced care. In the enhanced care group, all patients also completed the Decision Regret Scale identified, and their oncologists were aware of the ongoing LCSS results. Also, in the enhanced care group, the results of the LCSS symptomatic and quality of life scores over time, and the results of the decision aid were discussed with the patients and their supporter. The LCSS was completed every 3 weeks using the electronic LCSS (eLCSS-QL). The LCSS analysis included using the 3-item Global Index (“3-IGI,” assessing; distress, activities, and quality of life). All patients, in both arms of the study, completed the Decision Regret Scale (Brehaut et al, J Clin Oncol 2013;31:281-292) at 3 months after starting treatment, and at the conclusion of treatment. Results: 164 patients signed consent and 160 received treatment (the modified intent to treat group). Patient characteristics included: 43% women; 92% Stage IV; median PS = 1; mean age 63, and 41% of patients were patients enrolled into the DELOS low risk of regret group. The 20% 3-IGI decline had regret, as contrasted to 15% with 20% or greater decline. The 20% decline was associated with regret in the patients and their supporters. The LCSS was completed every 3 weeks using the electronic LCSS (eLCSS-QL). The LCSS analysis included using the 3-item Global Index (“3-IGI,” assessing; distress, activities, and quality of life). All patients, in both arms of the study, completed the Decision Regret Scale (Brehaut et al, J Clin Oncol 2013;31:281-292) at 3 months after starting treatment, and at the conclusion of treatment.

Immunoo-oncology (IO) exploits the patient’s immune system by blocking immune checkpoints (PD-1/PD-L1) to effect tumor cell killing and has shown superior response rates and survival outcomes relative to conventional chemotherapy in a variety of clinical contexts. IO has shown efficacy in solid tumors with a high burden of immunogenic neoantigens, including non-small cell lung cancer (NSCLC), and represents standard of care for many subsets of patients. Not all patients benefit from IO, and efforts to enrich for responders have been confounded by the lack of a highly predictive biomarker. PD-L1 immunohistochemistry (IHC) has evolved with clinical trials of IO in the form of companion and complementary diagnostic markers and algorithms for selecting patients who should receive IO. However, the PD-L1 assay has limitations as a biomarker. First, rather than the specificity or sensitivity of this biomarker is optimal. Over 10% of PD-L1 negative patients can show clinical responses to IO. Conversely, 40–50% of patients with PD-L1 positive status do not respond. Second, the diversity of commercially available PD-L1 assays used for retrospective IO studies with specific IO agents, some of which have different performance characteristics, has complicated practice in diagnostic laboratories. Third, tumoral PD-L1 is a dynamic biomarker that may be induced by the immune environment or endogenous stressors and may be expressed heterogeneously within the tumor. As a result, sampling bias can affect the proportion of cells showing PD-L1 expression. Finally, tumor genomics significantly influence response to IO, with certain driver alterations (e.g., EGFR, ALK) predicting a lack of response irrespective of PD-L1 status. All of these features speak to the need for an alternative biomarker(s) that offers moresensitive and specific prediction of response, is stable throughout the tumor, and can be standardized across laboratories and IO agents. In NSCLC, PD-L1 expression is thought to be driven predominantly by adaptive immune resistance, in which tumor mutations produce aberrant proteins (neoantigens) that can trigger cytokine-mediated PD-L1/PD-1 engagement, which in turn dampens the tumor-specific immune response. The tumor genome, therefore, appears to trigger the cascade of events leading to resistance with IO responses. Neoantigeneity can only be assessed via costly approaches like whole exome sequencing and requires complex bioinformatics generally outside of the scope of available clinical practice. It appears, however, that higher tumor mutational burden (TMB) increases the likelihood of neoantigen-driven immune engagement. Hence, TMB, a genomic variable that can be assessed readily using targeted next generation sequencing (NGS) assays in clinical use today, may serve as a surrogate for adaptive immuneresistance and predict response to checkpoint blockade. This correlation has been born out in retrospective analyses of outcomes data from IO clinical trials as well as from routine practice. Prospective clinical trials of combined IO agents have shown significantly longer progression free survival (PFS) with the combination therapies in patients with higher TMB, irrespective of PD-L1 status. These agents show enhanced benefit in TMB-high small cell lung carcinoma patients as well—tumor subtype where PD-L1 IHC appears to play no role as a biomarker. TMB calculated from NGS panels containing as few as ~150 genes may be predictive of IO response. Genomic profiling-based evaluation of biomarkers of response to tyrosine kinase inhibitors and identifies patients unlikely to benefit from IO. Widespread adoption will require standardization of inclusion and exclusion criteria for TMB; informatics solutions such as in silico downsampling may be required to further harmonize TMB across disparate sequencing panels. In contrast to PD-L1 expression, TMB status is likely relatively stable across a patient’s tumor at any point in time, recognizing that subclonal evolution may lead to subtle differences across samples, sites of disease and that TMB may be less predictive at scores close to established “high” cutoffs. The optimal biomarker may not yet exist, however a holistic view of the tumor that takes into account tumor genomics, immune milieu, and checkpoint status is likely to offer the greatest clinical benefit to patients most likely to benefit from IO. established that immune system plays a critical role in destroying cancer cells. Tumor cells, however, use different strategies to avoid recognition by the immune system, including "immunologic checkpoints" and "immunosuppression.

Programmed death-1 (PD-1) immune checkpoint pathways have been the most extensively studied. Several agents interfering with the PD-1 axis have been evaluated in clinical trials. Since these drugs directly target the patient’s own immune system, they have the potential to be effective across multiple tumor types, including lung cancer. The PD-1 receptor is expressed on activated T-cells, and the key ligands for this receptor are programmed death ligands 1 (PD-L1) and 2 (PD-L2). PD-1 is up-regulated in many tumors and high-level expression (≥50%) has been observed in approximately 30% of NSCLC. This overexpression helps tumor to evade immune responses. Binding of PD-L1 or PD-L2 to PD-1 receptors inhibits T-cell activation reducing antitumor immune responses. Therefore, PD-1 represents a logical target for cancer immunotherapy, but not as a single first-line setting. Immuno-oncology as single agent or in combination with chemotherapy is the standard of care in PD-L1 expressing patients, target therapy is recommended in oncogene addicted and the proportion of patients still candidate for exclusive chemotherapy is gradually decreasing. Agents targeting PD-1 or PD-L1, such as pembrolizumab, nivolumab or atezolizumab, are now approved in clinical practice in first or in second-line setting. Results from several randomized clinical trials comparing immunotherapy as single agent or in combination with chemotherapy versus chemotherapy alone are rising the question on what is the best first-line treatment and whether platinum-based chemotherapy could be avoided in our patients. Three phase III studies compared immunotherapy as single arm with platinum-based chemotherapy. One of the phase II studies, the Keynote 042 trial, compared pembrolizumab monotherapy versus platinum-based doublet in NSCLC patients with high PD-L1 expression. The study demonstrated that pembrolizumab is superior to chemotherapy by doubling median overall survival (OS; 30.0 versus 14.2 months, p=0.002). Similar results were obtained in the Keynote 024 trial comparing pembrolizumab versus chemotherapy in patients with at least 1% of PD-L1 expression. This study, including a large percentage of patients with PD-L1 expression ≥50%, confirmed the superiority of pembrolizumab versus chemotherapy in terms of OS (20.0 versus 12.2 months, p=0.003). In contrast, the Checkmate 206 study, comparing nivolumab versus chemotherapy in patients with at least 1% PD-L1 expression, showed no OS difference in both arms even in the subgroup of patients with PD-L1 expression ≥50%. Importantly, both Keynote 042 and Checkmate 206 trials showed no survival improvement in patients with low levels of PD-L1 expression (1-49%). Four different phase III trials, two in non-squamous (Keynote 189 and IMPower 150) and two in squamous histology (Keynote 407 and IMPower 131), compared standard chemotherapy plus a checkpoint inhibitor versus chemotherapy alone. The Keynote 189, evaluating pembrolizumab plus chemotherapy versus chemotherapy alone, showed a significant improvement in OS when pembrolizumab was added to chemotherapy in all patient subgroups, irrespective of PD-L1 expression. Interestingly, the OS Hazard Ratio (HR) was better than the HR obtained in studies with pembrolizumab monotherapy, suggesting that combination of immunotherapy and chemotherapy could be superior to chemotherapy alone even in patients with high levels of PD-L1 expression, because the combination was better in controlling toxicity. The IMPower 150, a large 3 arms study (atezolizumab plus carboplatin-paclitaxel: Arm A; or atezolizumab carboplatin-paclitaxel-bevacizumab: Arm B; or carboplatin-paclitaxel-bevacizumab: Arm C), demonstrated a significant survival improvement in Arm A versus Arm C, but not Arm A versus Arm B at the initial survival analysis. The Keynote 407 compared pembrolizumab plus carboplatin-taxol (paclitaxel or nab-paclitaxel) versus the same chemotherapy regimens in patients with squamous histology. Similarly to Keynote 189, addition of pembrolizumab to chemotherapy yielded in a OS improvement in patients receiving immunotherapy, irrespective of PD-L1 expression. The IMPower 131 was a 3 arms study comparing atezolizumab plus carboplatin-paclitaxel (Arm A) or atezolizumab plus carboplatin-nab-paclitaxel (Arm B) versus carboplatin-nab-paclitaxel as first-line therapy in squamous histology. Although the HR was superior to arm C in terms of progression-free survival (PFS), the first interim analysis showed that OS improvement was confined to individuals with PD-L1 expression ≥50%. Finally, of particular interest is the recently published results from the De-De combo arm of the Checkmate 227 study. In this trial, PD-L1 negative patients were randomized to nivolumab plus ipilimumab versus platinum-based chemotherapy versus platinum-based chemotherapy plus nivolumab. In patients with high TMB no difference in PFS was observed in the three arms. Overall, these 3 large randomized phase III trials include a relevant biomarker for refining selection of patients candidate to immunotherapy. Overall, all available data demonstrated that immunotherapy is the new standard of care as initial therapy in patients with NSCLC irrespective of histology. Current evidence support usage of immunotherapy single agent only in PD-L1 ≥50%. For patients with low or no PD-L1 expression immunotherapy plus chemotherapy is superior to chemotherapy alone, but the "checkpoint" and "TMB" could better define in which patients chemotherapy can be avoided and in which patients immunotherapy is not effective.

The longstanding dogma that local therapies do not apply for metastatic cancers like non-small cell lung cancer (NSCLC) because “the horse is out of the barn” is predicated on two concepts that do not necessarily apply to a subset of patients with oligometastatic NSCLC. First, local ablative therapy (LAT) is assumed to be futile when the pace of the cancer is defined by a diffuse disease process. Second, LAT is presumed to be excessively toxic that limits its application in oligometastatic NSCLC. These limitations do not apply, making LATs a standard treatment strategy. Patients with a solitary brain or adrenal “precocious metastasis” have long been recognized as having a potential for prolonged survival after definitive treatment of both the primary tumor and the (usually) resected metastatic focus, with approximately 25% remaining alive and without evidence of recurrent cancer years later (1). This underscores that metastatic disease is not a binary variable that necessarily connotes a diffuse process and highlights that effective local therapy can render some patients in the spectrum of metastatic disease durable cancer-free. Patients with advanced NSCLC who are now strong candidates to benefit from LAT include those with oligometastatic disease, whether as their “de novo” presentation, induced oligometastatic disease after highly effective systemic therapy, the “oligoprogressing” disease following prior treatment, or “oligoprogressing” disease after a prolonged duration of good disease control (2). The population of appropriate candidates has increased in recent years due to the growing range of systemic therapies that may produce deep and prolonged responses that becomes an oligometastatic state, or sustained disease control prior to oligoprogression. Along with the minority of patients with driver mutations who benefit dramatically from targeted therapies, a majority of patients with NSCLC who receive immunotherapy alone or in combination with chemotherapy can now achieve a good response to their first-line systemic therapy. Along with a greater anticipated pool of strong candidates with oligometastatic NSCLC, LATs can now be pursued with markedly lower risk for the same or greater efficacy. Surgery to resect solitary metastases is typically feasible, but requires a more invasive approach with good outcomes but fewer complications and easier recovery than the historical open surgeries required in the past (3). At the same time, stereotactic ablative body radiation (SABR) for primary or metastatic sites has now been shown widely effective and generally very well tolerated option for patients (4), with a steadily growing body of evidence leading to wider availability of SABR. But are the theoretical benefits from LAT realized in this setting? Retrospective case series have consistent demonstrated that a subset of patients with oligometastatic NSCLC can achieve very favorable outcomes, particularly in terms of progression-free survival (PFS) as well as overall survival (OS) in some series (5). Of course, it is not possible to determine from a retrospective case series whether these patients do extremely well because of the interventions or that the interventions are causally connected to their outcome. LAT is limited by the fact that the most common site of progression is in the area(s) of known disease, but the fact that LAT extends the time to development of new and distant metastases illustrates that local therapy can change the trajectory of systemic disease, rather than eradicating it. First, LAT is an appropriate standard only for the subset of patients with very limited foci of disease that are amenable to LAT and without a more diffuse disease process. Whether the subset
of patients for whom LAT is a standard should be 1-2 or 3-5 lesions has

Historically, brain metastases from non-small cell lung cancer (NSCLC) have been associated with short prognosis with limited benefits from whole brain radiotherapy (WBRT) or cytotoxic chemotherapy. The effectiveness of tyrosine kinase inhibitors (TKIs) in advanced EGFR- and ALK-driven NSCLC has translated into survival times far longer than chemotherapy or unselected patients. Among these patients, brain metastases may occur in 20–40% at first presentation, and up to 50% over the course of their illness.4,5 In spite of this, patients may live for several years following diagnosis of brain metastases and are accordingly a target of longer-term systemic therapy (CNS)-directed treatments.4,6,7 For patients diagnosed with brain metastases from EGFR- or ALK-driven NSCLC, initial treatment options range from TKI alone, through WBRT, stereotactic radiosurgery (SRS) to craniotomy and resection. All eligible patients will ultimately receive systemic therapy with TKI, and this is likely to be the most important component in preventing or delaying further CNS metastases. The utility of local radiotherapy is therefore worthy of debate in this patient population. Multiple retrospective series have attempted to examine this effect, the largest of which was a US multi-institution study, which reported a median overall survival (OS) for patients treated with SRS and TKI over TKI alone (median OS 46 vs 25 months, p<0.001).7 Studies in Canada and China did not find a difference in survival, but all of these are largely subject to confounding bias based on the selection of patients for local treatments, as well as potential bias in the follow-up of brain lesions.4,6,7 In addition, most patients included in all of these studies were treated with 1st generation TKIs targeting EGFR or ALK. Within randomized trials including patients treated with modern TKIs, relatively few develop CNS progression, at least as their first evidence of progressive disease. This is evident among patients with brain metastases enrolled in the FLAURA trial in first-line EGFR mutation positive NSCLC, where CNS progression was seen in 12% of the osimertinib group and 30% of the control group, contrasting with 4% in the 2nd generation TKI (p<0.001).8 In ALK-rearranged NSCLC, results from the ALEX trial demonstrate much better CNS control with alectinib, with brain progression in 12% compared with 45% of those treated with crizotinib (p<0.001).9 Among patients with measurable CNS metastases treated with alectinib, the objective response rate (ORR) was 81%, with complete responses seen in 45%, compared with an ORR of 59% for crizotinib and complete responses in 9%. Patients in both studies with CNS disease at entry were treated with SRS for control of brain metastases at study entry, but the high response rates and relatively low rates of progression speak to the efficacy of these TKIs in suppressing micrometastatic disease that would not be controlled by focal radiotherapy. With promising results like these, why would we wish to delay or avoid local therapies, especially if the use of palliative treatments for patients with advanced cancer is generally to preserve quality of life and function for as long as possible, with treatments that are not overly burdensome or toxic. The data from these trials of modern TKIs would suggest that for most patients, systemic therapy will effectively control the overt or occult brain metastases and they can be spared the inconvenience and potential toxicity of locoregional treatments. Recently, there has been a move from WBRT towards SRS even for the treatment of multiple brain metastases, driven primarily by data reporting the non-inferiority of SRS over WBRT.6 However, the rates of decline in neurocognitive appear lower with SRS, in the setting of questionable clinical benefit and when patients are expected to live several years with CNS metastases, the risk of toxicity may not be justified. There are, however, patients with oncogene-driven brain metastases who have received TKI alone or as radiotherapy or surgery, and others – those with major neurological symptoms, hydrocephalus, or in circumstances where molecular testing is delayed or where effective TKIs are unavailable or contraindicated. However, for most patients with oncogene-driven lung cancer who will receive TKI therapy, delaying upfront radiotherapy for brain metastases may not negatively affect patient outcomes. Data from randomized trials of targeted therapy alone or with radiotherapy will be required to definitively answer this question. References: 1. **PC09 APPROACHES TO MANAGEMENT OF ADVANCED NSCLC**

**WEDNESDAY, SEPTEMBER 26, 2018 - 10:30-12:00**

(PC09.01 DEBATE 1: EARLY VS DELAYED TREATMENT OF ASYMPTOMATIC BRAIN METASTASES IN WILD-TYPE NSCLC - EARLY VS DELAYED TREATMENT OF ASYMPTOMATIC BRAIN METASTASES IN WILD-TYPE NSCLC - EARLY VS DELAYED TREATMENT OF ASYMPTOMATIC BRAIN METASTASES IN WILD-TYPE NSCLC - EARLY VS DELAYED TREATMENT OF ASYMPTOMATIC BRAIN METASTASES IN WILD-TYPE NSCLC)

Q. Zhou
Guangdong Lung Cancer Institute, Guangdong General Hospital & Guangdong Academy of Medical Sciences, Guangzhou/CN

Brain metastases (BM) appear in about 25% patients at the diagnosis phase in non-small cell lung cancer (NSCLC), and almost half of the patients will eventually develop to BM during their disease progress. Median overall survival (OS) for NSCLC patients with BM ranges from 3–15 months. Metastatic NSCLC is difficult to treat in general. In ESMO guideline, we suggest treating patients with these effective systemic therapies upfront, delaying or omitting the use of local CNS treatments, and therefore avoiding their accompanying toxicities. This recommendation pertains particularly to oncogenic driven asymptomatic BM, since intracranial control can be achieved with TKIs in the majority of cases and therefore has the potential to offer a cure or to achieve long-term disease control.

**Keywords:** Brain Metastases, Systemic Therapy, Local CNS Treatment, Systemic Therapy Frontline.
The SWI/SNF complexes are ATP-dependent remodelers of the chromatin structure, by disrupting of DNA–histone interactions to activate or repress gene expression (Wilson et al. 2011). In healthy adults and during embryonic development, the complex is involved in the control of cell differentiation and in the specification of different tissues. Components of the SWI/SNF complex bind to various nuclear receptors, such as those of estrogen, progesterone, androgen, glucocorticoids and retinoic acid, thereby adapting the gene expression programs to the demands of the cell environmental requirements. The effect of the SWI/SNF complex on some of these processes, at least, in part, related to its involvement in regulating hormone-responsive promoters (reviewed Romero et al. 2014). A few years ago, we discovered that, in lung cancer, the SWI/SNF component, SMARCA4 (also called BRG1), is genetically inactivated in about thirty per cent of non-small cell lung cancers (NSCLC), and that its inactivation is in a background of wild-type MYC (Medina et al. 2008). Nowadays, it is well established that other components of the complex are also commonly inactivated in most cancer types, including lung cancer (reviewed in Romero et al. 2014). Gene alterations of the SWI/SNF complex are significantly more common in NSCLC, as compared to small cell lung cancers (SCLC), and tend to be associated with smoking habit. In addition, we reported the presence of tumor-specific inactivation of the MYC-associated factor X gene, MAX, in about ten percent of SCLC (Romero et al. 2014). These two events are mutually exclusive among them and with alterations at the MYC-family of genes. We also demonstrated that SMARCA4 regulates the expression of MAX and that depletion of SMARCA4 specifically in MAX-deficient cells strongly decreased cell growth, heralding a synthetic lethal interaction with potential therapeutic implications. Furthermore, MAX regulated expression of SMARCA4 to activate neuroendocrine transcriptional programs and to up-regulate MYC targets, such as glycolytic-related genes. Finally, we observed genetic inactivation of the MAX dimerization protein, MGA, in lung cancers with wild type components of the SWI/SNF or MYC pathways. The widespread occurrence of alterations at genes encoding different components of the SWI/SNF complex reveals an important new feature that sustains cancer development. Retinoic acid (RA) and glucocorticoids (GC) are well known modulators of cell differentiation, embryonic development and morphogenesis. GCs and RA are part of the cutaneous treatment of some malignancies, mostly leukemias (Collins et al. 2002; Rutz et al. 2002; Pottier et al. 2008). However, most solid tumors, including lung cancers, are refractory to both RA-based therapy and to the underlying somatic alterations of refractoriness to GC and RA is a dysfunctional SWI/SNF complex, for example due to alterations at SMARCA4 (Romero et al. 2002). On the other hand, compounds that modulate the structure of the chromatin are currently used to treat cancer. These include histone deacetylase (HDAC) inhibitors, in hematological malignancies and cutaneous T-cell lymphomas, and inhibitors of DNA methylation such as azacitidine for myelodysplastic syndrome (Liu et al. 2013). HDACs and DNA methylation inhibitors promote gene transcription by increasing DNA accessibility through the inhibition of histone deacetylation and DNA methylation, respectively. In a preliminary study, these drugs, in combination, have shown promising results in the treatment of lung cancer patients. In lung cancer cell lines, we observed that GC plus RA (GC/RA) in combination with the epigenetic drugs azacitidine and SAHA (A/S) reduced cell growth, triggered pro-differentiation gene expression signatures and downregulated MYC, in MYC-amplified but not in most SMARCA4–mutant cells (Romero et al. 2017). In vivo, treatments with GC/RA improved overall survival of mice implanted with MYC-amplified cells and reduced tumor cell viability and cell proliferation. We also found some effect of the SAHA treatment, alone in reducing the cell growth of MYC-amplified lung cancer cells but not those that are SMARCA4-deficient. Thus, we propose that the combination of retinoids, corticoids and epigenetic treatments of lung tumors with MYC amplification constitute a strategy for therapeutic intervention in this otherwise incurable disease. Altogether, the genetic observations coupled with the functional evidence demonstrate that an aberrant SWI/SNF–MYC network is essential for lung cancer development and optimizes novel possibilities for the treatment of lung cancer patients. Immunotherapy has revolutionized the field of oncology in an increasing number of tumor indications [1]. The challenge is how to incorporate these into the toolbox of medical oncologists, given the complexity and inequities of the distinct healthcare system throughout the globe, limiting financial resources and numerous health needs. Here we provide a series of recommendations that are likely to improve access and reduce the cost of these medications. Nonetheless, there are numerous challenges that must be overcome if the entire cancer population eligible to receive immunotherapy will benefit from this remarkable advancement in health care. In the last 15 years cancer drugs prices have been escalating and have become an issue for patients and the entire healthcare system. Earlier to 2000, the average price for a year of therapy or total treatment was $10,000. By 2012, this had increased tenfold with 92% of the new drugs approved for cancer indications that year costing more than $100,000 per year of treatment. Globally, the costs of oncology therapeutics and supportive care increased 11.5% from 2010 to 2015 [2].

Predictions that integrate trends in incidence, survival, oncology therapeutics and supportive care increased 11.5% from 2010 to 2015 than $100,000 per year of treatment. Globally, the costs of oncology therapeutics and supportive care increased 11.5% from 2010 to 2015 [2].

Keywords: Clinical trial design, immunotherapy
At the time of writing this summary, only the US and Canada had approved national screening with low-dose computed tomography (LDCT) and this was based primarily on the US National Lung Screening Trial (NLST).[1] Since this landmark study, there has been much debate and further research work to clarify the best way to undertake a screening programme. Initially, uncertainty about the details of an optimal programme that ensures that benefits outweigh harms in a cost-effective manner, was a reason to delay initiation of programmes in other countries.[2] However, many now believe that there is sufficient evidence to design a programme that will deliver a substantial reduction in mortality within the commonly quoted willingness to pay thresholds, in developed countries.[3] What is making policy makers cautious is the fact that the results of the only other randomised trial powered to detect a lung cancer mortality difference, the Dutch-Belgian NELSON trial, are still awaited. Figure 1 shows one of the factors that may be crucial in producing a favourable balance between benefits and harms and these are summarised below.

**Selecting** people at high risk of lung cancer, who are more likely to benefit than those at low risk makes the intervention more cost effective. The use of multivariable risk prediction models increases the cost effectiveness over simple age and smoking criteria used in NLST. It is important that people who are at low risk, some being the 10-15% of people who develop lung cancer but have never smoked, understand why they should not be screened. There is also an intermediate risk group where cost is the main consideration. Modelling has shown that annual *scanning* is more cost effective than biennial. However, where a previous CT is negative (no significant pulmonary nodules) the risk of cancer a year later is low, allowing a 2-year interval and cost savings. Imaging and reporting standards are well-developed.

**Indeterminate findings** need to be managed according to guidelines that employ initial interval LDCT, recognising that the risk of malignancy is low, avoiding overdiagnosis, higher radiation dose imaging and false positive diagnosis.[4] The false positive rate is 1-3% with this patient-centred definition is applied. **Clinical work-up and treatment** should also follow modern pulmonary nodule management and other clinical guidelines.[5] To reduce overdiagnosis and harms from biopsies and surgery by avoiding intervention when the risk of malignancy is low, or when cancers are indolent and unlikely to cause harm. Applying this “intelligent” approach yields a benign resection rate of around 10% and the in most recent UK pilot it was 2%. [6-8] **Smoking cessation** support should be integral as the overall quit rates are greater than in the general population and further increased by intermediate findings. Some issues are unresolved and could further improve cost-effectiveness.

**Participation** in screening has been disappointing in the US and active research into ways to increase this is needed to ensure an impact at population level. Strategies involving add-on health interventions and addressing incidental findings needs to be carefully evaluated using the same principle of benefit outweighing harm. **Information** to support people to make an informed decision about whether screening is right for them are area that is heavily on the minds of patients and the public. An undoubted challenge to implementation in some countries is the demand on human and physical resources.

**Screening for lung cancer makes logical sense and has a strong evidence base but delivering an optimum programme is dependent on attention to detail.** It is important that country-specific pilot programmes now are underway adhere to best practice so we see detection of early stage disease in the population and further increased by intermediate findings. Some issues are unresolved and could further improve cost-effectiveness.

Misinformation or false myths about cancer generate fear and a negative perception by the person affected by this disease. Lung cancer patients experience a higher level of cancer-related stigma than other cancer patients, because the general negative attitude about smoking, recognized as one of the main risk factors, contributes to the stigmatization of people who live with this condition. Although the ratio between tobacco use and lung cancer is established, worldwide lung cancer patients are affected by a noteworthy and unjustified stigma and considered responsible for their disease in a different way from other cancer patients. For it, they are often reluctant to disclose the disease, because of the fear to be discriminated, and patients’ stories show that stigma could be harmful and detrimental to them and their loved ones and may cause limitations in working toward a cure. The lack of public empathy and support adds an emotional burden to an already frustrating situation that can affect quality of life and may contribute to depression, anxiety, poor self-esteem, guilt, shame, blame, negatively impacting psychological adjustments and interpersonal communication. Low public support for lung cancer is not restricted to popular perceptions and attitudes, but can also be seen in research funding. Lung cancer remains an underfunded disease and despite the higher mortality, it received less funding compared to other common cancers, such as breast cancer. **What can be done?** Stigma impacts all spheres of a person’s life and patients, caregivers, advocates and healthcare professionals have started years ago actively working in this area developing programs and campaigns that can help to change this situation, partly persisting because smoking is still considered as a bad habit rather than a serious addiction. It’s important to motivate and encourage smokers to quit rather than blaming them, and even when the lung cancer has already been diagnosed, smoking cessation is important for a better quality of life. Providing smoking-free policies and tailored and effective campaigns is essential for improving the people awareness about the issue that smoking contributes to the larger of diseases and can even if most people associate it exclusively with lung cancer. But, lung cancer is not just a smoker’s disease, there are additional factors to consider and the education of patients, the general public and the health care personnel on these topics plays a valuable role. To help dispel stigma it is crucial the dissemination of correct and up-to-date information, the commitment of celebrities, patient families and friends, doctors in campaigning and advocating on their behalf, sharing the stories of lung cancer patient’s in order to increase the visibility of this disease and to generate a movement able to create a support network more sympathetic with these people, because they need and deserve care and support, not an evaluation of the possible causes of the disease. Raising the awareness is one of the main goals of any Lung Cancer Advocate worldwide and in conjunction with Lung Cancer Awareness Month, observed annually in November, many advocacy groups improve their efforts independently or in cooperation for promoting public campaigns about prevention, screening, new treatments and other issues. With the purpose of harmonizing the action, some years ago the International Association for the Study of Lung Cancer (IASLC)
proposed and lead a unified effort among a consortium of non-profit lung cancer patient organizations and individuals to produce a coordinated public awareness campaign for Lung Cancer Awareness Month (LCAM) in November in order to reach the maximum amount of impact on media coverage, policy makers and public support. Reducing stigma is also one of pillar of the global action of GLCC (Global Lung Cancer Coalition) that in 2010, commissioned a research carried out by Ipsos MORI, which surveyed over 16,000 people in 16 countries, and found some evidence that sympathy levels were influenced by rates of smoking in each country. Between 10% and 29% of people admitted to feeling less sympathetic towards lung cancer sufferers because of its association with smoking. In 2017, GLCC commissioned a new multi-national study to Populus agency to undertake an online survey of adults across 25 countries for understanding attitudes towards lung cancer among the public. The results confirmed that 21% of people, out of least 1,000 adults per country still agree that they have less sympathy for people with lung cancer than other forms of cancer. In conclusion, in lung cancer there is a strong need to overcome many challenges to ensure that all of the patients may have the same hope and equal chances to fight against this disease. Lung cancer patients and cancer survivors face a number of significant challenges and more has to be done to increase public awareness, to provide diagnostic tools and access to safe and effective treatments, to support efficient research and to combat the stigma. We’ve come a long way, and we certainly have a long way to go. We should work all together to effectively diminish the stigma that surrounds lung cancer and move forward in a positive way. MS04 E-CIGARETTES - WHAT DO LUNG CANCER ADVOCATES NEED TO KNOW? M. Peters Faculty of Medicine and Health Sciences, Macquarie University, Macquarie Park/NSW/AU

Since the release of the IASLC Statement on e-cigarettes in 2014(1), opinion in relation to their role has become more not less polarised. E-cigarettes are going away as an issue and advocates should be aware of the state of knowledge generally and of reputable information to which they can refer. Lung cancer advocates and patient supporters should have enough knowledge to assist individual patients to make an informed decision, to educate if that is their role and to advocate for the best care environment for those who have lung cancer or are at elevated risk for the development of lung cancer in the future. Some scenarios are worthy of consideration. The smoker who needs surgical resection. Smoking cessation is standard-of-care before thoracic surgery. Cessation reduces respiratory morbidity and improves wound healing. Almost all smokers in this situation quit easily. Limited studies suggest an adverse effect of e-cigarettes on wound healing that is similar to smoking. More disturbingly, a bronchoscopy study found severe bronchial inflammation (tuberculosis) where there is sufficient, robust evidence that smoking is associated with severe bronchial inflammation and ça on any inflammation. Cessation should be the aim. There are also practical problems with few health-care providers permitting e-cigarette use in enclosed spaces. NRT in contrast can be used in any location. Current smokers involved in lung cancer guidelines need programs of nicotine cessation. Therefore, is unquestionably a high value group for effective smoking cessation intervention. The considerations are those for the availability and recommendation for e-cigarettes in the community generally. What is the benefit of e-cigarettes in promoting cessation in its report, NASEM concluded that there is limited evidence that e-cigarettes are effective aids to promote smoking cessation, moderate evidence from randomized controlled trials that e-cigarettes with nicotine are more effective than e-cigarettes without nicotine and that There is insufficient evidence from randomized controlled trials about the effectiveness of e-cigarettes as cessation aids compared with no treatment or FDA–approved smoking cessation treatments(3). Since that report was released, the largest RCT of e-cigarettes vs other treatment options published in NEJM found no benefit for e-cigarettes(4). What are the harms especially long-term when long term use is encouraged There are probably few harms of a short-course (6 weeks) of e-cigarette use. A relatively significant decline in lung function is detected at 3 months. Airway inflammation is also seen rapidly. Some Much attention has been focussed on the claim that e-cigarettes are 95% safer than smoking. This claim is supported by no evidence. It is true that tobacco smoke contains putative cancer-causing chemicals that are at low levels in e-cigarette vapour but the real situation is more complex. In the bronchoscopy study looking at airway protein levels, there was a cluster of adverse changes seen only with smoking, another seen with smoking and e-cigarette use and a third seen only with e-cigarette vapour(2). Whether these are from the base chemicals, nicotine or flavourings is uncertain. Long-term studies are few. Use of e-cigarettes for two years in a study sponsored by a tobacco-company subsidiary detected very rapid (5%/year) loss of lung function(6). There are no meaningful long-term studies for CV risk and smoking-related cancers. What are the wider harms in promoting smoking in youths and young adults? The NASEM report concludes that there is “substantial evidence that e-cigarette use increases risk of initiation, progression, and nicotine dependence in young adults”. Based on a meta-analysis, after adjustment for all reasonable confounders the risk is about 3-fold. It is inevitable that promotion amongst children and young adults will occur generating concerns as now seen with the JUUL product. Where is the role of e-cigarettes at the cessation time as a smoking alternative? For the Lung Cancer Advocates, we must recognize that smoking is the most powerful single predictor of poor health outcome datasets that have evolved in conjunction with staging during the adoption of the AJCC 7th and now 8th edition for lung tumor staging. It has become evident that the evaluation requires an integration of clinical, radiologic, pathologic and molecular data to produce the most precise stage to guide patient management. In younger patients, multiple nodules were largely assumed to represent advanced disease; however, the survival data point to a more heterogeneous patient group. Differences in histology were cited as reasons for a conclusion of synchronous primary tumors, but these differences needed to

ABSTRACTS IASLC 19 th World Conference on Lung Cancer | 63

MSN DIAGNOSTIC DILEMMA IN LUNG CANCER
MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00

The evaluation of patients with multiple lung nodules, which include situations of synchronous as well as metachronous presentations, has become an area of focused interest. This is in part due to the outcome datasets that have evolved in conjunction with staging during the adoption of the AJCC 7th and now 8th edition for lung tumor staging. It has become evident that the evaluation requires an integration of clinical, radiologic, pathologic and molecular data to produce the most precise stage to guide patient management. In younger patients, multiple nodules were largely assumed to represent advanced disease; however, the survival data point to a more heterogeneous patient group. Differences in histology were cited as reasons for a conclusion of synchronous primary tumors, but these differences needed to
be relatively stark—for example adenocarcinoma versus squamous carcinoma. Three major shifts in knowledge impacted this field: 1) in pathology, movement away from the “lung tumor into mixed subtype with recognition of categories of early non-mucinous lepidic tumors 2) imaging advances, including the advent of successful lung cancer screening and imaging correlates of early lepidic pattern tumors and 3) the explosion of molecular pathology in lung cancer, particularly in adenocarcinoma. The result of these advances is a sophisticated approach that integrates these data into a stage as well as a conceptual conclusion regarding tumor biology and pathogenesis. Once lung malignancy is confirmed pathologically in a patient, the radiologist can use imaging features, especially ground glass nodules and the configuration of part solid nodules, to lead to clinically relevant conclusions about the likelihood of synchronous primaries when multiple nodules are encountered. In fact, other parameters, such as persistence, size growth, imaging characteristics and evolution of the solid component in a part solid lesion may lead to relevant predictions in the absence of histologic confirmation. For the pathologist, non-mucinous lepidic tumors (adenocarcinoma-in-situ, minimally invasive adenocarcinoma and lepidic predominant adenocarcinoma) and the recognition of unusual patterns of invasive carcinoma, function well in the decision making process, as non-mucinous AIS, MIA and LPA are considered primary tumors and unusual patterns of invasive carcinoma (e.g. micropapillary or invasive mucinous) within the multifocal lesions are an important feature in recognizing intra-pulmonary metastasis. This area still requires refinement, especially among the LPA tumors and tumor in which common patterns such as acinar patterns predominate. Several molecular changes can also be detected in invasion. Certain molecular events, such as particular patterns of copy number alterations, may occur in an individual patient’s tumor but would otherwise be uncommon in that tumor type overall. Such a feature or set of features can assemble to form a molecular fingerprint of that primary tumor that is different and preserved in metastatic foci but unlikely to occur by chance in a new primary. In a similar fashion early molecular drivers of adenocarcinoma such as EGFR mutation and KRAS mutation, most often persist in metastatic foci. Discordance in such drivers can be valuable evidence to support synchronous primary carcinoma when used in conjunction with other information. Use of a wider set of mutational alterations may lead to more accurate information with regard to the likelihood of tumor evolution from one primary (i.e. intrapulmonary metastasis). A combination of these data from the authors of this study is used to form the IASLC staging 8th edition recognize 4 disease patterns with associated imaging, pathologic, TNM classification and conceptual viewpoint. Second primary lung cancer (unrelated tumors), multifocal ground glass or lepidic nodules (separate tumors, despite common non-mucinous lepidic morphology), pneumatic-type adenocarcinoma (often mucinous, single tumor with diffuse pulmonary involvement), and separate tumor nodule (single tumor with intrapulmonary metastasis). While data already exist suggesting the staging, often downstaging, of multiple pulmonary carcinomas, widespread use of the AJCC 8th edition and accrual of cases, with survival information, that fit the above conceptual approach are needed to support its biological significance. MS05.03 TUMOR HETEROGENEITY IN LUNG CANCER
E. Brambilla
Pathology, Institut Albert Bonniot, Hopital Albert Michallon, Grenoble/FR

Lung cancer is composed of populations of cells with distinct molecular genetics, epigenetics and phenotypic features. This phenomenon called intra-tumor heterogeneity (ITH) adds complexity to the already well-known inter-tumor heterogeneity which is responsible for the huge number of types and subtypes in each main histological category type as defined in the 2015 WHO classification. Intra-tumor heterogeneity impacts on tumor biopsy strategy, characterization of actionable targets, treatment planning and drug resistance. Tumor types which display the highest histological heterogeneity are adenocarcinomas (ADC), adenosquamous carcinoma, pleomorphic carcinoma and the high grade neuroendocrine tumor small cell lung cancer (SCLC) and large cell neuroendocrine(LCNEC) when combined. However intra-tumor heterogeneity is not restricted to histology since molecular heterogeneity at the levels of genetics (mutations, copy number alterations), DNA methylation, mRNA expression profiling and immune context (PD1 expression) show high intra-tumor variability in most conventional lung tumor histologies. Capturing the full molecular landscape of each tumor and choosing the right target is indeed a crucial clinical dilemma facing intra-tumor heterogeneity. Although histological main type correlates with characteristic genomics, histological heterogeneity relies more on transcriptomic expressions profiles and functional pathways (embryonal, stellencell, EMT+). On the other hand drivers are still guided by molecular alterations. The mechanisms of tumor plasticity and resistance.(2) A-Histological Heterogeneity 1-Adenocarcinoma (60% of lung cancer) present with up to 5 histological patterns declined as predominant or not, lepidic, papillary, acinar/cirriform, micropapillary and solid (WHO 2015) requiring resection samples to allow an accurate diagnosis of combinations. Advantages derive from this complexity: some patterns have high prognostic value; high grade patterns solid, micropapillary and cirriform (even not predominant >= 5%) are independent determinants of short survival, whereas the pure lepideric pattern (AIS) or minimally invasive MIA predict 100% 5 years survival and predominant lepideric invasive ADC have statistically better prognosis than all other ADC. Spatial heterogeneity is well conserved temporally allowing discrimination of multiple primaries versus lung metastases when different or same combinations are compared. Disadvantage resides in interpretation of small samples showing only a part of the patterns. At molecular levels (genomics, expression profiling, immune context) adenocarcinoma show extended intra-tumor heterogeneity. Unfortunately each pattern does not predict specific driver mutations (EGFR,KRAS, BRAF, gene amplification). 2- Adenosquamous carcinoma (2% of lung cancer) is typically composed of both squamous cell carcinoma (SQCC) and adenocarcinoma (ADC) components (at least 10%). Both components might be morphologically obvious (ADC pattern, keratinizing SQCC) or one is obvious and IHC is necessary to identify the other as SQCC (P40+) or ADC (TF1). Diagnostic challenges include size of the sample, one component missing on small sample with its associated mutations, and variable components in primary and metastases. Molecular features are characteristic of one or both components: 56% tyrosine kinase mutations (32% EGFR; 11% KRAS,1-4% others) in ADC or in both. FGFR1 amplification in SQCC: Dual histospecific mutations indicate a common cell of origin with early clonal trunk mutation maintained at progression (2) 3-Pleomorphic carcinoma: (0.5% of lung cancer) is the most heterogeneous entity, composed of one or several components of NSCLC (ADC, SQCC, large cell) with at least 10% of spindle or giant cell carcinoma a clear feature of EMT (epithelial mesenchymal transition). Diagnosis requires resection sample. In undifferentiated areas IHC (TF1/P40) will identify the NSCLC component and predict genetic markers. Mutations regionality is predicted and parallels histological components, if ADC (Kras, EGFR,BRAF Met ALK rearrangement) if SQCC FGFR1 amplification. The most frequent MET exon 14 skipping mutation (20%) is heterogeneously distributed. Tumors with SMARC4 mutations described also in adenocarcinomas with obvious EMT transdifferentiation and BRG1 negative IHC are not considered as pleomorphic carcinoma. 4.-Combined high grade tumors: Combined SCLC small cell Lung Carcinoma (SCLC) and combined Large cell neuroendocrine carcinoma LCNEC account for 20% of each in resected samples, less readily detectable on small samples, 10% SCLC or LCNEC are sufficient. The genetic alterations are not therapeutically actionable yet, excepted in trials (DLL3). Occurrence of mutations in the non-neuroendocrine component deserve recognition since it can induce drug resistance and transdifferentiation. Transformation of SCLC to NSCLC has been reported after cytotoxic SCLC chemotherapy (E. Brambilla JCO 1991) suggesting intra-tumor heterogeneity or cell plasticity under therapeutic pressure, and a common initiating stem cell between SCLC and NSCLC. Inter-tumor heterogeneity at molecular level is better documented than the intra-tumor heterogeneity, in absence of multi-region sequencing. NOTCH and DD3 therapeutic targets shows both inter and intra-tumor heterogeneity(7) B-Temporal intra-tumor heterogeneity Genetic dynamics characterizes tumor progression, well studied during ADC progression from AAH to invasive ADC. The conservation of driver clonal but not subclonal mutations occur in metastases vs primary. Transdifferentiation is a typical example of temporal heterogeneity where a tumor treated ,more rarely spontaneously, transforms in another tumor type, SCLC to NSCLC, EGFR mutations adenosquamous to SQCC or SCLC or pleomorphic carcinoma with EMT, showing that tumor plasticity conferred by EMT results in temporal intra-tumor heterogeneity with transdifferentiation (2) C-Spatial intra-tumor heterogeneity across histology All studies (2-3) establish the concept of trunk and branches in the phylogenetic tree, the clonal trunk mutations are present in all regions (EGFR MET BRAF TP53 ALK...). In 75% of tumors and additional variant subclonal mutations in some but not all regions. Lessons: -One biopsy may not capture the extent of landscape IT -The trunk mutation is homogenously distributed whereas branched mutations are heterogeneously distributed. Cell free DNA overtime better capture genetic landscape. References: 1- A genomic-based classification of human lung tumors, Sci Transl. Med 2013 5:209,153 2-Xue et al. MS05.04 DIAGNOSIS AND CLASSIFICATION IN BIOPSIeS
A. Moreira
Pathology, New York University Langone Health, New York/US

In the last decade, significant progress has been made in the field of thoracic oncology, mostly in the management of patients with non-small cell carcinoma (NSCLC). The carcinoma of subtypes of NSCLC is now directly linked with options of chemotherapy regimens, and further screening for targetable molecular alterations. In the 2015 W.H.O Classification of Lung cancer, the importance of small biopsies has been highlighted as well as the use of immunohistochemical stains as ancillary test to separate adenocarcinoma from squamous cell carcinomas. Despite the use of IHC, the classification of NSCLC remain based on histologic features and IHC is recommended in cases with no clear evidence of differentiation between adenocarcinoma and squamous cell carcinoma. It is important to notice that the diagnosis of Large Cell Carcinoma is not recommended in small biopsy specimens. For the histological diagnosis of adenocarcinoma, the following features need to be presence in the biopsy: acinar, papillary, micropapillary and lepidic patterns, and for the histological diagnosis of squamous cell carcinoma, the presence of...
keratinization and intracellular bridges must be present. Therefore, in a biopsy with solid growth pattern and no evidence of keratinization, the use of IHC is recommended. The use of IHC improved diagnostic accuracy in the lung carcinoma classification, but the interpretation can be challenging and the pathologists must be aware of many interpretation pitfalls that can involve antibody clones, interpretation of the staining pattern, and more stains for more antibodies. When confronted with a tumor of likely lung origin for which the main question is subtyping of adenocarcinoma versus squamous carcinoma, the recommendation is to use a limited panel that includes TTF1 and p40. The use of this panel can simplify cases with unclear evidence for marker testing. Naspi-A can be added to the panel in challenging cases but there is no clear evidence that the latter marker is superior to TTF-1. Differences in sensitivity and specificity for naspi-A depends on whether a monoclonal or polyclonal antibody is used. Keratin 7 is not useful to separate adenocarcinoma from Squamous carcinoma. According to the classification, a NSCLC with immunohistochemical evidence of adenocarcinoma differentiation (any nuclear TTF-1 positivity) should be diagnosed as NSCLC-favor adenocarcinoma, whereas a tumor with evidence of squamous differentiation (strong and diffuse p40 positivity) should be classified as NSCLC, favor squamous cell carcinoma. In tumors with inconclusive immunoprofile, the best diagnostic term is NSCLC-NOS. For tumors with double positivity (TTF1+p40), it is important to remember that double positivity in the same cells does not define an adenocarcinoma. For the diagnosis of adenocarcinoma each marker should be seen in different components/areas of the tumor. Double staining is seen in adenocarcinomas or in NSCLC-Nos that carries mutations in the gene of the naspi-A protein. For example, for naspi-A negativity (TTF1-neg/p40 neg) in patients with no other history of malignancy, the diagnosis of NSCLC-NOS can be accepted because approximately 20-30% of adenocarcinoma of the lung are negative for these markers. If clinical history is not known, however, other stains should be added to the panel to rule out metastatic disease. An important marker for keratin, because metastatic melanomas or other non-epithelial tumors may mimic carcinoma, especially in small biopsy samples. For patients with known history of other malignancies, histological comparison with prior tumors should be pursued, targeted IHC with organ specific markers (PAX-8, GATA-3, NKX3.1, etc.) provides strong support to this interpretation, particularly when previous materials are unavailable for review. The current WHO classification recommends that neuroendocrine (NE) markers be performed only when NE morphologic features are present. IHC positivity for NE markers alone is not diagnostic of a NE tumor because positivity for NE markers may be encountered in approximately 10-30% of adenocarcinomas. A panel of chromogranin A, synaptophysin and CD56 is the best combination for the diagnosis of NE tumors. There is no consensus on how many markers should be used for the diagnosis of NE, most cases of NE tumors are positive for ≥2 out of the 3 NE markers. Positivity for at least one NE marker is necessary for the diagnosis of Large Cell Neuroendocrine Carcinoma (LCNEC) in association with histological features (chromatin pattern, palisading etc). The diagnosis of LCNEC in a biopsy or cytology specimen is not recommended but can be suggested if a combination of histological features and NE markers positivity is encountered. A proliferative marker such as Ki-67 is very useful for the classification of NE tumors in small biopsy specimens, especially in samples with significant crush artifact. In small biopsies Ki-67 stains can separate a low-grade NE tumor (carcinoid) from a high grade tumor such as small cell carcinoma. Ki-67 is not recommended in the classification of typical from atypical carcinoid in excision specimens. In cytology samples, the marker does not work well in alcohol-fixed specimen and can lead to misclassification of NE tumors. Suggested reading: Sauter JL., Grogl KL, Vranja JA, et al. Lung cancer is an aggressive malignancy with low (< 10%) 5-year survival rates when metastases appear. Historically, surgical resection in metastatic setting has not been beneficial in term of survival; this was especially true when options for effective systemic therapy were limited. It is now recognized that up to 50% of patients who presents with metastatic NSCLC have (up to 5) number of metastases. Common sites of metastases include brain, lungs, adrenal glands, bones, or liver. In appropriately selected patients, surgical resection in metastatic lung cancer may be considered. The use of molecular, pathological and transparenchymal approaches. With the increasing use of molecular techniques to distinguish cancers even of the same morphological appearance, such diagnostic approaches are of increasing clinical utility. For intrathoracic therapeutics, local Interventional Radioablation techniques such as radiofrequency and microwave ablation increasingly popular. In parallel with diagnostics, emerging Pulmonology techniques are also research the potential application of these techniques applied endobronchially in addition to new modalities such as steam ablation. Interventional Radiologists also have a useful role to play in the management of extra-thoracic oligometastatic disease, as techniques such as radiofrequency and microwave ablation can be used such as for liver lesions. This session will review the emerging data for the key role of Pulmonology and Interventional Radiology in the Management of Oligometastatic NSCLC.

regarded as a relative contra-indication. If brain metastases are present, they should be treated first; other metastatic sites maybe addressed based on symptoms. Commonly, systemic platinum-based chemotherapy has been administered as the 1st-line therapy for 3–4 cycles to sort out the cancer biology and response to chemotherapy. Stable or improved disease following chemotherapy makes proceeding with surgical resection of primary tumor and control of oligometastases possible. However, this paradigm continues to evolve in the era of immunotherapy and targeted therapy. There are a number of advantages to surgical resection of lung cancer in oligometastatic setting, as compared to other local modalities. Complete resection provides the best chance for prolonged local and regional disease control. It hypothetically removes all or at least the majority of cancer clones, it allows for detailed pathological analysis of the tumor and lymph nodes, and it provides adequate tissue for translational studies or personalized experimental treatment approaches. With current modalities, such as video assisted or robotic assisted thoracic surgery, recovery from surgical treatment of lung cancer can be expeditious. With the use of enhanced recovery pathways, even recovery after thoracotomy mimics surgical treatment of lung cancer can be expeditious. With the use of pathological analysis of the tumor and lymph nodes, and it provides evidence that is not conclusive and biomarkers are still under investigation. Surgical therapy and radiation therapy should be considered complementary modalities in oligometastatic lung cancer. If lobectomy is possible from a primary disease control in an acceptable-risk surgical candidate, it should not be discarded as an option over radiation. Considering current operative experience following prolonged immunotherapy, it is hypothesized that salvage surgical resections for local recurrence following immune-radio therapy may be difficult and may not convert possible routine early lobectomy to an eventual salvage pneumonectomy. As the therapeutic options for oligometastatic lung cancer continue to evolve with much improved systemic options, effective local and regional therapy will become more important. Novel surgical techniques and enhanced recovery pathways have decreased the morbidity and speed up patients’ surgical recovery. Surgical resection should therefore continue to play a role in the multi-modality setting for oligometastatic lung cancer in appropriately selected patients. MS05 PRACTICAL ISSUES IN THE MANAGEMENT OF OLGOMETASTATIC NSCLC MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00

MS06.04 SYSTEMIC THERAPY FOR OLIGOMETASTASES: BEFORE, DURING, OR AFTER LOCAL THERAPIES? R. Camidge University of Colorado Cancer Center, Denver/US

Oligometastatic disease reflecting the concept of limited metastatic spread may be discussed in the setting of the sites of disease at diagnosis of stage IV disease. However, an analogous situation may also occur at progression on a therapy controlling all other sites of disease – so called oligoprogressive disease. Both may be considered for local ablative therapies (usually radiation or surgery, but also some other techniques such as radiofrequency ablation). When considering systemic therapy the therapy before the local therapy is usually as induction or preoperative neoadjuvant oligometastatic disease; as part of the radical local therapy (for example, combination chemoradiation therapy); or as maintenance therapy after the local therapy. The latter could reflect continuation of a tyrosine kinase inhibitor, pembrolizumab, nivolumab, or durvalumab to the oligoprogressive scenario. The issues to address are the adequacy of assessing oligometastatic disease at the time local therapy is considered; the details that appropriately define oligometastatic or oligoprogressive disease suitable for local therapy; and the potential for a direct interaction with the local therapy.

MS07 ANTIBODY-DRUG CONJUGATES IN ADVANCED NSCLC MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00

MS07.01 BASIC SCIENCE D. Gerber DT Southwestern, Dallas/TX/US

While in some cases antibodies that specifically bind tumor surface antigens can have therapeutic effects, many unmodified (naked) antibodies lack anti-cancer activity. Conjugation to cytotoxic drugs, radionuclides, or toxins can expand the utility of monoclonal antibodies and improve their potency. In this way, antibodies are employed as a means to target and deliver a toxic payload to the selected tissue. Factors critical to the success of antibody drug conjugates include the target antigen, antibody, and linker. This target antigen should be overexpressed in the tumor relative to healthy tissue. The antibody should have high affinity and avidity for the targeted tumor antigen. The linker should be stable in circulation but must efficiently release the payload after internalization within the cancer cell. The payload should be highly potent (picomolar range) cytotoxic agents with efficacy against the cancer under treatment, with a reproducible and optimal drug-to-antibody ratio (usually 3–4 drug molecules per antibody molecule), that does not meaningfully compromise the antibody’s biological and pharmacokinetic properties. The steps entailed in the mechanism of antibody-drug conjugate action include: (a) antigen binding; (b) antigen-antibody-drug conjugate complex internalization into endosomal vesicles; (c) processing along the endosomal-lysosomal pathway; (d) degradation into an active and proteolytically-rich environment; (e) intracellular release of cytotoxic compound. Antibody-drug conjugates may also retain antibody interactions with host immune effector functions, including antibody-dependent cellular cytotoxicity (ADCC). Mechanisms of resistance include (a) reduced target gene expression or presence of increased antigen mutations resulting in reduced target antigen on cell surface; (b) reduced antibody-drug conjugate internalization due to reduced cell surface trafficking or recycling; (c) multidrug resistance transporter efflux out of the targeted cell. In addition to differential expression on tumor cells, antibody-drug conjugate treatment may increase the expression of some antigen, provide a new identification target, or reduce the cell surface density of the target antigen, the more antibody-drug conjugate can be taken up and metabolized by the cell, to release the active cytotoxic agent. Rapid uptake of antibody-drug conjugate not only enhances efficacy, but also reduces opportunity for extracellular payload release. Antigens that are shed should be avoided. Antibody-drug conjugate technology has improved considerably in recent years. The employed antibodies are now chimeric, humanized, or fully human, and therefore less immunogenic than early murine antibodies. Efficient linkers (disulfide, dipetide, hydrazone) have improved stability in circulation as well as better release of active drug within the tumor cell. Finally, highly potent agents with IC50 in the subnanomolar range (matzinsane derivatives [DM1, DM4], auristatin [MMAE, MMAF], all of which are microtubule disrupting agents) have replaced conventional chemotherapy drugs such as doxorubicin, vinca alkaloids, and methotrexate. Despite the targeted nature of antibody-drug conjugates, toxicities may occur through multiple mechanisms: (1) Non-specific systemic release of the cytotoxic drug payload; (2) Non-selective cytotoxicity of target-negative cells in proximity to target-positive cells (bystander effect); (3) internalization of the antibody-drug conjugate by target-negative cells. Prior experience has shown that unrecognized expression of target antigen on healthy tissue can result in immunotoxicities: Lewis antigen (gastric mucosa-associated gastric) CD44v6 (deep layers of skin/fatal exfoliation); CA9 (intestinal mucosaassociated gastrointestinal toxicity). Further complicating the development of antibody-drug conjugates, preclinical models may not adequately predict clinical activity and tolerability. In mouse models, the target antigen is not commonly expressed in host tissues, resulting in misleadingly favorable preclinical activity. As evidence of the inherent challenges facing antibody-drug conjugates, only two have been approved by the U.S. Food and Drug Administration: ado-trastuzumab
emtansine (anti-HER2; for HER2-positive breast cancer) and brentuximab vedotin (anti-CD30; for Hodgkin’s lymphoma and anaplastic large-cell lymphoma). Target antigens relevant to non-small cell lung cancer under investigation include mesothelin (antitetan complex, vedotin), folate receptor (vinmecetin soravtansine), sodium-dependent phosphate transporter (2f122) (lifatuzumab vedotin; DNI0600DA), glycoprotein nonmetastatic B (gpnmb) (anti-gpnmb emtansine), and epidermal growth factor receptor (depatuzumab mafodotin). Perhaps the most developed antibody-drug conjugate in thoracic oncology, rovalpituzumab tseririne (r-Va-T) targets delta-like ligand 3 (DLL3), which is highly expressed in approximately two-thirds of small cell lung cancer, but not NSCLC. Ultimately, several factors may influence the efficacy of an antibody-drug conjugate, among them target expression, sensitivity to the payload, and aspects of target biology that may impact internalization and intracellular trafficking. Revisiting longstanding principles of cytotoxic therapy may improve the performance of antibody-drug conjugates. These principles include the importance of combination therapies and the recognition that not all tumors are sensitive to microtubule-disrupting agents.

MAYDAY, MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00

**MS07.03 CLINICAL DATA**
T. Stinchcombe
Duke Cancer Institute, Durham, NC/US

Antibody drug conjugates (ADC’s) are currently being developed for several thoracic malignancies, and preliminary studies have revealed activity in patients with progressive disease after standard therapy for non-small cell lung cancer (NSCLC). Saccituzumab Govitecan, an ADC targeting Trop-2 which is overexpressed on many epithelial cancers compared to normal tissues and the antibody is bound to SN-38 which is the active metabolite of irinotecan. In a single arm phase 2 trial (n=54) investigated in patients with NSCLC with disease progression after at least one line of therapy. The ORR was 17%, median DFS 5.2 months, and median OS 9.5 months. The grade 3 adverse events observed were neutropenia, anemia, diarrhea, nausea, and fatigue. Trop-2 staining was not associated with benefit from therapy in patients who had high Trop-2 staining. Telisotuzumab vedotin (ABBV-399) targets the c-Met protein and is conjugated to monomethyl auristatin E. 3 microtubule inhibitor. A phase 1 trial in metastatic solids tumor included an expansion cohort of in patients with NSCLC who were c-Met+ (defined as IHC H-score of ≥150). An objective response was observed in three of 16 patients (18.8%) with c-Met positive NSCLC, and at week 12 six of 16 (37.5%) experienced disease control. The treatment related adverse events observed (at all dose levels) were fatigue, anemia, leukopenia, hypomagnesemia, or at least with a minimal expression on healthy tissues, to reduce off-target toxicity. Importantly, the ideal antigen should be tumor specific or at least with a minimal expression on healthy tissues. This complex is able to recognize tumor antigens by way of a monoclonal antibody bound to cytotoxic chemicals showing high potency, relative hydrophilicity and a lack of susceptibility to P-glycoprotein, which is a very common resistance mechanism for ADCs. Linkers connecting the MoAb to the warhead must be transmembrane and able to internalize into the target cell after MoAb binding. Importantly, the ideal antigen should be tumor specific or at least with a minimal expression on healthy tissues, to reduce off-target toxicity. However, the type of non-cancerous cells on which the target antigen is exposed may also play a role in predicting ADCs toxicity. Because of the high turnover of the cell cycle–dependent mechanism of action, non-highly proliferating cells may be less vulnerable to the ADC cytotoxic damage. Despite these limitations, the fact that the tumor target antigen is not required to drive tumor growth, constitutes an appealing advantage for ADCs application in malignancies lacking acknowledged driver mutations. To circumvent these issues, alternative strategies to target tumor cells have been studied. Antibody drugs conjugates (ADC) represent a novel class of anti-cancer treatment designed with the aim to combine the cytotoxic activity of chemotherapeutics with the selectivity of target agents, thus increasing the therapeutic interval of available compounds. The paradigm of ADCs is to convey cytotoxicity selectively into tumor cells, by way of a monoclonal antibody (MoAb) bound to cytotoxic chemicals via synthetic linkers. To circumvent these issues, which serve as Trojan horse for ADC internalization into cancer cell. To date, two ADCs have entered clinical practice, brentuximab vedotin for hematological malignancies and trastuzumab emtansine in advanced breast cancer overexpressing human epidermal growth factor receptor 2 (HER2) [2]. In the field of thoracic malignancies, ADC research has focused on rarer “orphan” diseases, for which neither target therapies nor valuable second-line treatment options are available. In fact, the two ADCs currently underway in most advanced phases of clinical trials are rovalpituzumab tesirine for SCLC and anetumab emtansine for unresectable mesothelioma; however, with suboptimal early results [2;3]. In NSCLC, no ADC has been experimented yet in phase III trials. However, several basket trials are currently evaluating anti-cancer activity and safety of ADCs mainly targeting HER2 and NaPi2b, among others [4-6]. In NSCLC treatment, as well as in other malignancies, ADC development has been limited by several factors. First, to realize a suitable ADC numerous criteria must be fulfilled [7]. About the cytotoxic (also known as warhead), this must be an antibody molecule showing high potency, relative hydrophilicity and a lack of susceptibility to P-glycoprotein, which is a very common resistance mechanism for ADCs. Linkers connecting the MoAb to the warhead must be stable in blood, but they are also required to be able to release the drug inside the target cancer cells. Apart from these technical issues, which are under way of further improvement, the major unaddressed concern for ADCs in clinics may be finding the optimal antigen target. Cancer antigen must be transmembrane and able to internalize into the target cell after MoAb binding. Importantly, the ideal antigen should be tumor specific or at least with a minimal expression on healthy tissues, to reduce off-target toxicity. However, the type of non-cancerous cells on which the target antigen is exposed may also play a role in predicting ADCs toxicity. Because of the high turnover of the cell cycle–dependent mechanism of action, non-highly proliferating cells may be less vulnerable to the ADC cytotoxic damage. Instead of these limitations, the fact that the tumor target antigen is not required to drive tumor growth, constitutes an appealing advantage for ADCs application in malignancies lacking acknowledged driver mutations. In the context of thoracic cancers, squamous lung differentiated entities would be amenable for greater research efforts in finding an adequate ADC antigen target. A further barrier to the design of viable ADCs is the unavailability of a reproducible, standardized and economic technique to identify and validate valuable target antigens. So far, the techniques used are immunohistochemistry or -more recently - functional genomic mRNA profiling, with the latter failing to localize the predicted protein into cancer cells [1]. In NSCLC setting, concern is raised by the ruthless competition with the numerous systemic treatments and the importance of combination therapies and the recognition that not all tumors are sensitive to microtubule-disrupting agents.

MS08.01 HOW CAN REAL WORLD DATA IMPROVE CLINICAL EVIDENCE GENERATION AND IMPACT REGULATORY BODIES - EUROPEAN PERSPECTIVE Y. Lienes Radiation Oncology Department, UZ Ghent, Ghent/BE

Health technology assessment (HTA) evaluates the efficacy and effectiveness of new interventions, integrates these data with the costs to define efficiency and addresses future availability and distribution. As such, HTA focuses on accessibility and equity. Economic evaluations are central in this concept: weighing costs and effects, it supports evidence-based decisions on reimbursement, thus endorsing the introduction of innovative healthcare interventions in daily practice. After randomising 20942 of voluntary cooperators on HTA in Europe, currently more than 50 HTA bodies are currently operating in the European Union, (EU), it be still fragmented with different systems, different procedures and different requirements regarding the type of clinical evidence. Efficacy, the outcome a new intervention provides in the well-defined circumstances of a randomised controlled trial (RCT) and typically the input used to derive cost-effectiveness evidence, may not provide the best insight into the impact of an intervention in daily clinical care. Moreover, in contrast to what is common with pharmaceuticals, it may present much more difficult to prove with RCTs on radiotherapy or surgery, especially when it comes to evaluating the incremental evolution typical for new techniques and technologies, or the long-term benefits anticipated to follow more accurate treatment delivery. This has resulted in different regulatory systems for systemic and non-systemic treatment strategies, with attempts to come to a more homogenised HTA approach in the EU having so far failed. Real-world data are gradually expanding their role in the evidence generation of lung cancer radiotherapy. A first step moving away from RCTs is to adopt a more pragmatic approach to evidence generation, as is the case in the OligoCare project. This joint ESTRO-EORTC initiative is evaluating the outcome of oligometastatic patients, amongst others from primary lung cancer, treated with radical radiotherapy in a large prospective cohort study. Various patterns of care studies have generated clinical evidence on the uptake of new treatment techniques such as SBRT (Stereotactic Body Radiotherapy), on the value of multimodality treatments for locally-advanced non-small cell lung cancer (NSCLC) beyond the context of RCTs, or have allowed to develop prediction models to support decision-making. Furthermore, the analysis of such data available in cancer registries and other nation-wide databases can be leveraged to learn more about the quality of care, actual access to different treatment strategies, geographical and institutional variations and their potential impact on lung cancer survival. Real-life data can also be used to generate the cost information necessary to perform cost-effectiveness evaluations. Besides the more frequent approach to derive this evidence from reimbursement data, actual resource costs can also be computed in daily practice. One such initiative was undertaken in Belgium using Time-Driven Activity-Based Costing to compute real-life costs of radiotherapy, and more specifically of innovative radiotherapy techniques such as SBRT. Whereas all these examples provide interesting insight into the clinical and financial consequences of access to standard-of-care and innovative lung cancer radiotherapy, there is a dearth of information on how this evidence defines policy. One interesting approach to change practice is using coverage with evidence generation to provide early access to radiotherapy innovations, while stimulating the further generation of data. Such a programme of provisional financing has already in multiple tumour set-up in Belgium, with encouraging results on SBRT for primary tumours, most typically early-stage NSCLC, and for oligometastatic disease. While this programme allowed radiation oncologists to develop and provide SBRT without being financially penalised, it also generated the reassuring clinical evidence that will soon lead to the inclusion of SBRT in the formal national radiotherapy reimbursement system.

MS09 TUMOUR BOARD - TISSUE ACQUISITION AND STAGING MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

MS09.02 CASES PREPARED BY DRS. EDELL/MURGJI K. Steinke Medical Imaging, Royal Brisbane and Women’s Hospital, Brisbane/QLD/AU

Lung cancer remains the leading cause of cancer-related mortality worldwide. In order to provide adequate and appropriate treatment, staging is crucial. The TNM staging system is the established uniform method of staging lung cancer, both non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC). The revised classification of the most recent edition (TNM8) of the TNM staging system, proposed by the International Association for the Study of Lung Cancer (IASLC) and introduced in 2016, is based on an in-depth analysis of a new large international database of almost 78000 lung cancer cases from 16 countries. The first part of this talk will focus on tissue diagnosis, specifically CT-guided core biopsy. In the era of targeted therapies and customised treatment, the acquisition of an adequate and representative sample, especially in non-surgical patients, is pivotal. Complications, pitfalls and pearls of CT-guided lung biopsies will be addressed. The second part of the talk will be focussing on the changes between TNM-7 and TNM-8 – downstaging of lung atelectasis and pneumonitis, upstaging of squamous apical metastatic disease; the IASLC recommends that radiologists should document the number of metastatic lesions, the diameter of individual metastatic lesions and the number of involved organs at staging examinations. The second part of the talk will be focussing on the changes between TNM-7 and TNM-8 – downstaging of lung atelectasis and pneumonitis, upstaging of squamous apical metastatic disease; the IASLC recommends that radiologists should document the number of metastatic lesions, the diameter of individual metastatic lesions and the number of involved organs at staging examinations. The second part of the talk will be focussing on the changes between TNM-7 and TNM-8 – downstaging of lung atelectasis and pneumonitis, upstaging of squamous apical metastatic disease; the IASLC recommends that radiologists should document the number of metastatic lesions, the diameter of individual metastatic lesions and the number of involved organs at staging examinations.
techniques have been utilized for localization of the GGNs using various
methods 5. That can be done either percutaneously or transbronchially,
using various materials including a dye, colored collagen, barium, lipiodol,
micro coil, metallic wire, or fiducial 6. In our center, we have been using
various methods for preoperative localization and but currently, we
favor to use electromangetive navigational bronchoscopy (ENB) guided
dye marking technique. Once surgery is decided, deciding the extent
of resection is another issue. The size of solid portion measured on the
CT can be helpful. If it is less than 5 mm, a simple wide wedge resection
can be performed by which the goal of diagnosis and treatment can be
achieved. If it is larger than 5 mm, the specimen is examined by frozen
section and if the malignancy is confirmed, anatomic lung resection is
conducted.

INVITED SPEAKER
MINI SYMPOSIA

However, the CT findings have not yet proven sufficiently reliable to
guide the management plan. Intraoperative frozen section diagnosis
is an alternative that can guide the extent of the subsequent surgical
procedure. The problem of frozen section is, however, the fact that
deflated lung specimens often makes the correct diagnosis difficult. To
obviate this problem, the technique of inflating the lung specimen with
the embedding medium for frozen section (EMIT) has been used, which
allows better interpretation, and facilitated correct diagnosis in the
frozen section 7. In our center, we have been using EMIT and found a high
diagnostic accuracy with the concordance rate of 90.6% between EMIT
and permanent pathology. Based on our experience, it is our current
practice to perform a wide wedge resection of the GGNs and send the
specimen for EMIT. If the result of EMIT is pre-invasive lesions (benign,
AAH, AIS, or MIA), we do not perform additional resection. If the invasive
adenocarcinoma is diagnosed, we prefer to proceed anatomic lung
resection with systematic lymph node dissection. Several studies showed
that limited resection could be beneficial, especially in early stage lung
adenocarcinoma, including GGN 8. On the contrary, in one prospective
study that reported a long-term outcome, limited resection of GGNs
showed a low disease-control rate. They reported adenocarcinomas
developed in four out of 26 patients in the surrounding area of initial
resection site after more than five years 9. However, as GGNs usually show
favorable prognosis, limited resection could be generally recommended
10
. Additionally, in cases of deeply located GGNs, where wedge resection
is not technically feasible, direct segmentectomy without wedge
biopsy for the purpose of diagnosis and treatment, is recommended.
For the segmentectomy, various technics can be used, but it is our
current practice to use ENB guided dye marking to define an adequate
parenchymal resection margin during the segmentectomy. To summarize,
although there are several CT findings that can differentiate between
pre-invasive and invasive lesions, those findings have not yet proven
sufficiently reliable to guide the management plan for GGNs. In addition,
attempt to sample solid component in GGNs using a biopsy needle is
often not feasible and therefore, not helpful for being used in clinical
decision. Currently, the best practice for the management of GGNs is to
carefully follow the patient with CT, and if malignancy is suspected, to
perform a surgical biopsy with the guide of various localization methods
and/or other innovative methods to differentiate between pre-invasive
versus invasive adenocarcinoma. 1. Yamagami T, Yoshimatsu R, Miura

Spread through air spaces (STAS) is a recently recognized pattern
of invasion in lung cancer defined as spread beyond the edge of the
main tumor into the air spaces surrounding the tumor. It was originally
described as a poor prognostic factor in Stage I lung adenocarcinoma.1
STAS has been observed in 15-62% of lung adenocarcinomas and
associated with poor prognosis in multiple independent cohorts
worldwide.2-4 In addition, it has now been shown to occur with
prognostic significance in most all major types of lung cancer including
squamous cell carcinoma (SQCC),5 small cell carcinoma SCLC),6 large
cell neuroendocrine carcinoma (LCNEC),6 atypical carcinoid (AC)6 and
pleomorphic carcinoma.7 Three dimensional evaluation has shown most
STAS clusters are attached to alveolar walls rather than floating in air
spaces suggesting a mechanism of detachment then reattachment
perhaps by vessel co-option.8 Criteria for STAS The original definition of
STAS by Kadota et al and the 2015 WHO consisted of tumor cells within
the first alveolar air spaces in the lung parenchyma beyond the edge
of the main tumor. It can occur as one of three morphologic patterns
including 1) micropapillary structures within air spaces; 2) solid nests
or tumor islands and 3) scattered discohesive single cells.1, 9 The solid
nest pattern is characteristic in other lung cancer histologies. Although
other criteria have been proposed our group has used these same criteria
for STAS to demonstrate its prognostic significance in SQCC, LCNEC,
SCLC and AC. Warth et al defined STAS with different criteria including
a detachment of small solid cell nests of least 5 tumor cells where < 3
alveolar spaces were regarded as limited STAS and tumor cells nests
>3 alveolar spaces away from the tumor as extensive STAS.4 Distance
of and Quantitation of STAS Gaber R et al found that circumferential
STAS was associated with a higher risk of recurrence free probability
(RFP) than focal STAS (5yr RFP in circumferential vs focal; 67% vs 87%,
p=0.027) and that longer distance of STAS was associated with a higher
risk of recurrence (5yr RFP >7 alveoli vs ≤ alveoli, 69% vs 91%, p=0.003).9
However, Quantitation of STAS was not prognostic (5yr RFP in >3/HPFs
vs ≤3/HPF, 75% vs 88%, p=0.15).9 Uruga H et al found that high vs low
STAS (≥5 vs 1-4 single cells or clusters) was an independent predictor of
worse (p=0.015).2 Warth did not find a prognostic difference between
extensive vs limited STAS as described above.4 Implications of STAS for
Radiation Therapy In the setting of sterotactic body radiation therapy
(SBRT) for lung cancer, the documentation of microscopic extension
has been appreciated for many years.10 Radiologic and pathologic
studies have shown that tumor cells can extend beyond the edge of the
tumor from 1.3 centimeters to 2.6 cm.10 Although the concept of STAS
emerged many years later, it provides morphologic and clinical support
to radiation therapists concerns to address microscopic extension and
STAS in planning the radiation field. Implications of STAS for Surgical
Management There is limited data evaluating pathologists ability to
recognize STAS in frozen section. Kameda et al found the sensitivity
and specificity of frozen section for prediction of STAS were 71%,
92.4% respectively and the accuracy was 80%.11 Kappa statistics for
interobserver agreement were 0.4-0.74. Walts AE et al studied frozen
section for evaluation of STAS and recommended that current evidence
did not warrant frozen section evaluation for STAS.12 However, frozen
section sensitivity to detect STAS positivity was 50%, with a 100%
positive predictive value and an 8% negative predictive value. So from
the two studies, it appears if a pathologist sees STAS on a frozen section
there is a 92-100% likelihood it will be present on permanent sections.
Both of these were retrospective studies where tissue sampling for frozen
sections was not made to include the tumor edge and adjacent lung to
search for STAS. More studies are needed to evaluate the potential role
of frozen section in detecting STAS and guiding intraoperative decisions
by surgeons. REFERENCES 1. Kadota K, et al. Tumor Spread through Air
Spaces is an Important Pattern of Invasion and Impacts the Frequency

MS11.01 IDENTIFYING CONSEQUENCES OF STIGMA ON LUNG CANCER CARE DELIVERY AND PATIENT OUTCOMES

H. Hamann

Departments of Psychology and Family & Community Medicine, University of Arizona, Tucson/AZ/US

Lung cancer stigma (the experience and internalization of negative appraisal and devaluation from others) is a formidable barrier to fulfilling the promise of high quality patient care and reduced lung cancer burden. Attention to the robust causal connection between smoking and lung cancer, although crucial for tobacco control, may have unintended consequences that generate blaming responses and biased negative perceptions toward lung cancer patients. Lung cancer stigma can have far-reaching, deleterious effects that range from reduced involvement in prevention and early detection interventions, negative psychosocial impact, impaired patient-clinician communication, inadequate access to diagnosis and treatment, and limited funding and public support for lung cancer research and care. The goals of this presentation are to describe the nature of lung cancer stigma and highlight research that addresses consequences of stigma on lung cancer care delivery and patient outcomes. The presentation also focuses on multilevel interventional opportunities to mitigate the negative effects of stigma. Based on both qualitative and quantitative assessment, our team has identified three primary components of patient-reported lung cancer stigma: perceived stigma, internalized stigma, and constrained disclosure (Hamann et al., 2018). Cross-sectional data indicate associations between stigma and impaired patient/provider communication, higher rates of depressive symptoms, and reduced engagement in care among lung cancer patients. Recent work has also demonstrated potential provider-level stigma toward lung cancer patients, with implications for treatment decisions and other aspects of lung cancer care. Intervventional opportunities include patient-based education and counseling to address the psychosocial and behavioral consequences of lung cancer stigma. Focusing on provider communication training also represents a promising opportunity to reduce stigma toward lung cancer patients.

MS12 IMMUNOTHERAPY AND RT

MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

MS12.01 BIOLOGY IO+RT

D. De Ruyschier

Department of Radiation Oncology (Maastro), Grow-School for Oncology and Developmental Biology, Maasricht University Medical Centre, Maasstricht/NL

Checkpoint inhibitors have changed the outcome of patients with metastatic non-small cell lung cancer (NSCLC) in first and in second line, with improved progression-free survival (PFS), overall survival (OS) and quality of life. Radiotherapy has consistently been shown to activate key elements of the immune system that are responsible for resistance for immune therapy. Radiation upregulates MHC-class I molecules that many cancer cells lack or only poorly express, tumor-associated antigens, provokes immunogenic cell death, activates dendritic cells, decreases regulatory T-cells (Tregs) in the tumor, broadens the T-cell repertoire and increases T-cell trafficking, amongst many other effects. Radiation may convert a completely or partly poorly or non-immunogenic tumor immunogenic. Radiotherapy in combination with different forms of immune therapy such as anti-PD-(L)1, anti-CTLA4, immunocytokines, dendritic cell vaccination and Toll-like receptor agonists improved consistently local tumor control and very Interestingly, lead to better systemic tumor control (the “abscopal” effect) and the induction of specific anti-cancer immunity with a memory effect. Moreover, as PDI/PO-L1 is upregulated by radiation and radiation can overcome resistance for PD-(L)1 blockage, their combination is logical. The best timing, sequencing and dosing of all modalities is a matter of intense research, but in pre-clinical models, the concurrent administration of anti-PD-(L)1 was superior to sequential. Clinical studies in NSCLC such as the subgroup analysis of the KEYNOTE-001 trial, the PACIFIC trial and the phase II results of NICOLAS support the rationale to view radiation as an immunotherapeutic drug that may enhance the immune response without limiting side effects when combined with the correct immunotherapy drugs for a given tumor and patient.

MS12.02 CLINICAL DATA AVAILABLE

F.M. Kong

Radiation Oncology, Case Western Reserve University, Cleveland/OH/US

The role of radiation is evolving in the era of immunotherapy. The abscopal effect of radiation on immune modulation has been discussed and researched greatly during recent days, and there is a significant amount of laboratory data suggesting its positive effect on tumor control. This presentation will focus on an objective review of clinical evidences for the clinical significant outcomes of radiation on immune function aiming to maximize the positive effect of Radiation immunomodulation. Standing from the clinic, I will not only review the GOOD side of abscopal effect, i.e. the increased tumor control distant from a focused local radiation, and examine the BAD effect of radiation immunomodulation, i.e. radiation immunosuppressive effect which can worsen the tumor control outcome and overall survival. Starting from an overview of these two conflicting effects of all solid tumors in general, the presentation will specifically focus on the literature of radiation immunomodulation effects in patients with non-small cell lung cancer. Predictive and correlative biomarkers for both GOOD and BAD effects will also be reviewed through thorough literature search. The ultimate goal of this presentation is to motivate us, the oncologists to search, and research on finding a way to deliver a more effective radiation therapy and a more effective way of combined therapy with radiation and immunotherapy, to maximize the GOOD abscopal benefit while minimize the BAD effects of radiation on immunofunction.

MS12.04 IMPLICATIONS FOR ROUTINE PRACTICE
P. Mitchell
Medical Oncology, Olivia Newton-John Cancer, Wellness and Research Centre, Heidelberg/VIC/AU

Over the last 3 years checkpoint inhibitors (CPI) have become established as key components in the treatment of stage III and IV NSCLC. The established CPI are PD-1 and PD-L1 inhibitors and more recently CTLA4 inhibitors, with ongoing research into other modulators of T-cell function. Used alone, these agents have their greatest efficacy in a subset of patients while in combination with other treatment modalities may enhance efficacy. Already concurrent pembrolizumab and chemotherapy has been shown to be more effective than chemotherapy alone for first-line metastatic NSCLC. In the clinic there are two major issues to consider when combining radiotherapy and CPI therapy. The first is whether there is a particularity when irradiating lung or the brain. The second issue is, can we harness radiotherapy to improve the efficacy of immunotherapy? Pneumonitis is a major concern when combining radiotherapy to the lung. Lower dose palliative radiotherapy is less of a concern but when treating primary lung cancer with curative intent, especially concurrent with chemotherapy, toxicity may impact on patient survival. In the phase III PACIFIC trial, of the 476 stage III NSCLC patients who received concurrent chemoradiation lung followed by durvalumab consolidation, grade ≥3 pneumonitis was 4.5% and no different from chemoradiation alone. In 93 stage III patients treated with concurrent chemoradiation followed by 12 months pembrolizumab consolidation grade ≥3 pneumonitis was 6.3%. We now have safety data for stage III patients with nivolumab given concurrently with thoracic chemoradiation, followed by pembrolizumab consolidation. For the 58 patients evaluable for toxicity in the NICOLAS trial, grade ≥3 pneumonitis was 10.3%. We now also have safety data for SABR (Stereotactic Ablative Radiotherapy) combined with CPI. Seventy-nine patients (53 NSCLC) received SABR to multiple metastases, followed within 7 days by pembrolizumab. The toxicity was as expected for pembrolizumab alone. Similarly Campbell has reported on treatment with concurrent SABR and pembrolizumab with either melanoma or NSCLC, with no increased toxicity. Treating brain melanoma metastases with radiosurgery concurrent with ipilimumab in 57 patients, Mortier found toxicity to be as expected for immunotherapy alone while a similar study by the same group found toxicity was not increased beyond that for pembrolizumab alone. There have been multiple reports, mostly in local case series, where local radiotherapy to a tumour causes shrinkage of a distant non-irradiated metastasis, termed an abscopal effect. It is hoped that likewise radiotherapy will enhance the effectiveness of CPI. Prior to CPI entering the clinic, in the START trial stage III patients treated with consolidation tecmecium (liposomal MUC1) vaccine following concurrent chemoradiation showed a 10 month survival advantage not seen in those who had received sequential chemoradiotherapy. Although overall the START trial was negative for the primary endpoint, this suggested that concurrent chemoradiation might enhance immunogenicity. In the PACIFIC trial of stage III NSCLC, all patients received concurrent chemoradiation. Patients randomised to a year of consolidation durvalumab had markedly improved PFS, and PFS with respect to tumour PD-L1 expression overall survival data are awaited. There are now also data suggesting an outcome benefit for NSCLC patients treated with concurrent SABR and CPI. In the PEBMRO-RT trial 74 NSCLC patients were randomised to receive SABR (3 x 8GY) to a single metastasis followed within 7 days by pembrolizumab, or pembrolizumab alone. All endpoints trended in favour of the combination. The primary endpoint of response rate at 12 weeks was 39% vs 21% (p=0.28), for SABR + CPI vs CPI respectively, while PFS (HR 0.61 p=0.08) and OS (HR 0.58 p=0.1) favoured combined SABR and pembrolizumab. A similar trial, NIVORAD, is being conducted by the ALTG co-operative group, where patients are randomised to receive nivolumab with or without SABR to a metastasis site during week 2. There are now good data to indicate that combining CPI and radiotherapy is safe, including radiotherapy to the lung and to the brain. Sequential concurrent chemoradiation in stage III NSCLC followed by durvalumab is highly effective. Emerging data suggest that radiotherapy may enhance the effectiveness of immunotherapy in stage IV disease but further randomised data are required. 1 Gandhi L. Keywords: Checkpoint inhibitors, radiotherapy, NSCLC
therapy) or neoadjuvant therapy (i.e. cytoreductive before a radical local therapy). Adjuvant setting Adjuvant therapy for resected NSCLC came into focus when the large international Adjuvant Lung Cancer Trial (IALT) demonstrated OS benefit with cisplatin-based chemotherapy. No further progress with other types of adjuvant therapy has been made since then. The progress in patients with advanced NSCLC in stage IV with pembrolizumab, durvalumab and EGFR mutations TKIs was not translated into the adjuvant setting [1]. As for immunotherapy, the MAGRIT trial assessed antigen-specific immunotherapy directed to the MAGE-A3 antigen in completely resected MAGE-A3 positive NSCLC [2]. The adjuvant setting = in the air = to eliminate sparse tumor cells remaining after surgery = was judged to be the ideal setting for this approach. Unfortunately, the trial did not improve survival. One of the hypotheses why is that the generated MAGE-A3 directed T-cells with cancer killing properties did not travel nor enter easily in tumors, and even if they did, they encountered checkpoints that blocked their potential benefit. Immune checkpoint inhibitors (ICI) immunotherapy, which revolutionized the approach to metastatic NSCLC, is now tested in the post-surgical setting with micrometastatic disease and low tumor burden. In contrast to directly cytotoxic chemotherapy, however, agents blocking the PD-1/PD-L1 axis require an interaction between antigen-presenting cells, CDB+ T cells, and tumor cells. It is far from certain that these intracellular interactions will occur sufficiently in patients with micrometastatic disease, where low tumor (mutation) burden may not sufficiently incite the tumor microenvironment. Because of the adjuvant setting, without detectable disease, no early effectiveness read-outs of efficacy nor translational tissue research is feasible. The results of the different ongoing trials with neoadjuvant therapy in early stage NSCLC needs to be validated in a Neoadjuvant setting. Because of the aforementioned limitations, the neoadjuvant use of PD-1/PD-L1 blockade is of greater interest for several reasons. From a biologic perspective, PD-1/PD-L1 blockade before surgery, when the tumor mass and intact locoregional lymph nodes with antigen-presenting cells T cells may be more readily available in a breast cancer model in mice, it has been suggested that neoadjuvant ICI is more effective than adjuvant ICI [3]. In the neoadjuvant setting, there was a stronger systemic tumor T-cell response with maintenance of tumor specific CDB+ T cells in the blood early after immunotherapy. High levels of CDB+ T cells predicted long-term survival in this mouse model. Moreover, induction of this systemic immune response could lead to immune memory that may prevent metastatic relapse over time. From a clinical perspective, the neoadjuvant setting may have advantages as we learned from the chemotherapy era. The systemic therapy has better distribution because of the intact vascularization, which may reduce the locoregional tumor extension. There is an early attack microscopical microscopic disease. The effects can be evaluated in vivo with pre- and post-imaging. From a clinical trial perspective, a big advantage is the possibility to study surrogate endpoints. The crucial outcome in this setting is OS, but this endpoint requires many years of follow-up. Here as well, lessons learnt from neoadjuvant chemotherapy followed by surgical resection are of use. Tumor-free lymph nodes and pathological response in the primary tumor have been associated with significantly better outcome. In a dedicated study on the prognostic impact of morphometric tissue analysis of tumor regression, the latter was graded in I: no regression; II: remaining vital tumor tissue ≥10% (grade Iia) or >10% (grade ib); and III: no evidence of vital tumor tissue [4]. Patients with tumors of regression grades Iib or III showed significantly longer OS than the others (3-year OS 52% vs 9%, P=0.02). These findings, however, do not translate to patients for surgery, as they are post-hoc analyses on the resection specimen. Ideally, one should have pre-surgical (pre-hoc analysis) predictors, but the standard clinical restaging with repeat CT after neoadjuvant only is a raw tool for this purpose. Our group first demonstrated that morphometric tissue analysis of mediastinal lymph nodes after induction was a strong prognosticator in that setting [5]. This was then validated in a prospective multi-center setting, using the first video-mediastinoscopy after neoadjuvant chemotherapy [6]. Patients with a grade Iia or III regression (<10% viable tumor) had much better outcome than the others; 5-year OS 13% versus 19%. A recent study investigated the clinical, pathological, and immunologic effects of short-term neoadjuvant PD-1 blockade in NSCLC [7]. Here again, major pathological regression was defined as ≤10% residual viable tumor on sections of the resected tumor. With this criterion, 45% of the patients had a major pathological response, with clear infiltration of CD8+ T cells in regressing tumors. Moreover, a systemic immune response with T-cells of similar T-cell receptor repertoire as in the tissue were described. Even with a very small sample size (N=21), this a strong mechanistic hint, both in the tumor and on distant sites, and has resulted in a promising surrogate endpoint effect. Whether this will translate in better 5-year OS now needs to be defined in larger multi-center phase 3 trials, several of which are currently started. References 1. Desyger E. G. et al. in e-cigarette aerosols were 9 to 450 times lower than in tobacco smoke [2]. Concerns have also been raised about the presence of metal particles in e-cigarette aerosol (particularly nickel and chromium, main elements in heating coils). The inhalation of these metals in large quantities may cause respiratory diseases, bronchitis, and pneumonia [3], however, these effects have not been definitively elucidated. The size of particulates generated from e-cigarettes affects pulmonary nicotine absorption and determines settlement of particulate matter into various parts of the upper or lower airways. There is likely substantial variation across generations of e-cigarette devices, and across brands. Results from laboratory studies indicate that e-cigarettes may expose users to small particles and lower amounts of particulate matter in general. While inhalation of high levels of particulate matter has been linked to greater mortality risk from cardiopulmonary illnesses, the available data indicate that e-cigarette particulate emissions expose users at a level akin to WHO guidelines and are far lower than those of conventional cigarettes. Issues raised about toxicological effects mostly question effects on cells, with a special interest in lung epithelial cells. For instance, many flavorings used in e-cigarettes (e.g. cinnamaldehyde, benzaldehyde, diacetyl) are already approved for use in food, yet their impact on respiratory health via repeated inhalation is currently unknown. Several studies have shown that e-cigarette flavorings could lead to lung cell damage (mostly by releasing free radicals) and inflammation in lung tissue [4]. Studies on cytotoxic effects of e-cigarette constituents have also identified negative effects on DNA. In one in vitro research, e-cigarette liquids aerosolized at biologically relevant doses induced increased DNA strand breaks and apoptosis while decreasing survival in both normal and cancerous human epithelial cell lines [5]. Moreover, in experiments conducted by Yu et al. [6] e-cigarettes aerosol has shown cytotoxic effects on epithelial cell lines and acted as a DNA-breaking agent. Given multiple potential etiologic mechanisms related to incident case development coupled with the long latency period in developing lung cancer, there is currently no definitive evidence to commenting on the role of e-cigarettes in increasing lung cancer risk. As an intermediate assessment, cross-sectional biomarker data can be suggestive of possible carcinogen exposures related to cancer development. For instance, Shahab et al. [7] examined a large panel of biomarker data among e-cigarette users, cigarette users, and users of both products (“dual users”). The e-cigarette-only users had significantly lower metabolite levels for tobacco-specific nitrosamines (TSNAs), particulate matters, and DNA adducts within the lung compared to e-cigarettes users [8]. Although evidence from biomarker studies is insufficient to evaluate causal mechanisms, but show users of e-cigarettes display lower levels of exposure to biomarkers of lung carcinogens when compared to smokers, such as NNK. Since e-cigarettes have only been on the market for a decade, it is presently not possible to assess all potential long-term harmful effects of e-cigarette use. To date, findings from clinical studies have demonstrated that e-cigarettes are likely less harmful compared to conventional tobacco cigarettes, and any harmful side effects are noticeably milder compared with regular cigarettes. Furthermore, it is also clear that e-cigarette aerosols are “not a harmless water vapor”, as claimed by manufacturers and retailers, and potential health effects from vaping may emerge after long-term use. term for the category. The question to be addressed is whether they ‘burning’ (combusting) the tobacco, so, HTP is a more accurate, broad cigarettes (HNB). The tobacco control community tends to call them the current market-disrupters which are the so-called ‘heat not burn’ the topic of this dissertation. Rather the topic for this paper will discuss marketplaces - those arise from a multitude of mostly small companies.

**INDUSTRY’S NEXT PROMISE**

**MS15.05 HEAT-NOT-BURN TOBACCO: REAL RISK REDUCTION OR**

The manufacturers also know Japan is a country of electric gadget geeks. 1946. Many Japanese smokers feel shame at releasing HPHC and ash. community. An American anthropologist Ruth Benedict described it as “Japanese people are very anxious about their reputation within their public acceptance of such products. The tobacco manufacturers aimed at public tobacco harm reduction and this is true for the HNBT ads. According to the guidelines set down by the Ministry of Finance, access to HNBT advertising/information web sites and purchase at virtual/real shops have been strictly restricted, requiring proof of age such as a driving license. In their web sites and on product packages, there are always some messaging to the effect of reduced HPHC. But not necessarily guaranteeing less harm to health, which is in accordance with the Ordinance for Enforcement of the Tobacco Business Act. Reduction in HPHC exposure and lower levels of biomarker responses have been vigorously reported in peer-reviewed journals, but many of them are funded, studied and reported by the tobacco manufacturing companies themselves. There have been several contradictory articles and in media coverage suggesting that some HPHC are released more from HNBT than from cigarettes. However, manufacturers refute the findings by pointing out inappropriate methods, evaluation and data presentation in these reports. The truth will need to wait for the academic and public health community to sort out the reality of the potential for HNBT to reduce the morbidity and mortality caused by tobacco product use. Currently, it seems reasonable to understand that HNBT is likely to expose users and bystanders to lower levels of HPHC. Although the extent of the reduction found so far varies between studies, reduced exposure to some HPHC is reported to be associated with less short-term harm. To this extent, HNBT might be beneficial for smokers who cannot quit and non-smokers around them. However, less is not zero. It will take 15-20 years to confirm long-term health harm caused by reduced HPHC, such as clinical carcinogenesis. It requires tremendous effort to maintain and watch a large cohort of HNBT users for that long period of time. In this light, on judgment which party ought to do and publish the study. Another question is who pays the cost and whether the study is worth the cost. Because zero is zero, tobacco products including HNBT are desired to be completely abandoned in the future, eliminating the need for long-term harm studies.

So, the question is: what are we to think about the products emerging from the global tobacco manufacturers that are being marketed in upper income countries? To be clear the topic is not about electronic nicotine delivery systems (ENDS) that have been sweeping the world’s markets, but rather products that arise from a multitude of mostly small companies, ENDS are an interesting topic that is quickly changing also - but, not the topic of this dissertation. Rather the topic for this paper will discuss the current market-disrupters which are the so-called ‘heat not burn’ cigarettes (HNB). The tobacco control community tends to call them ‘heated tobacco products’ (HTP). As some of them do come close to ‘burning’ (combusting) the tobacco, so, HTP is a more accurate, broad term for the category. The question to be addressed is whether they are less harmful than cigarettes or are they the usual ‘overall’ or untruthful marketing claims that have been the usual practice of the global tobacco manufacturers. A brief review: the global tobacco manufacturers (PM-Philip Morris, International, Philip Morris Asia) and the British American Tobacco (BAT-UK); Imperial Tobacco (UK); Altria (USA) and Japan Tobacco International (JTI- Japan).(see: https://www.statista.com/ statistics/259204/leading-10-tobacco-companies-worldwide-based-on- net-sales/). Altria is really a spin-off from Philip Morris International who sells their products in the USA, including trying to do so for their HNB product (IQOS). Each of them have their own offerings in the HNB category: PMI/Altria is the current leader with IQOS, quipped as standing for ‘heat not burn’. glo: and Thermacell have both marketed a HNB product but had thought to stay with their ENDS (blu) product. Reportedly, Imperial is considering getting their own HNB, as this category appears to be growing (commerically renumerate). JTI has PloomTECH. IQOS and glo use a lithium battery to heat compressed/ powdered tobacco to around 300 Celsius which creates an aerosol for inhalation. PloomTECH heats a liquid that has nicotine in it (closer to an ENDS) A recent paper by Farsalinos et, tested IQOS, an ENDS and a regular cigarette for emitted carbonyls, like formaldehyde and acrolein. (1) They found that IQOS emitted 82-98% less carbonyls compared to smoking 20 tobacco cigarettes. The ENDS emitted 92-99.8% less carbonyls. So, IQOS were better than cigarettes by alot, but the ENDS was better still. in a webpage hosted by RIVM (National Institute for Public Health and the Environment, ministry of Health, Welfare and Sport), their research to date is quoted as: “Heated tobacco products are newly available on the market. An example of such a product is the heatstick which is heated with an IQOS, a device that looks like an e-cigarette. However, the heatstick is heated with proper tobacco heads and not with heat meant for other harmful substances. The use of heatsticks with the IQOS is harmful to health, but probably less harmful than smoking tobacco cigarettes. This is RIVM’s conclusion, based on its research into heated tobacco products (HTPs).”(2) in another recent paper from Japan, HTPs, IQOS, glo and glo from PloomTECH were compared with reference cigarettes that are well-defined and not for human consumption (as if any should ever be!). (3) Chemists interested in these findings should check this paper. For the rest of us - it just demonstrates the tremendous variability in the products. Cigarettes deliver nicotine better than the other tested products, and IQOS does better than glo which does better than PloomTech. Since users are going for the nicotine, it seems that the order of preference will be cigarettes, IQOS, glo and PloomTech. However, the manufacturers are correct about inappropriate components used to make these products so they could be different next month. (This is the problem of unregulated products)

Most of the published/available research is by the tobacco industry. For the hardy, there is a very large amount of scientific information from PM on their IQOS submission to the US FDA. (4) This is all publicly available information - and actually, a very interesting read. The question always remains when reviewing tobacco industry research - can it be verified? Overall, however, it does seem that heated tobacco products (or, ENDS) deliver lower levels of most toxicants to the human lung. Low enough to prevent disease is a different question. BUT, cigarettes kill more than half of the people who use them, cause a huge amount of morbidity and healthcare costs - and, are addictive. So, the question facing society - or, public health - is it possible or probable that if people are already using cigarettes,-delivering nicotine to the lung (cigarettes) vs. delivering nicotine to HTP products - would there be lower morbidity and mortality than we currently experience from cigarettes? No one knows the answer at present - and, we are unlikely to know for a few decades the real answer. However, are we horrified enough at the currently greater than 7 million deaths globally per year from cigarettes to radically alter our passionless inactivity and push, by regulation (and social pressure) for people to quit cigarettes. If they use HTPs (or ENDS) to quit the unacceptably deadly cigarettes, so be it. I don’t know how they could be worse than what we currently allow. (Disclaimer: I am still passionate about the standard tobacco control measures that are working in some countries, per the Framework Convention for Tobacco Control. I do not trust the global tobacco manufacturers that they are willing to help everyone in the world, particularly in low income countries. Where are these HTP products would be more expensive (unaffordable?) for their current customers. I believe the industry is still interested in maintaining tobacco addiction - I want to ultimately reduce it as far as possible. First however, I want people who are nicotine addicted to stop dying from that addiction.) 1. Farsalinos KE et al. Types of Cancer Since the Beginning of This Century[2]. As a highly lethal disease, lung cancer has been a leading cause of cancer-related death in the world, and lung cancer mortality has steadily declined in some developed countries due to effective tobacco control and improvement of early detection and treatment. In U.S. Lung cancer death rates declined 45% between 1990 and 2015 among males and 19% between 2002 and 2011 among females[3]. However, as the sequence of population age, high smoking prevalence and serious air pollution, Lung cancer in China increased 465% during the past 30 years, and has ranked the highest among all types of cancer since the beginning of this century[2]. As a highly lethal disease, the 5-year survival of lung cancer in China was 19.5% and 11.2% in urban areas and rural areas respectively. Though smoking control is the most effective measure for the primary prevention of lung cancer, an upward trend of lung cancer incidence and mortality is still expected in future decades in China because of the high prevalence of smoking and severe air pollution. In addition, Lung cancer survival is closely related to the stage at diagnosis, that is, its prognosis is more favorable when diagnosed at an earlier stage. Accordingly, as a measure of secondary prevention, screening and early detection play an important role in lung cancer control. With the increasing disease burden from lung cancer, the widespread availability of spiral CT scanners in China, and the excellent survival of early lung cancer cases detected by LDCT, in 2009, lung cancer screening with LDCT were included into program of early detection and treatment of cancer which was the public health special subsidy from the central government[33]. And later, this prospective, multi-centre observational program was renamed as early detection and treatment of cancer in rural China[4]. From 2009 to 2015, lung cancer screening in this program has expanded from 2 centers to 10 centers from 6 provinces/Municipalities. Up to July 2007, a total of 54164 LDCT scans among about 13000 high risk individuals were conducted which including 19068 baseline screens and 35096 annual screens. The detection rate and early detection rate were 1% and 40% in baseline screening and were 0.4% and 56% in annual screening respectively(table 1 and 2).

Based on the protocol of lung cancer screening program in rural China, experts developed lung cancer screening guideline in China in 2015, and revised it recently[5,6]. Besides LDCT screening, the above two screening programs involved several other items including health promotion to increase screening acceptance, technical training for local doctors and technical personnel, delivery of smoking cessation intervention, biomarker discovery and validation to evaluate whether early lung cancer biomarker can refined high risk population and augment LDCT accuracy through classify nodules detected by LDCT. In addition, to keep a sustainable development of a national screening program, the two programs had been included into the special program of medical insurance system reform in China to explore the possibility of incorporating lung cancer screening in the routine health insurance system in China.

identify potential participants but primary care physicians determined if patients were appropriate for screening. Of 18,083 potential candidates, only 5,035 were assessed by their primary care physician. Of those considered appropriate, 50% went on to be screened. The participation of the primary care physician was key to successful recruitment [8]. The UK Lung Cancer Screening (UKLCS) used a population based approach through local primary care records. 23,794 (26.8%) of those contacted indicated willingness to participate in a screening study. Ex-smokers, those of higher socioeconomic status and in the 66-70 year age group were more likely to participate. Men and women were equally willing to participate [9]. Wake Forest University School of Medicine identified that their NLST participants did not reflect local demographics as only 3% of participants were black whereas blacks represented 25% of the local population [10]. PLCO strategies to increase participation among the black population included support from a prominent black business owner and local churches, including black individuals in the planning team, in community outreach and as interviewers. Focus groups or semi-structured interviews have identified that using members of ethnic minorities to promote or recruit are more likely to be successful in these groups [11]. Recruitment through primary care or other respected individuals in the community is also important [12]. Observations from NLST included: “go to where the smokers are”; build trust through local physicians; and use recruiters of the same ethnicity as target populations [3]. Interviews with current smokers identified themes that may contribute to reduced participation including fatalism, fear of diagnosis/treatment, pessimism about survival and stigma that lung cancer was a self-inflicted disease [13] Cancer Care Ontario High Risk Lung Cancer Screening Pilot Cancer Care Ontario (CCO) launched a screening program on June 1, 2017, at three centers that differed based on demographics, geography and academic or community hospital. Individuals are recruited, assessed for eligibility, screened and followed. The Tammemägi Risk Prediction model was used to identify eligible individuals. Those with a risk score ≥2 were eligible. Provider and public-led recruitment strategies were used. A major aim of the pilot was to recruit individuals who are known to have the highest rates of cigarette smoking: lower socioeconomic status (SES) and First Nations, Inuit and Metis. Areas of predicted high risk populations were identified within the catchment area of each pilot site. Market research was used to recommend recruitment modalities (eg TV, radio or print) for specific sub-groups such as lower SES, older middle-income suburbanites, and rural populations. An accredited Continuing Professional Development course was developed for primary care and collaborative educational sessions were held with primary care providers and First Nations, Inuit and Métis provider groups. In the first year, 3,294 individuals were recruited. The majority 3,294 (81%) were physician referred (Table 1). The leading methods of recruitment were physician referrals (65%), newspaper advertisements (11%), word of mouth (6%) and nurse practitioners (6%). Only 4% of individuals identified as First Nations, Inuit or Métis. Level of education at high school or lower was self-reported by 48% of individuals. Based on early results, June – November 2017, approximately 27% of eligible individuals were recruited from low income postal codes (average annual household income < $70,000 CAD). Health Sciences North used primary care providers to identify and refer potential participants leading to the highest participation rate across all three centres. The Ottawa Hospital utilized media recruitment methods which led to a high number of applicants but eligibility was lower than for physician referred participants. Provider-led recruitment was more successful at reaching target populations and enlisting eligible participants. At Lakeridge Health, provider-led strategies were less successful, so public-led recruitment strategies were increased. Public-led methods such as road shows and newspaper were used and led to a boost in volumes. Conclusions First year CCO pilot results have shown that provider-led recruitment strategies have been effective in enrolling appropriate individuals and is the primary source of recruitment for the pilot. Importantly, the proportion of eligible individuals recruited through their primary care physician is double that reported in the PANCAN study. Providers were also important in the VHA study. Use of Emr is helpful in identification of potentially eligible individuals. Mass mailing may reach more individuals, but is costly and inefficient. Our results demonstrate that support from primary care physicians is important in successful recruitment to lung cancer screening. Recruitment of First Nations, Inuit or Métis and those with a lower socioeconomic status remains a challenge. Utilizing previously identified strategies such as respected individuals in FNIM communities as well as members of ethnic minorities to promote the program and recruit participants will likely improve recruitment in these hard to reach populations.

Lung cancer remains the leading cause of cancer mortality worldwide. Early-stage lung cancer is usually asymptomatic and most patients present with symptoms are diagnosed at advanced stages with poor treatment outcome. Early detection is the most effective way to improve survival of lung cancer patients. Low-dose computed tomography (LDCT) scan is a proven tool for lung cancer screening. The National Lung Screening Trial (NLST) demonstrated a 20% mortality rate reduction in high-risk smokers who had undergone LDCT screening as compared to conventional chest X-ray. The effectiveness of LDCT screening among never-smokers is unknown. Evidence showed that the incidence of lung cancer among never-smokers is increasing. It is estimated that 25% of the lung cancer occurs in never-smokers and the prevalence is relatively high in East Asian women. In Taiwan, more than half of the lung cancer patients are never-smokers. We hypothesized that the diagnostic consensus reached and the risk models developed in non-Asian populations may not be suitable for Asians. Based on this unmet clinical need, we conducted a four-year LDCT screening program that enrolled 12,000 subjects with a three-year follow-up period. We also tempted to validate the risk SNPs associated with lung cancer susceptibility in never-smokers. Methods: This is a prospective, nationwide, multicenter study sponsored by the Ministry of Health and Welfare, Taiwan. The study protocol was approved by the institutional review boards. Informed consent was obtained from every participating subject. Individuals who fulfill the following criteria are eligible for the study: (1) aged between 55-75 years, (2) being a never-smoker, and (3) having one of the following risk factors: (i) family history of lung cancer within third-degree relatives, (ii) passive smoke exposure, (iii) history of pulmonary tuberculosis or COPD, (iv) cooking index ≥ 110, or (v) not using ventilator during cooking. The LDCT was conducted according to the guideline suggested by the American College of Radiology. A solid or part-solid (PS) nodule larger than 6 mm in diameter or a pure ground glass nodule (GGN) larger than 5 mm in diameter was designated as positive on LDCT. The LDCT were performed annually for three consecutive years. If LDCT was positive, short-term follow-up (3-6 months) or tissue diagnosis would be arranged. DNAs were extracted from peripheral blood mononuclear cells for SNPs typing (TERT, TP63, VIT1A, BAP1, HLA-DRB1, HLA-DQA1, HLA-DRB8/HLA-DRB5, DCBLD1 and YAP1) in every enrolled subject. In addition, a risk score prediction model integrated effects from family history and SNPs were developed and the risk of each individual was calculated. Results: This is the interim report. The data cut-off date was May 13, 2018. A total of 10,397 subjects were enrolled (Table1), with 4,498 subjects completed in Stage 1(2014-2015), 4,679 in Stage 2(2016-2017), and 1,220 in Stage 3(2018), respectively. A total of 329 subjects received biopsy for tissue pool (31 by bronchoscopy or CT guide, 298 by surgery) prior to the date of data cut-off. The final pathology diagnoses revealed 12 atypical adenomatous hyperplasias, 42 (17.3%) adenocarcinoma in situ, 46 (19.0%) minimally invasive adenocarcinoma, 152 (62.6%) invasive lung adenocarcinoma, one adenosquamous cell carcinoma, one squamous cell carcinoma, and one small cell carcinoma. In 243 lung cancer patients, 240 patients were adenocarcinoma, 208 patients were stage 1A and 23 patients were stage 1B. The lung cancer detection rate was 2.34% (243/10,397) with 95.1% being stage I. The risk score point was significantly different between normal (mean±SD = 50.1±28.84) and case (mean±SD = 59.4±28.23) (p< 0.0001). Conclusion: In the NLST study, the LDCT detection rate in the first stage was 1.03% (270/26,309). Our interim results showed that, in our pre-defined never-smoking high-risk population, the LDCT lung cancer detection rate was higher than NLST study (2.34% vs 1.03%). Previously reported 4 SNPs were still significant in this cohort. In addition, risk score model showed a high odds ratio of the high score group, suggesting that it may be useful to predict the risk of lung cancer in never-smokers. References: 1. MS16 IMPLEMENTATION OF LUNG CANCER SCREENING
TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MS16.05 OPTIMAL APPROACH TO INTEGRATE SMOKING CESSATION INTO SCREENING PROGRAM
M. Callister
Department of Respiratory Medicine, Leeds Teaching Hospitals, Leeds/GB

Smoking cessation should be an integral part of low dose CT (LDCT) screening for lung cancer. Smoking cessation and LDCT screening have additive effects on reducing lung cancer mortality, with 7 years smoking abstinence delivering a mortality reduction comparable with the benefit of screening itself [1]. It is well known that a positive screening result increases the likelihood of quitting [2]. However, the majority of people undergoing screening receive a negative result (73% and 78% in the National Lung Screening Trial at prevalence and incidence rounds, rising to 86% and 94% when scans were re-evaluated using the Lung-RADS classification) [3]. A negative result has the potential to falsely reassure patients and thus reduce the incentive to quit - the so-called 'licence to smoke' effect. This effect can only be properly assessed by comparison with an unscreened control population. Analysis from the NELSON study suggested such an effect may exist by demonstrating a higher quit rate in the unscreened control group compared to screened participants, although the effect lost statistical significance following intention to treat analysis [4]. However, this finding has not been replicated in two subsequent European studies. LDCT screening appeared to have no effect on smoking behaviours in the Danish Lung Cancer Screening Trial [5], and the LDCT screened arm had a higher quit rate than non-screened controls in the UK Lung Screening Pilot [6]. All three studies showed higher quit rates in both study arms compared to the background population, although such comparisons are likely to be subject to significant bias related to participation in a CT screening study. Thus although there is no convincing evidence of a licence-to-smoke effect, smoking cessation interventions in screening programmes are vital to guard against this, and to maximise the mortality benefits of these two interventions combined. One of the key questions regarding smoking cessation and screening is whether interventions that have worked in other settings should simply be transferred to screening programmes, or whether bespoke smoking cessation interventions are needed for this particular scenario. LDCT screening for lung cancer is itself a relatively recent phenomenon, having been introduced in the US and Canada following recommendations in 2013 and 2016 respectively. Accordingly, research into Smoking Cessation in the context of Lung Cancer Screening is in its relative infancy, a point acknowledged by the joint guideline on this topic produced by the Association for the Treatment of Tobacco Use and Dependence, and the Society for Research on Nicotine and Tobacco published in 2016 [7]. Most of the active research in this area is occurring within the SCALE collaboration (Smoking Cessation within the Context of Lung Cancer Screening) [8], constituting 8 clinical trials. 7 were funded by the National Cancer Institute and 1 by the Veterans Health Administration. These trials are assessing various strategies of smoking cessation support including on-site individual counselling, use of a telephone quit-line, digital cessation tools, the motivation of pre-screening smoking cessation interventions combined. One of the key questions regarding smoking cessation interventions in screening is likely to significantly improve the cost-effectiveness of the bundle. Whilst outcome data is awaited from these studies, interventions that have been shown to be effective in other settings should be applied to lung cancer screening programmes. Brief interventions by clinicians should cover the 5As of smoking cessation (ask, advise, assess, assist, arrange follow-up). Analysis of primary care delivered smoking cessation in NLST showed that arranging follow-up was associated with the highest chance of quitting (OR 1.46; 95% CI 1.19-1.76) but was only delivered in 10% of cases [9]. The UK National Institute for Clinical Excellence (NICE) has published guidelines for Stop Smoking Interventions and Services [10]. These include providing behavioural support by trained stop smoking staff together with provision of bupropion, varenicline or nicotine replacement therapy; setting quit dates; and checking self-reported abstinence using carbon monoxide monitoring at 4 weeks after the quit date. Studies mentioned above are testing whether less labour intensive alternatives might achieve similar results to on-site individual smoking cessation counselling. However, until such proof of equivalence is available, it might be argued that pairing smoking cessation services with lung cancer screening: A clinical model.

MS17 LIFE AFTER LUNG CANCER: SURVIVORSHIP
TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MS17.01 UNMET NEEDS AND QOL OF LUNG CANCER SURVIVORS
M. Giuliani
Radiation Oncology, University of Toronto and Princess Margaret Cancer Center, Toronto/ON/CA

Patients with lung cancer are living longer and more are being cured of their disease with advances in surgery, radiotherapy, systemic therapy and earlier detection through screening programs [1,2]. However, these treatments can result in physical disability, psychological morbidity and increased care needs. Lung cancer patients experience large amounts of unmet survivorship needs and these needs are often complex. In addition, lung cancer patients are less likely than other cancer patients to utilize supportive services [3]. This session will review the magnitude of unmet needs in lung cancer survivors, the nature of these unmet needs and potential mitigating interventions. The majority of lung cancer survivors report unmet needs and often patients experience multiple unmet needs. In one study, the mean number of unmet needs per patient was 7.6. The most common domains of unmet needs are in the psychological domain followed by the physical and the health system information domains. Patients with more advanced disease and those with increased symptoms...
are more likely to have unmet needs. The nature of common unmet needs include fears of the cancer returning, fatigue, facing an uncertain future, coordination of medical care, completing housework and having information on managing health. Addressing and mitigating the unmet survivorship needs in lung cancer patients is a complex undertaking. There are patient and caregiver factors, cancer center factors and systems level factors which must be addressed. This session will explore the role physical activity, survivorship care plans and self-management approaches to mitigate unmet needs and promote improvements in quality of life. Increased physical activity has been shown to have a significant impact on improving quality of life in lung cancer survivors.

Increased physical activity is also associated with improving cancer related fatigue. The Institute of Medicine has recommended that each cancer survivor receive a survivorship care plan. These survivorship care plans should include all aspects of their cancer diagnosis and treatment, coordination of care for the cancer team, information on prognosis, recommended surveillance activities for treatment related toxicity and cancer recurrence, recommendations for healthy behaviors and any additional supportive resources. Finally, employing effective self-management programs for lung cancer survivors can be an effective strategy to reduce unmet needs. There are other critical issues faced by lung cancer survivors. Surveillance for secondary cancers is an important aspect of survivorship care as patients cured of one lung cancer are at risk of developing a subsequent malignancy. Patients who survive with lung cancer can face significant financial toxicity and returning to work can be challenging. Resources to assist patients to return to work are an integral part of cancer survivorship programs. Finally, assisting lung cancer patients who who are older and frail, not only to treat cancer outcomes including disease control and survival, but also to improve quality of life and to reduce morbidity from other tobacco related conditions such as cardiovascular. These three topics will be covered in greater detail in other presentations in this session.

MS17.02 FINANCIAL TOXICITY AND OUT OF POCKET COSTS
B. Gyawali
Medicine, Brigham and Women’s Hospital, Boston/MA/US

Increasingly, patients are sharing the burden of high cancer care costs, even when patients have insurance, due to increases in co-payments and high-deductible health plans. The out of pocket (OOP) costs borne by patients with lung cancer in the US was $4 billion in 2014. In an analysis spanning between 2011-2014, the average per patient OOP costs in the first year after diagnosis were between $3,600 and $5,500 depending on the cancer type. The OOP costs were the highest on the month of diagnosis and declined substantially but never reached the pre-diagnosis level. In countries without a universal insurance system patients bear the total cost of the drug costs OOP. This usually means that the patient and family must cut down on other daily living expenses or draw from savings and even sell their properties to compensate for the extra health care expenditures. Sometimes, it can mean treatment non-adherence, bankruptcy, or personal or familial stress. Such adverse outcomes due to economic impact of cancer treatment on patient and family are now collectively referred to as “financial toxicity”. House work treatment. Financial toxicity refers to all the downstream detrimental effects on the survival, quality, and daily life activities of patients and their families as a result of excess financial strain caused by the diagnosis of cancer. In my presentation, I will discuss the causes and effects of financial toxicity in the context of lung cancer and propose some solutions.

MS17.03 SURVEILLANCE & SECOND PRIMARY MALIGNANCES IN LUNG CANCER SURVIVORS
V. Westeel
Jean-Minjoz University Hospital, Besançon/FR

Surgery is the treatment cornerstone of stage I to IIIA operable non-small cell lung cancer (NSCLC), along with perioperative chemotherapy and/or radiotherapy, depending on stage. Five-year survival rates vary between 73% and 90% in pathological stage I, 56 and 65% in stage II, and 41% in stage IIIA. Disease recurrences occur mainly during the first two postoperative years, up to 10% per year in stage I-II NSCLC, up to 40% per year after surgery for a stage IIIA NSCLC (1). The risk of second primary malignancies, and particularly second primary lung cancer, remains over time reported around 6% per year during the fifth postoperative year (2). The rationale for surveillance is the early detection of recurrence and second primary malignancies. No follow-up strategy has never been demonstrated to increase survival. The only large phase III trial conducted to date is the IFC-T (French Cooperative Thoracic Intergroup) 0302 study, reported at the ESMO meeting in 2017 (3). The IFC-T-0302 trial questioned the interest of chest CT-scan in the follow-up of resected stage I-II NSCLC patients. Patients were randomised 1:1 between two follow-up strategies: a minimum follow-up based on history, physical examination and chest X-ray, and a maximal follow-up including history, physical examination, chest X-ray with the addition of chest CT-scan (with sections of the upper abdomen and contrast enhancement) and fibroptic bronchoscopy (only mandatory for non-adenocarcinomas). In both groups, follow-up procedures were performed every six months during the first two postoperative years and annually from the third to the fifth year. The main objective of the trial was overall survival. A total of 1775 patients were included between January 2005 and November 2012. Eighty-eight percent of patients had undergone a lobectomy. Stage I or II in 82% cases. Thirty-nine percent of patients had received adjuvant chemotherapy and 7% perioperative radiotherapy. There was no difference in overall survival between both follow-up groups, with a 5-year survival of 75% in the minimal follow-up arm and 65.8% in the maximal follow-up arm (HR=0.95; 95% CI=0.82-1.09; p=0.37). There was a trend toward increased disease-free survival (DFS) in the minimal follow-up arm, with 5-year DFS rates of 54.1 and 49.7 %, respectively (HR=1.14; 95% CI=0.99-1.31; p=0.07). Subgroup analyses revealed no survival difference in any subgroup (3). Two postoperative years, there was no survival difference with median survival durations of 48 months in both arms. These results show that the CT-scan based surveillance detected significantly more asymptomatic events (128/291 (44%) vs 42/245 (17%), p<0.0001) for recurrences; 60/97 (62%) vs 37/101 (37%), p<0.0001 for second primary cancers). The risk of second primary malignancy was 11%, comparable in both groups. Among the 198 second primary malignancies, the most frequent sites were lung cancer (n=66), prostate cancer (n=26) and ENT cancers (n=19). Metachronous lung tumours were considered as recurrences or second primary lung cancers using the definition by Martini and Mekamed (4). Second primary lung cancers were significantly more frequent in the maximal follow-up arm (n=40 vs 26; p=0.02) and more frequently treated with surgery and/or a second surgery (8 vs 5; p=0.03). Exploratory analysis of survival in patients who had experienced no recurrence or second primary malignancy at 2 years, showed a significant survival advantage from the CT-scan-based surveillance (median survival not reached vs 10 months; p=0.04). On the contrary, in patients who had experienced an event within the two postoperative years, there was no survival difference with median survival durations of 48 months in both arms. These results show that the CT-scan based follow-up did detect recurrences and second primary cancers earlier than the control follow-up with only clinic visits and chest X-rays. However, recurrences which occur mostly within the two postoperative years reflect the aggressiveness the disease and treatment, even if delivered earlier with curative intent, did not translate into survival benefit. CT-scan might be more useful in patients with a late recurrence or second primary lung cancer, detecting a more relevant disease or a new pulmonary nodule for which locoregional therapy can be given with better chances of cure. After complete resection for NSCLC, most guidelines recommend to follow up patients with regular clinic visits and chest CT scans (5). (www.nccn.org). Although such follow-up
was not demonstrated to increase survival over clinic visits with chest X-rays. CT-scans may be proposed for long-term surveillance with the objective of detecting second primary lung cancers who have undergone surgery for lung cancer are just logically good candidates for lung cancer screening. In the first two postoperative years, chest CT-scan does probably not need to be performed as often as every six months. But the first five postoperative years, chest CT-scan should be performed every 6 months.

MS18 MANAGEMENT OF SCLC PATIENTS NOT REPRESENTED IN CLINICAL TRIALS TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MS18.01 TREATMENT OF PATIENTS WITH POOR PERFORMANCE STATUS (ECOG 3-4) L.H. Araujo Instituto Nacional de Câncer (Inca), Rio de Janeiro/BR

Performance status (PS) is a strong prognostic factor in most solid tumors, often impacting on oncologists’ approach.1 In small cell lung cancer (SCLC), treatment decision in patients with poor PS is a challenging and complex one. To fully contemplate this matter, one must take into account the specifics of this disease, the current knowledge on the field and possible alternatives in order to take the most ethical and supported decision.2 Let’s start by imagining a case of a 60-year-old male with a history of heavy smoking, that was admitted due to extensive-stage SCLC presenting with shortness of breath, superior vena cava syndrome (SVCS), and significant weight loss. The ECOG PS was 3. His serum LDH was 600 U/L, and sodium was 120 mEq/L. A PET-CT showed an infiltrative mediastinal mass causing compression of the superior vena cava, in addition to several liver metastases (TNM stage IVb). No brain metastasis was detected on a brain MRI. This case may seem quite familiar to many attending clinicians that routinely care of lung cancer patients. For instance, this case highlights the early metastatization of SCLC, which presents with extensive stage in around two-thirds of patients. It is also known that SCLC cases, independently of therapy.3 In particular, all SCLC patients requiring mechanical ventilation died within 3 months of ICU admission, leaving oncologists with the difficult task of deciding if immunotherapy – alone or in combination – is appropriate in these settings. One possible approach to be evaluated in clinical trials is to start combination immunotherapy after the best response to induction CT, hence selecting for responding patients that may present a more favorable prognosis. This study concept illustrates the importance of designing specific trials for “real world” patients that often present with limited PS. In summary, SCLC patients may often present with poor PS. These cases should be approached by a multidisciplinary team with expertise to conduct both aggressive and palliative measures with the primary goal of providing symptom relief and, whenever feasible, extend survival. At the end of the day, the Hippocratic处方 is quite more up to date than ever: “To cure sometimes, to relieve often, to comfort always.” References 1. Lilenbaum RC, et al. MS18 MANAGEMENT OF SCLC PATIENTS NOT REPRESENTED IN CLINICAL TRIALS TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MS18.02 TREATMENT OF ELDERLY PATIENTS WITH SCLC K. Kelly University of California Davis Comprehensive Cancer Center, Sacramento/CA/US

Small cell lung cancer accounts for approximately 30,450 (13%) new cases of lung cancer each year in the United States. The worldwide incidence is unknown. SCLC frequently occurs in elderly patients as defined by 70 years of age. A recent analysis of the surveillance, epidemiology & and results (SEER) database showed the incidence of elderly patients diagnosed with SCLC increased from 2.3% in 1975 to 4.0% in 2010 with a quarter of patients age 80 or greater (1). Due to comorbidities associated with the aging process resulting in frailty and organ dysfunction, elderly patients (especially patients over the age of 80) may not be offered aggressive treatment and are often not included in clinical trials. This presentation will review the available retrospective and prospective data. Limited Stage SCLC (LS-SCLC) Concurrent chemoradiation is the standard of care for patients with limited stage disease. Three age-specific retrospective analyses of randomized trials from North American cooperative group studies evaluating cisplatin-based regimens did not demonstrate significant differences in overall survival or other efficacy endpoints by age (2). However, two of the studies reported similar treatment related toxicity rates in the elderly population. To address the toxicity issue, phase II trials evaluated modified chemotherapy and radiotherapy regimens. These studies showed modified regimens were active and less toxic but no definitive trials have been performed. Alternatively, carboplatin is frequently substituted for the more toxic cisplatin in the concurrent regimen. Another approach is to omit the radiation and administer chemotherapy alone. However, a retrospective analysis of elderly LS-SCLC patients from the National Cancer Data Base from 2003-2011 demonstrated the use of modern chemoradiation was superior to chemotherapy alone.
on univariate and multivariate analysis with a 3-year OS of 22% vs 6.3% respectively, P<0.01. This effect was seen in patients 80+ years and in patients with no nodal involvement (3). A subset of concurrent treatment significantly improved survival over sequential treatment. Similar findings were observed by the Dutch (4). Extensive Stage SCLC (ES-SCLC) Etoposide and a platinum agent (cisplatin or carboplatin) is the standard of care for upfront treatment of ES-SCLC. Despite the acceptability of etoposide plus carboplatin as a tolerable and equivalent regimen, elderly patients may not receive treatment. A review of the Alberta Cancer Registry revealed that 32% of patients age 75+ did not receive chemotherapy (5). Of the patients who received chemotherapy, 52% completed all cycles and 66% did not require a dose reduction. Patients who completed all cycles with a dose reduction had a decreased risk of death 1.02 (95% CI: 0.57-1.82) compared to a risk of death of 2.72 (95% CI: 1.52-4.87) for patients who did not complete therapy. Four phase II studies evaluating dose modifications of carboplatin and etoposide in the elderly found similar survival outcomes to standard doses (5). In a recent phase II study from China 34 elderly patients or patients with a PS of 2 who received carboplatin and etoposide had a median PFS of 5.8 months and an OS of 14 months (6). Toxicity was acceptable with Grade 3 or greater neutropenia and febrile neutropenia occurring in 40% and 7% of patients, respectively. Prophylactic Cranial Irradiation The role for prophylactic cranial irradiation (PCI) in the elderly population is controversial. Retrospective population based and trial specific analyses have shown that PCI improves survival compared to no PCI but concern over increased neurocognitive dysfunction has resulted in limited uptake of PCI (7-9). Indeed, a comparison of tested and self-reported cognition in the elderly at progression after administration of a SCLC-directed therapy demonstrated higher rates of cognitive decline with advanced age (10). Modern radiation techniques, hippocampal sparing and memantine may reduce the rate of cognitive decline. Recent data also suggests that MRI surveillance may be an option for patients with ES-SCLC (11). Geriatric Assessment Tools: Geriatric oncology is drawing more attention to the care of these patients through the development of geriatric assessment tools to better define risks and benefits. Investigators are encouraged to incorporate these tools into their clinical trials. Treating physicians should also consider using validated geriatric assessment tools in their routine practice such as the new ASCO 2018 guideline (12). Overall, elderly patients should be offered standard treatment but they may require dose modifications. Participation in clinical trials and trials that address specific needs of the elderly patients is encouraged. REFERENCES Abdel-Rahman O. Keywords: Elderly, Small Cell Lung Cancer, Treatment MS18 MANAGEMENT OF SCLC PATIENTS NOT REPRESENTED IN CLINICAL TRIALS TUESDAY, SEPTEMBER 25, 2018 - 13:00-15:00 MS18.03 TREATMENT OF SCLC TRANSFORMED FROM EGFR MUTANT ADENOCARCINOMA N. Marcoux Medical Oncology, CHU de Quebec, Quebec QC/CA While most molecular findings at time of resistance to EGFR tyrosine kinase inhibitors (TKIs) involve point mutations in the EGFR gene or the development of specific signaling bypass tracts, more fundamental changes in cell functioning can occasionally be seen. Indeed, neuroendocrine transformation, specifically to small-cell lung cancer (SCLC), is a relatively rare but biologically significant finding that has been the focus of recent interest in understanding of resistance to EGFR TKIs, developing in 3-10% of cases[1][2][3]. De novo, EGFR-mutant SCLC has also been reported and represents a subset of the very rare cases of SCLC seen in never-smokers[4]. In both instances, biomarkers are selectively lost in tumors from the smoking-associated SCLC. Although the transformed tumors maintain the same founder EGFR mutation as the initial adenocarcinoma at the DNA level, dependence on EGFR signaling is typically lost through reduced expression of the EGFR protein[5]. Patients with alterations of both TP53 and RB1 at the time of initial diagnosis of adenocarcinoma seem to be at significantly higher risk of transformation[6]. Although this finding was initially described with immunohistochemistry (IHC) assays, it is likely applicable to mutations found by next-generation sequencing (NGS). In a recent study of 160 SCLCs, 34% had TP53 alterations, 30% had RB1 alterations, and 21% had alterations in both genes. Although the percentage of patients with these anomalies that will eventually go on to transform is unknown. The threshold for obtaining tissue biopsy at progression should be lower in patients who are incidentally found to have mutations in TP53 and RB1 at initial diagnosis, but no intervention is currently known to decrease transformation risk. Mainly for that reason, specifically obtaining TP53/RB1 IHC or mutational status at diagnosis should be considered investigational. Rather than a linear evolution from NSCLC to SCLC, many experts believe that small-cell transformation occurs in the context of multiple clonal subpopulations evolving dynamically. The cell population that eventually becomes clinically apparent as SCLC has been shown to branch out early from the initial adenocarcinoma subpopulation[7], sometimes equivocally described as a “proliferative clone”[8]. The clinical diagnosis of lung cancer. Clinically, small-cell transformations are usually seen after months to years of TKI therapy as discussed next, which leads to the hypothesis that the small-cell-prone clonal subpopulation can remain dormant for long periods of time. Although ASCT has been shown to delay progression in this setting, the specific mechanisms at play during this apparent prolonged period of cell dormancy remain largely unknown. Another proof of the polyclonal nature of these cancers can be seen in the occasional reversal to NSCLC histology at progression after administration of a SCLC-directed therapy such as platinum-etoposide[9]. Due to the rarity of SCLC transformation, published clinical data related to patients’ evolution is retrospective and almost exclusively in the form of case reports. However, a retrospective study of 67 EGFR-mutant patients with SCLC transformation in 11 high-volume North American centers was recently presented[10]. Demographic characteristics, including age, race and smoking status, were concordant with the general EGFR population and median time between initial diagnosis of metastatic NSCLC and SCLC transformation was 18 months. Almost all patients were actively receiving TKI therapy at time of transformation. Median overall survival from initial diagnosis was 32 months, similar to what is seen in standard EGFR-mutant NSCLC. However, once SCLC was identified (including in 9 patients with de novo EGFR-mutant SCLC), median survival was 11 months, more in line with what is seen in smoking-associated SCLC. While high clinical response rates to platinum etoposide (54%) and taxanes (50%) were noted, these responses were mostly transient, with median progression-free survivals of only 1-2 months. Importantly, considering the setting of these therapies, no responses were seen in 17 patients who received checkpoint inhibitors, including the ipilimumab-nivolumab combination. Cytotoxic chemotherapy, especially the classic regimen of platinum-etoposide, thus appears to be the favored in the elderly patient setting of SCLC-transformation. Potential for reversal to NSCLC, performance status and toxicity profiles must be taken into account for later lines of therapy. Although CNS involvement is frequent, prophylactic cranial irradiation is not recommended. Despite these recent improvements in our understanding of EGFR-mutant small-cell transformation, its rarity makes it challenging to prospectively evaluate novel therapeutic strategies. Prospective identification of patients at high risk of transformation and multicentric collaborative efforts will likely be needed to improve our knowledge for this entity. [1]Houghton et al. 2011. MS18 MANAGEMENT OF SCLC PATIENTS NOT REPRESENTED IN CLINICAL TRIALS TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

C. Butts Division of Oncology, University of Alberta, Edmonton/AB/CA

Extensive stage small cell lung cancer (SCLC) is characterized by an initial response to chemotherapy followed by progression usually within 6 months. The clinical approach to second line therapy and beyond depends on patient wishes, performance status (PS), and duration of response to initial therapy or progression free interval (PFI). While some have challenged the importance of PFI in selection of subsequent therapy (1), guidelines by the European Society of Medical Oncologists (ESMO) (2) and the American College of Chest Physicians (ACCP)(3) recommend treatment options based on PFI. This presentation will focus on retreatment with platinum-based chemotherapy and treatment beyond second line. The ACCP guidelines, which have been endorsed by the American Society of Clinical Oncology (ASCO) (4) recommend re-challenge with the first line regimen in patients with a PFI of at least 6 months. The ESMO guidelines define sensitive relapse as a PFI of more than 3 months and suggest these patients may derive benefit from re-challenge with the chemotherapy regimen used based on first line treatment. Genestreti (4) evaluated the benefit of re-challenge with platinum-etoposide in a retrospective, multi-institutional review. In 112 patients who progressed more than 90 days after initial chemotherapy, re-challenge with platinum-etoposide resulted in a second response rate (RR) of 45% and a median survival (mOS) from re-challenge of 7.9 months. There was no difference in survival using PFI of 90, 120, or 150 days. A second European multicenter study (5) reported outcomes of 161 patients receiving second line therapy. Platinum sensitive patients (PFI 3 months) who were re-challenged had a higher RR and longer mOS. Response to first line therapy and PS were independent predictors of survival. Single institutional series have also supported the importance of sensitivity to first line therapy in determining second line treatment. Nagy-Mignotte (6) defined sensitive disease as PFI of at least 3 months. Of the 300 patients who received first line platinum-etoposide therapy, 48% had sensitive disease and the majority of these (72%) were re-challenged. The RR to re-challenge was 65% (21% complete response) and mOS from second line was 9.3 months. Patients with resistant or refractory disease were primarily treated with taxanes or topotecan. The RR in these patients was 21% with mOS of 5.2 months and 3.8 months. Kim et al (7) found response to initial therapy and PS to be significantly associated with survival after second line therapy in 232 patients from a single institution in Japan. Beyond Second Line There are currently no approved third line therapies for SCLC and the evidence for benefit from any therapy consists of retrospective reports and phase II trials. In the largest series reported from Japan (8) only 30% of SCLC patients receiving first line therapy went on to receive third line treatment. The majority of patients received single agent therapy in third line with amrubicin being most common (47%). Independent prognostic factors were time to treatment failure of at least 5 months and PS at time of third line therapy. A Dutch study found only 18% of their SCLC patients received at least 3 lines of therapy. The RR to third line was 25% with mOS of 5 months (9). An international multi-center retrospective analysis (10) found that the majority of patients were re-challenged with a regimen previously received in first or second line, with 6% of patients receiving platinum-based chemotherapy in all 3 lines. The RR was modest at 18% with mOS from third line of 4.7 months. Response to second line therapy was predictive of response to third line but only one third of cases of pneumonitis are asymptomatic (4) and documented solely on imaging hence a high index of suspicion is required to make the diagnosis. Most commonly pneumonitis has been reported to occur within the first few months of first line chemotherapy. Radiation pneumonitis can occur as early as the first dose or may even emerge after ICI treatment has been discontinued (4, 6, 8). Often, the onset of pneumonitis coincides with other immune related adverse events (irAEs) (4). Concurrent use of other checkpoint inhibitors (CTLA-4, PD-1, blockades) may increase the risk of pneumonitis (1, 2, 4, while age, ethnicity, and chemotherapy do not (9). The influence of smoking history (4, 9), tumour type (1-2) and radiation (7, 9) on developing ICI-related pneumonitis is less clear as various groups have reported differing incidences. There is also considerable variability in radiographic presentation (4, 6, 8) and bronchoscopy and lung biopsy may be valuable tools to exclude alternate diagnoses. Even on pathology though, there are no definitive findings characterizing pulmonary irAEs (4); histopathological findings ranging from diffuse alveolar damage to sarcoid granulomas have been described (4, 6). In small series, a correlation has been noted between anti-tumour activity with ICI and the occurrence of irAEs (3), but this too remains unsupported and is not specific to pneumonitis. At present, there are no validated treatment recommendations for pneumonitis resulting from treatment with ICI. Management of ICI pneumonitis follows the same general guidelines as other irAEs namely, withholding ICI, starting steroids, and if needed, using additional immunosuppressants such as mycophenolate mofetil or infliximab (10). Likely irAEs such as pneumonitis is generally steroid-responsive and usually resolves within 4-6 weeks (10). The prolonged half-life of the antibodies necessitates the protracted period of corticosteroid treatment and slow tapering. Only very limited data is available regarding re-challenge with ICI after development of pneumonitis. Again, in small series— all involving 10 or fewer patients - 25-30% of patients re-challenged with ICIs developed recurrent pneumonitis (1, 4, 9). In conclusion, immune-related pneumonitis is a rare, but potentially fatal, side effect of ICI for which vigilance in monitoring and managing rare, but serious, side effects including pneumonitis is often required to make the diagnosis. The results from meta-analyses and several large reviews on irAEs provide reassurance that for the vast majority of NSCLC patients, irAEs can generally be managed and are well tolerated treatments. MS19.02 WHAT ARE THE CLINICAL FEATURES OF IO PROGRESSION/ PSEUDOPROGRESSION AND RADIATION FIBROSIS VS RECURRENCE

C. Liam

Department of Medicine, Faculty of Medicine, University of Malaya, Kuala Lumpur/ MY

IO Progression vs Pseudoprogression The patterns of response to treatment with immunotherapy differ from those with molecularly targeted agents or cytotoxic chemotherapy where responses can take appreciably longer to become apparent. In addition, a unique response pattern termed “pseudoprogression” may be encountered with immunotherapy with checkpoint inhibitors in which patients appear to have a transient worsening of disease, manifested either by progression of known lesions or the appearance of new lesions, before disease stabilizes or regresses. While pseudoprogression is rare in lung cancer with reported rates of < 5%, it is a worrying situation for both clinicians and patients on immunotherapy.1-2 It can be difficult to differentiate pseudo-progression from true disease progression, but close monitoring of the following clinical features may help identify pseudoprogression - Pseudoprogression is often asymptomatic, whereas true progression is more likely to be associated with clinical decline. - The patient’s performance status remains stable or improves if it is pseudoprogression while the performance status may deteriorate in true disease progression - Systemic symptoms often worsen in disease progression - Symptoms of tumour enlargement may or may not be present in pseudoprogression whereas true progression may be associated with symptoms of tumour enlargement - There is an initial increase in baseline tumour burden followed by a response in pseudoprogression while there is an increase in baseline tumour burden in true progression. New lesions that appear in pseudoprogression remain stable and/or subsequently respond while in true progression, new lesions appear and increase in size. Biopsy may reveal evidence of immune cell infiltration in pseudoprogression and evidence of tumour growth in true progression. However, histological confirmation is not always possible. Smaller deposits of tumour may continue to grow or new lesions appear in the first few months of effective immunotherapy during this period of immune priming and appear as progressive disease on restaging scans. These areas of apparent pseudoprogression should be carefully followed to distinguish nonresponding patients with progressive disease from those with delayed response. Distinguishing treatment-induced imaging changes from progressive disease has important implications to avoid premature and inappropriate discontinuation of a treatment regimen. Radiation Fibrosis vs Recurrence vs Pseudoprogression Radiation-induced lung injury (RILI) which can occur in the acute phase (within six months) as radiation pneumonitis and in the late phase (after six months) as radiation fibrosis. With SABR, the incidence of acute- and late-onset RILI is high with acute benign computed tomography (CT) changes in 54-79% of patients and late changes in 80-100% of patients. Radiation pneumonitis may appear as ground-glass opacities, consolidation or both. The late phase of radiation fibrosis frequently appears as a well-defined area of volume loss with a linear scar or consolidation, parenchymal distortion and traction bronchiectasis that conforms to the treatment portals which may either stabilize or evolve up to 24 months. Shrinkage of the region of fibrotic consolidation or a more sharply defined demarcation between normal and irradiated lung parenchyma may occur as the process progresses. Such benign CT changes can mimic tumour recurrence, especially when they develop as mass-like patterns.3 Distinguishing radiological changes due to radiation-induced fibrosis after SABR and local tumor recurrence can be quite challenging. A systematic review by Huang et al.4 identified several high-risk radiological features on CT scan to discriminate between SABR-induced fibrosis and tumor recurrence. These include an enlarging mass-like lesion at the primary site, sequential enlarging opacity, enlarging opacity after 12 months, bulging margins, disappearance (loss) of linear margins, cranio-caudal growth, disappearance (loss) of air bronchograms, ipsilateral pleural effusion, or lymph node enlargement. While some sources caution against the use of PET scans to differentiate between post-SBRT fibrosis and recurrence, others have postulated a SUV Max of > 5 can be a useful discriminator.3,6-8 Due to a high number of false-positive findings on PET, patients suitable for salvage therapy should undergo a biopsy, whenever possible.3 The optimal follow-up schedule for patients treated with SABR for early stage NSCLC is unclear, although clinical practice guidelines of the European Society for Medical Oncology recommend CT imaging every 6 months for a period of at least 3 years in those patients suitable for salvage therapy.1 The timing of local recurrence after SABR, as well as a persistent risk of second primary lung cancer with an annual rate of 2% to 5%, suggests that long-term radiological follow-up using CT scans is needed, especially in patients fit enough to undergo any radical treatment. Others recommend a post SABR follow-up strategy similar to that of post-surgical cases, i.e. all patients eligible for any type of salvage undergo 6 months follow-up CT scans for a period of 3 years post-SABR, followed by annual CT scans thereafter.9 With suspicion of progressive disease, recommendations include a multidisciplinary team discussion with consideration for biopsy and/or surgical or nonsurgical salvage therapy if safe and when further investigations are non-reassuring.10 References 1. MS19.03 DIAGNOSTIC APPROACHES SUSPECTED IO PROGRESSION/ PSEUDOPROGRESSION AND WHAT/WHEN TO REBIOKYPSY FOR TT PROGRESSION

K. Czarnecka-Kujawa

Department of Thoracic Surgery, Department of Respiriology, Toronto General Hospital, Toronto/CA

The 2000’s marked the beginning of precision medicine era with treatment of NSCLC becoming increasingly personalized. This was driven by effective therapies in biomarker-defined populations, most notably treatments targeting the epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK), programmed cell death-1 (PD-1), and programmed cell death ligand-1 (PD-L1) pathways (1-4). In addition, given unique tumor behaviour upon treatment, programmed cell death ligand-1 (PD-L1) pathways has become the standard of care for majority of patients with NSCLC, both, at the time of diagnosis and with recurrent disease (2-4). In addition, testing indications emerged for other proto-oncogenes, many of which are actively investigated as therapeutic targets (3, 4). In addition, development of effective treatments for recurrent NSCLC in setting of acquired resistance (AR) to targeted therapies (TT), the minimally-invasive tumor sampling to identify resistance mutations has become increasingly attractive, given frailty of population with metastatic lung cancer (4, 6). Imaging and clinical patient status are used to diagnose cancer progression, pseudoprogression and recurrence. Conventional tumor response criteria serve as standardized measures for treatment response in NSCLC. However, given unique tumour behaviour upon exposure to immunotherapy, immune response criteria have been developed to assess treatment response in patients on immunotherapy (7). While preparing to obtain a diagnostic sample in setting of suspected disease recurrence/progression, following are key considerations: 1) site of sample; 2) size of tissue sample; 3) proportion of tumor cells in the sample; 4) fixative used to preserve tissue; 5) tumor heterogeneity; 6) difference in genetic make up of the primary and metastatic tumor (4). The choice of diagnostic procedure to confirm disease recurrence/ progression must be guided by the procedure safety and diagnostic yield.
Percutaneous or surgical lung biopsies, are often not possible for patients with advanced lung cancer. The minimally-invasive techniques have become an attractive alternative for tissue acquisition in this setting. The most common, minimally-invasive techniques utilized by interventional pulmonologists are: 1) transbronchial biopsy (TBBx) or transbronchial needle aspiration (TBNA); 2) Endoscopic techniques: Endobronchial Ultrasound-guided Transbronchial Needle Aspiration (EBUS-TBNA) and EsoPhageal Ultrasound-guided Fine Needle Aspiration (EUS-FNA); 3) and pleural fluid sampling. Studies show that endoscopic techniques provide tissue of comparable quality and quantity material for molecular testing compared to surgical or conventional needle biopsy. Reported adequacy of EBUS-TBNA samples for molecular diagnosis ranges from 77% to 98% (8). EBUS samples have one of the lowest insufficiency rates (4%) for EGFR and KRAS mutational analysis (compared with CT-FNA – 7.5%; ultrasound guided/superficial FNA - 10%) and can provide sufficient tissue quality for molecular testing (i.e. p53 mutation, BRAF and PIK3CA) (9). EBUS-TBNA samples have been shown to yield a higher number of viable cells with less crush artifact and better concordance with the primary tumor for expression of the PD-L1 than TBBx (9). TBNA has been shown to improve diagnostic yield in NSCLC when added to conventional TT. High concordance has been reported for detection of EGFR mutation and PD-L1 expression between primary and metastatic tumors. Some authors suggest that either of the two sites can be used for molecular testing. However, there is a significant heterogeneity in PD-L1 expression within tumors (10). Additionally, AR to Tyrosine Kinase Inhibitors (TKI) develops almost invariably within 8–16 months on TKI use, resulting in disease progression. The T790M mutation is the most common mechanism of acquired resistance to TKI (11). The target for patients baring this EGFR aberration. Overwork of recursivity, some of the patients will be diagnosed with transformation into a new primary lung cancer, which warrants different treatment than metastatic NSCLC. For these reasons, an attempt should be made to obtain a fresh tissue sample if disease progression/relapse is suspected. Pleural fluid cytology has been shown to be an excellent source of tumor cells with high yield in detection of both EGFR and ALK mutations (5). In all instances, bronchoscopist should work closely with cytopathologists seeking feedback on tissue quality, quantity for ancillary testing (5). In some cases, TT available for patients baring this EGFR aberration. In the era of personalized lung cancer treatment, surgery is following the trend of targeted therapy. As lung cancer becomes easier to detect at early stages with low dose computed tomography, innovations in surgery have been developed to make targeted surgery easier and more prevalent. This talk will focus on novel innovations in surgery for small pulmonary nodules. We will discuss targeted robotic surgery, mapping with near-infrared technology, electromagnetic navigation, 3D preoperative mapping and simulation, hybrid operating rooms, and minimally invasive staging. We will also touch on the role of Artificial Intelligence in the future of surgery. The focus of this talk would be to introduce the audience to the future of surgical treatment of early stage lung cancer.

of toxicity. There was no obvious safety concern postoperatively when compared to non-randomized controls treated with preoperative chemotherapy. The chemotherapy arm also did not show evidence of illipilumab in this study in an unselected population, comparable to studies in metastatic disease. The recently published study of neoadjuvant nivolubam was different by design. In this two-institution study resectability was defined pretreatment and 20 of 21 patients were completely resected without delay. A high rate of major pathologic response was seen after only 2 doses of nivolubam in this study. There were no safety signals. Preliminary presentations of data from the lung cancer mutation consortium study of neoadjuvant atezolizumab and the single institution study of carboplatin + nab-palictaxel + atezolizumab have met their pre-defined safety and efficacy boundaries for expansion, respectively. Ongoing studies: By nature of the presenting data, the present data is from neoadjuvant studies where efficacy and safety signals are available. Fast-tracking access, support grants, and access to health care providers. This should not negative the huge international efforts ongoing to evaluate the efficacy of adjuvant ICB after resection and standard adjuvant therapy for resected NSCLC. There are 4 ongoing randomized phase 3 studies comparing neoadjuvant chemotherapy to chemotherapy + ICB and some ICB combinations are actively recruiting internationally. These studies will answer important direct comparative questions and investigate the role of potential surrogates of survival, such as pathologic response. Complete resection has embraced the importance of investigating immunotherapy in this potentially curative space, but we are from years ago to define definitive conclusions from the randomized Phase 3 studies of perioperative ICB. Preclinical data suggest that the neoadjuvant approach may be superior to adjuvant ICB and the single small report from the neoadjuvant nivolubam showed a tremendous efficacy signal that ongoing studies hope to replicate. While the rapidly enrolling adjuvant studies remain extremely important given the high rate of pathologic upstaging at the time of surgical resection, emphasis on appropriate patient identification for neoadjuvant study enrollment will lead to earlier trial readouts, important correlative science, and essential study of potential surrogate efficacy endpoints such as pathologic response. MS21 GIANTS IN THORACIC ONCOLOGY
TUESDAY, SEPTEMBER 25, 2018 - 15:15-17:00

MS21.01 SURGERY AND ITS EVOLUTION
P Van Schil
Thoracic and Vascular Surgery, Antwerp University Hospital, Edegem (Antwerp)/BE

Slow rise Surgery would not be possible without detailed knowledge of human anatomy. In the 16th century Andreas Vesalius published his “De humani corporis fabrica”, providing very detailed anatomy of the human body. He also understood the importance of teaching, already internationally, and performed the first endotracheal intubation in pigs. William Harvey described the anatomy of the cardiovascular circulation. Ambroise Paré rediscovered blood vessel ligation, applied specific wound dressings and already designed rudimentary limb prostheses. General surgical interventions quickly developed (1). Thoracic surgery only developed very late due to the fact that opening of the chest resulted in collapse of the lung and pneumothorax (2). Opposing ventilation and deciding whether the thoracic interventions should be performed by “Unterdruck” or “Überdruck” (negative versus positive pressure). Gotthard Bulau introduced closed water seal drainage to re-expand the lung. After experimental studies, Ferdinand Sauerbruch designed a negative pressure chamber to perform thoracic interventions, principle of which was also used in the “iron lungs” during the polio epidemic. However, its use was not quite practical and finally, positive pressure became the preferred option after development of a portable pressure apparatus by Ludolph Bauer. Tuberculosis: start of thoracic surgery After introduction of endotracheal intubation and intratracheal anesthesia, thoracic surgery developed as a separate specialty from general surgery. Pulmonary tuberculosis became a wide-spread problem and specific tuberculosis centers (sanatoria) were created with multidisciplinary medical-surgical cooperation “avant la lettre”. This provided a clear impetus towards further development of thoracic surgery. Devastating infections were encountered necessitating a variety of special procedures as extrapleural decortication, rib resection, covering defects and sometimes an extensive thoracoectomy. Theodore Tuffier is credited for performing the first successful lung resection for tuberculosis in 1891, putting a clamp on the apex after extrapleural dissection followed by resection of diseased lung parenchyma and closure of the lung surface by a continuous suture. Lung resection: pneumonectomy Alexis Carrel who won the Nobel prize in 1912, contributed enormously to further development of surgical techniques by providing detailed description of the vascular sutures, organ transplantation and aorta-caval circulation. Thoracic surgical oncology started to develop with Evarts A. Graham performing the first one-stage pneumonectomy for lung cancer in 1933. Patient was a 48-year-old gynecologist who resumed practice afterwards and died at the age of 78 years. In the era before

MS20 INNOVATIVE AND EVOLVING STRATEGIES IN DIAGNOSIS AND MANAGEMENT OF STAGE I NSCLC
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MS20.44 FUTURE TRENDS IN PNEUMONOCYTE REGENERATION IN NSCLC
J. L. Anderson
Cancer Research, Cell Oncology and Thoracic Oncology, Cancer Institute of New South Wales/NSW/AS

Pneumonectomy for lung cancer is associated with a high risk of complications and long-term morbidity. While the procedure is still considered the gold standard treatment for patients with stage I and II NSCLC, almost 50% of these patients die within ten years of diagnosis without early detection. The current understanding of lung regeneration is mainly derived from studies in animals and limited clinical observations. In this review, we will discuss recent preclinical and clinical reports that shed light on the mechanisms of lung regeneration in NSCLC, and will identify future opportunities to enhance the rate of lung regeneration in patients with pneumonectomy. New insights into the role of cancer-driven inflammation and immune cells in lung regeneration may provide novel therapeutic opportunities to improve outcomes in this patient population.
The development of systemic therapies for lung cancer can be divided into three phases starting with the application of cytotoxic agents in the mid-20th century, followed by the introduction of targeted agents in the early 2000s with the recognition that gefitinib, an EGFR tyrosine kinase inhibitor, produced responses in patients with non-small cell lung cancer whose tumors harbored either small, in-frame deletions or amino acid substitutions clustered around the ATP-binding pocket of the tyrosine kinase domain. This milestone discovery spurred further studies that identified additional genomic abnormalities that may be actionable as therapeutic targets (e.g., ALK translocations, HER2 and BRAF mutations, etc.). Drugs that specifically target these genomic abnormalities became the major focus of much of the cancer drug development of the past 15 years and are now considered a cornerstone of genomic or precision medicine. In more recent years much attention has shifted to application of immunotherapeutic agents in solid tumors including NSCLC (and SCLC) and other malignant and malignant diseases. Drugs that specifically target these genomic abnormalities became the major focus of much of the cancer drug development of the past 15 years and are now considered a cornerstone of genomic or precision medicine. In more recent years much attention has shifted to application of immunotherapeutic agents in solid tumors including NSCLC (and SCLC) and other malignant and malignant diseases.

MS21.04 TARGETED THERAPY - THE SECOND REVOLUTION
F. Shepherd
Princess Margaret Cancer Centre, Toronto/CA/CA

Over the last 15 years we have witnessed a revolution in the development of molecularly targeted therapy for non–small cell lung cancer (NSCLC). At the same time, there has been an unprecedented evolution in the techniques available to detect molecular changes in tumours. The technology has evolved from single gene assessment in frozen tissues designed for lung cancer and mesothelioma with tested, published, and the role of these panels in clinical care has yet to be determined.

Keywords: MRI guidance, Radiotherapy, radiation oncology

MS21.03 REVOLUTION IN RADIATION
B. Slotman
Radiation Oncology, Amsterdam UMC, Amsterdam/NL

In the past few decades, there have been many changes in the field of radiotherapy. These include better imaging, better motion management, improvements in treatment planning, better position verification and more precise target delivery. This has led to an increased use of radiotherapy and to significant improvements in clinical outcome. Stereotactic body radiotherapy (SBRT, aka SABR) is currently the standard of care for patients with medically inoperable stage I NSCLC. The technique is now safely used for more centrally located, larger and multiple lesions as well. SBRT is increasingly being considered as an alternative to surgery in operable patients. The results of two randomized clinical trials which were closed prematurely due to poor accrual, suggest equivalence of SBRT and surgery. Comparative effectiveness studies point in the same direction. New randomized trials on this topic are currently recruiting. In stage III NSCLC, radiotherapy can also be delivered with increased precision. Although the use of much higher dose has not (yet) led to better outcomes, the newer radiation techniques are associated with less toxicity and over the years, there has been a steady improvement in control and survival rates. The use of immunotherapy in combination with radiotherapy holds many promises. The role of proton therapy is still investigational. For patients with oligometastatic disease or oligoprogression, local treatments including radiotherapy can be highly effective and may lead to long term control and improvements in survival. We are awaiting the results of randomized studies to unequivocally show this benefit. In LS-SCLC, there is still discussion on the schemes for thoracic radiotherapy. The current standard in median survival in both arms of the recent CONVERT trial compared to earlier studies are probably exemplary for the general improvements in radiotherapy techniques. In ES-SCLC patients, thoracic radiotherapy is advocated for those patients with a response after chemotherapy but with residual disease in their chest. In ES-SCLC, prophylactic cranial irradiation is nowadays sometimes replaced with MRI-surveillance. Delayed cranial irradiation is than used in about two out of three patients. An important breakthrough in radiotherapy is the introduction of MRI guidance on the linear accelerator. This allows better soft-tissue imaging, but also for the first time, continuous imaging during the delivery of the treatment. The anatomical information from the MRI made daily with the patient on the treatment couch can be used to adapt the daily treatment plan. This allows for the use of smaller margins and early results demonstrate important benefits, especially in high-risk patients.

Keywords: MRI guidance, Radiotherapy, radiation oncology

MS21.05 QUALITY OF LIFE - ARE WE PAYING ENOUGH ATTENTION?
R. Graila
Albert Einstein College of Medicine, Bronx/NY/US

The greatest challenge facing quality of life, symptom and patient reported outcome evaluation in advanced lung cancer is the incorporation of the measurement of these parameters into daily clinical practice. While all oncologists embrace the significant basic science and survival improvements of recent years, we must acknowledge that these benefits are still only measured in months of additional life for the average patient, and treatments continue to have significant risks. Are we meeting the goals and needs of patients regarding systemic therapy? There are several issues key to understanding the practicality and value of PRO evaluation. Recent studies have addressed these questions. How much do patients value and agree with the monitoring of quality of life? Are PRO issues accurately and reproducibly measured? Can we conduct PRO evaluation in clinical research and in daily practice in a practical fashion that can allow inclusion into all clinical settings? Most importantly, beyond demonstrating that oncologists wish to listen to the patient’s voice, does the measurement of PROs give guidance in daily practice that results in better patient care, economic benefit, and aids in better decision making? There can be no doubt that patients with advanced lung cancer place aspects of quality of life at the top of their concerns and goals in their treatment. Over 95% of patients stated that it was a key concept for them in a survey of 660 patients with lung cancer (1), and a similar percentage of 148 patients endorsed serial evaluation of quality of life and lung cancer symptoms (2). Today we have valid measures designed for lung cancer and mesothelioma with tested, published, and demonstrated important benefits, especially in high-risk patients.
and acceptable psychometrics. Such testing establishes feasibility, acceptability, reliability and validity. These measures, including the EORTC-QLQ-C30, the FACT-L, the Lcss and the LCSM surveys all meet high standards and are available in over 50 languages (3). Using electronic assistance makes the evaluation of PROs more practical in both clinical trials and daily practice. A trial using the electronic form of the LCSM placed on a tablet-like device (called the eLcss-QL*) demonstrated high patient, nurse and physician acceptance. The electronic form correlated very highly with the paper and took only about two minutes to complete (2). Other major advantages of using computer assistance is that results of PROs can be immediately displayed graphically, the data can be filed electronically, and the device can interpret the results. All of these features make evaluating PROs easy to incorporate into busy clinical practices and into research trials. To date, the greatest use of quality of life and PRO evaluation in patients with thoracic malignancies has been in clinical trials. Firstly, these assessments have been used to determine whether or not a new treatment which influences survival or PFS or response also affects quality of life. These results are generally used as secondary or tertiary endpoints in new agent approval. Shortcomings into PRO assessments in these trials, most frequently seen as failure to include all patients and in low percentages of patients with sufficient follow up. With high patient acceptance and available feasible questionnaires, the fault lies with the study design or the conduct of the investigators, and not with the patients. We recently completed a study which investigated several endpoints through the use of electronically conducted PRO evaluation, with the eLcss-QL164 patients completed the eLcss-QL every 3 weeks; all endpoints were evaluable in over 90% of patients. Specifically, we evaluated to just 3 items (quality of life, distress, activity level, called the 3-Item Global Index or “3-IGI”) of the 9 included in the LCSM could: 1) more accurately predict survival at baseline than performance status; 2) could predict risk groups for hospitalization; 3) identify those at greater risk for regret; and most importantly 4) indicate by change in the 3-IGI after just 2 treatment cycles which patients are likely or unlikely to benefit from treatment. The findings from this study, are presented at the 2018 WCLC (4.5). In brief, we found that assessing change from baseline (20% decline) with the 3-IGI after only 2 cycles of systemic treatment identifies those patients who have poor response and survival outcomes if continued on the same therapy. Patients with this decline continued to receive more than two additional treatment cycles on average, even though PRO assessment showed meaningful decline. From a much earlier point. The economic cost of this additional treatment was an average of almost $11,000 per patient. Additionally, nearly all patients who at 3 months after starting treatment regretted having received treatment were those who had this 20% decline of the 3-IGI at 6 weeks. This PRO assessment is rapid, easy, and inexpensive. Reports to physicians need to include analysis of the impact in that even when physicians were aware of the PRO worsening, they often did not act on the findings. The 3-IGI at baseline provided a better indication of the burden of the cancer experienced by the patient. This resulted in better prediction of survival, which could aid in better design of clinical trials. Quality of life, symptom assessment, and PRO evaluation has become practical for both research trials and clinical practice. Responding to PRO changes can result in better decisions concerning continuing treatment, changing treatment, or assessing toxicity, in cost of unhelpful treatment. References: 1) Gralla RJ, et al. MS21.06 IMMUNOTHERAPY - SEQUENCE OR COMBINATION? R. Herbst Section of Medical Oncology, Yale School of Medicine | Yale Cancer Center | Smilow Cancer Hospital at Yale-New Haven. New Haven/US

Advances in the treatment of cancer, with novel molecularly targeted therapies and drug combinations, lung cancer continues to be one of the leading causes of cancer death worldwide. For this reason, significant efforts have been made to examine the interaction between cancer and the immune system. This has led to the discovery of the programmed death 1 (PD1) and ligand (PD-L1) pathway, which was found to play a key role in immune evasion by cancer cells and the formation of a tumor microenvironment. Blockade of this pathway enables the ability of the innate immune system to activate their antitumor responses and to reverse the tumor microenvironment. Newly approved drugs, such as nivolumab and pembrolizumab, have mechanisms of action that inhibit PD1, while others like atezolizumab, block PD-L1. Although, responses with these drugs have shown significant activity in some patients, only 20-30% of patients respond overall. In this talk, mechanistic studies to identify predictive markers of response will be discussed along with molecular resistance (both intrinsic and acquired) and combinations of immunotherapy with chemotherapy, targeted therapy and even chemotherapy will be explored including their use in sequence or combination.

MS21.07 THE GROWING ROLE OF BIOMARKERS IN TREATMENT SELECTION: “THE TISSUE IS THE ISSUE” F. Gralla Department of Medicine, University of Colorado Cancer Center, Aurora/CO/US

Much progress has occurred in the treatment of lung cancer over the last decades. A main reason for this progress is due to technology developments, which make it possible to identify new targets and develop new active drugs targeting the molecular abnormalities. However, developing predictive biomarkers for selection of the right group of patients to the right treatment has been crucial in this progress. The detection of EGFR mutations as predictive biomarkers for EGFR TKI paved the way for biomarker development and was shortly followed by the detection of Anaplastic Lymphoma Kinase fusions and the development of ALK-inhibitors. Later, many other targets have been identified (i.e. ROS1, BRAF, RET, TRAKS) and specific targeted drugs developed with impressive clinical effect in biomarker defined subgroups, particularly of NSCLC (1). The International Association for the Study of Lung Cancer (IASLC) has together with the College of American Pathologists (CAP) and the Association for Molecular Pathology (AMP) developed guidelines for molecular testing of patients with advanced NSCLC, which second edition has recently been published (2). Those guidelines have been the role model for several other guidelines globally. Assays crucial in this are now included in the IASLC guidelines. While traditional immunohistochemistry (IHC) is still relevant for selection of patients to certain targeted therapies, e.g. ALK-inhibitors, more technological advanced assays based on DNA or RNA have become more “relevant” as multiplexed marker analysis seems in many cases “mandatory” (as sparse) “Tissue is the issue” (3). The last revision of the CAP/IASLC/AMP guidelines recommend the use of Next Generation Sequencing (NGS) if possible, as this assay gives more information and detect mutations as well as fusions. Today only a limited number of targets are linked to FDA approved drugs for treatment of lung cancer and the use of NGS gives a broad molecular profiling of the patients’ tumor. This knowledge gives the patient opportunity to seek clinical trials of, which many are ongoing, including a broad range of molecular targets. Many molecular targets have had direct impact to antibodies, testing platforms, and with different cut-off points for definition of “high” versus “low” PD-L1 expression in the clinical trials. IASLC has compared the analytical performances of the different assays in order to see if harmonization is possible, and the results of the “Blueprint Project” indicate that three assays (Dako’s 28-B and 22C3 and Ventana’s SP 263) perform very similar and seem to be interchangeable when the same clinical cut-offs for the different categories are used (5,6). Tumor mutation burden has also emerged as a predictive biomarker for immunotherapy (7). However, the tumor mutation burden assays need to be compared and standardized as well. Much research today is devoted to try to identify new and better predictive biomarker(s) for immunotherapy. While we have primarily focused on “single” biomarker assays for immunotherapy thus far, it might be time to look into the role of “combined” biomarkers or assays for the most optimal selection of patients, who benefit from immunotherapy. In conclusion, a tremendous development of biomarkers and assays have been seen over the last decade(s), which has made it possible to identify subgroups of patients
with dramatic effect of new targeted therapies. Future drug development needs to ensure the biomarker development occurs simultaneously in the clinical development to ensure validation of subgroups of patients, who will benefit from the new agents.

**MS21.08 WHERE WILL WE BE IN 10 YEARS?**

**P. Bunn, Jr.**
University of Colorado Cancer Center, Aurora/CO/US

Lung cancer is the leading cause of cancer death in the world, accounting for as many as one fourth of all cancer deaths. Mortality rates for lung cancer in the US and the world have been declining, albeit in varying amounts around the world. The decline is due mostly to decreasing tobacco consumption and early detection through CT screening. Improvements in therapy have also contributed and therapeutic improvements have come mostly in recent years. In the US, annual lung cancer deaths in males have decreased from 90/100,000 to 45/100,000 in males and from 45 to 35/100,000 in females from 1960-2018. Over this period 5 year survival rates have increased from 5% to 18%. However, the annual number of US deaths has remained about 160,000 per year due to increasing population and aging of the population. Social pressures and new agents to assist in smoking cessation should continue to reduce the incidence of lung cancer although some of these gains may be offset by increased air pollution. We should see agents that can reduce lung cancer incidence through prevention in high risk populations including the potential of low dose aspirin, eicosanoid, and immunotherapeutics including IL1beta inhibitors and checkpoint inhibitors. New biomarkers of early progression including circulating tumor DNA may markedly improve early detection. For early stage therapy in resectable patients, adjuvant chemotherapy improved 5 year survival by about 5%. For locally unresectable stage III lung cancer, the addition of chemotherapy (CT) to radiation therapy (RT) improved 5 year survival by 5-10%. More recently, the addition of immunotherapy to CT/RT for unresectable stage III disease has had a dramatic impact with improved survival. The use of immunotherapy for resectable lung cancer has produced considerably higher response rates than chemotherapy but its effects on survival remain to be determined. For stage 4 disease, the 5-year survival rates have increased from 1% to as much as 15%. Molecularly targeted therapy for patients with driver alteration have improved outcomes considerably with 4 year survivals of over 50%. At present, tyrosine kinase inhibitors (TKIs) are approved for EGFR and BRAF v600E mutations and for ALK and ROS1 rearrangements. It is likely that TAK 287, TAS-102 and HER2 and HTR2B and R705 will be approved in the near future. The most common molecular driver is KRAS mutation but not present in KRAS mutations and not for RET and HER2 rearrangements will be approved in the near future. The most common molecular driver is KRAS mutation but at present no KRAS inhibitors have been approved, although it is likely that KRAS inhibitors will be approved in the next decade. Immunotherapies with anti–PD-1 antibodies have improved 5 year survival rates for advanced disease to about 15% and the combination of chemotherapy and immunotherapy seems to produce even higher long term survival rates. Approved immunotherapies include the anti–PD-1 antibodies pembrolizumab and nivolumab, and the anti–PD-L1 antibodies atezolizumab and durvalumab. Other checkpoint inhibitor antibodies are in late clinical development and will likely be approved in the future. Combinations of checkpoint inhibitor antibodies with anti–CTLA-4 antibodies are in advanced clinical development and will likely be approved in the near future. Agonists and antagonists to multiple other immunotherapeutic targets have been developed and are in early phase clinical trials alone and in combination with checkpoint inhibitor antibodies. Therapies for other targets such DNA repair enzymes, stem cell pathways inhibitors, antibody drug conjugates are in development and should become available in the next decade. Over the next decade we can anticipate further lowering of death rates and improved survival rates which will be attributed to declining smoking rates, improved adherence to screening recommendations and to improved therapy. Wide-spread molecular testing and treatment and understanding the immune system with novel immune therapies should lead the improvements over this next decade.

**MS22 BIOLOGY OF THE LUNG AND LUNG CANCER**

**MS22.01 LUNG DEVELOPMENT AND STEM CELLS**

**J. Lee, C. Kim1, S. Rowbotham2**
1 University of Cambridge, Cambridge/GB, 2 *Hematology/Oncology, Boston Children’s Hospital, Boston/MA/US

Our laboratory has pioneered the use of stem cell biology approaches for the study of adult lung progenitor cells and lung cancer. Through a combination of mouse genetics and cell biology, we have developed tools to identify and characterize cells with progenitor cell activity in adult lung tissue. We have also applied our expertise to the study of lung cancer, which resulted in our definition of the cancer stem cell populations in the two most common types of lung cancer. We have elucidated the mechanisms that regulate lung progenitor self renewal and differentiation in the normal lung and in the context of lung cancer. One major focus in our lab has been the creation of three-dimensional co-culture and co-transplantation organoid systems that have begun to define the cell-cell crosstalk between epithelial progenitors, endothelial cells and mesenchymal cells in the lung. I will discuss how we have recently used our organoid system to define lung mesenchymal cell types that specifically regulate airway or alveolar epithelial cells. I will also present new studies in which we have examined how epigenetic factors, particularly H3K9 methylation and demethylation, affect lung injury repair, lung tumorigenesis and response to therapy in lung cancer.

**MS22.03 NON-CODING RNA IN LUNG CANCER**

**S. Diederichs**
Department of Thoracic Surgery, Division of Cancer Research, Medical Center - University of Freiburg, Freiburg/DE

Lung cancer is a disease of the genome caused by the aberrant activation of oncogenes and inhibition of tumor suppressor genes. However, the vast majority of the human genome is only transcribed into RNA and not translated into proteins. Hence, one major class of products derived from the genome are long non-coding RNAs (IncRNAs). These recently discovered class of molecules can execute a wide range of functions in the cell. Their versatility is based on their capability of specifically interacting with DNA, RNA or proteins. In the context of lung cancer, IncRNAs may contribute to the plasticity and complexity of lung cancer in general through regulation of tumor cell proliferation, invasion and metastasis by acting as scaffolding molecules to recruit multiple protein partners to the site of transcription. This may also impact cancer progression and therapy response. The role of IncRNAs in lung cancer is only beginning to emerge. As one of the first IncRNAs linked to cancer at all, we identified the conserved transcript MALAT1 as a marker significantly associated with development of distant metastasis and overall survival in early stages of lung adenocarcinoma (1). Although MALAT1 has been found deregulated in a plethora of pathological conditions after its discovery (reviewed in 2), it remained unknown whether it would only be a molecular marker or an active player in lung cancer metastasis. Hence, we generated a genetic loss-of-function model in human lung cancer cells using a then innovative approach combining gene editing and RNA degradation (3). Employing this model, we showed that MALAT1 was essential for tumor cell migration in vitro and metastasis formation in vivo in a mouse xenograft model. Moreover, an inhibitor for MALAT1 could also pharmacologically suppress metastasis formation in a mouse model (4). Thereby, the nuclear IncRNA MALAT1 acts as an epigenetic regulator of a signature of multiple genes associated with migration, invasion and metastasis mediating the aggressive cellular phenotype (4). Beyond MALAT1, we have screened for additional IncRNAs relevant for lung adenocarcinoma using gene expression profiling as well as RNAI screening with a customized library of
the phase III study ALEX demonstrated a higher IC-ORR for alectinib than of ceritinib in a population of patients with brain and/or leptomeningeal previously received RT and that the outcome of the remaining patients and IC-DCR 63% in ALK-inhibitor-naïve patients). Most of the cases had proved some intra-cranial activity in regulatory trials. However, brain activity and manageable toxicity [5]. First generation ALK TKI crizotinib activity and safety of osimertinib 160 mg qd (instead of 80 mg qd) in (B-TTP) was not reached. Brain response was rapid, being evidenced objective response rate (IC-ORR) of 54% and a disease control rate of patients with CNSMs enrolled in phase II trials showed an intra-cranial TKI osimertinib completely changed the perspective. A pooled analyses is the most common site of treatment failure [4]. Third generation

comprehensive tobacco control measures, including tobacco price regulations. Tobacco remains the most important preventable cause of premature mortality in the world. WHO, based on Framework Convention on Tobacco Control (WHO-FCTC), recommends the implementation of comprehensive tobacco control measures, including tobacco price policies, bans on tobacco advertising, promotion and sponsorship, health education, access to tobacco dependence treatment, strict regulation of tobacco products and their advertising. Tobacco control remains among the most respected and trusted community voices on health matters and should play a key role in all tobacco control measures. Their activities may be accomplished at both individual, institutional, community and society levels. In the everyday health-care setting physicians should counsel patients and their families against smoking and exposure to second-hand smoke and assist them to overcome tobacco addiction (1). Successful intervention begins with identifying users and appropriate interventions based upon the patient’s willingness to quit. To motivate patients to quit they should be informed about the health, economic and social benefits of quitting (2). The activities that can help patients ready to quit are summarized in the “5 A’s” model developed by The United States Department of Health and Human Services (3). This minimal intervention that may be accomplished within 3-5 minutes, includes asking about tobacco use, advising users all users to quit, assessing willingness to quit, advising quitting, and further referring and arranging for cessation services. To perform these roles, all physicians should be provided a basic training on brief interventions for smoking cessation and on evidence-based tobacco cessation measures. An indispensable condition for the effective physicians’ cessation counseling are their own behaviors and practices. Physicians should serve as role models in not smoking or quitting smoking for the general public. Compared to smokers, physicians who do not smoke are far more likely to engage in cessation advice and counselling (4, 5). Indeed, greater tobacco control progress has been made in countries where physicians do not smoke (6) Tobacco control activities at the community level, apart from those described above, may include speaking out publicly and lobbying for comprehensive public policies to control tobacco use, visiting schools to promote tobacco-free lifestyles and cultures, organizing campaigns that challenge tobacco-free publications, and disseminating evidence-based information and materials about tobacco related problems through local media. Professionals that have leadership positions should engage in the policy-making process at the community and national level. This may include promoting WHO-FCTC, developing tobacco-control strategies, participation in legislation processes and supporting comprehensive tobacco control measures, such as increased taxation and prices of tobacco products or lobbying for funding of tobacco control programs. An example of a bottom-up initiative undertaken by health professionals is the development of policy recommendations of a tobacco control bill and the legislation that banned smoking in public places in Poland (7). A similar initiative was undertaken by the British Medical Association that prompted the development of the legislation to smoking in enclosed public places in the United Kingdom (8). Medical societies should encourage their members to become engaged in tobacco control advocacy, organize plenary sessions and panel discussions at society conferences and workshops, adopt resolutions and issue ethical opinions on members, advocate for health care systems to reimburse for cessation counseling and treatment, issue press releases, hold press or organize direct lobbying by medical society leaders (9). In conclusion, the professionalism of physicians extends beyond the treatment of tobacco-related disease to include prevention, cessation counseling and policy advocacy, in the fight to eradicate tobacco use as an international public health pandemic. A guide for treatment of tobacco-related disease to include prevention, cessation counseling and policy advocacy, in the context of a bot...
Tobacco use remains a serious threat to global health and has killed almost 100 million individuals during the 20th century, and if current trends continue, approximately 1.3 billion people will die from tobacco use during the 21st century1. The rates of smoking prevalence are still increasing in many low- and middle-income countries, although decreasing in most high-income countries, thus, the number of tobacco-related deaths will continue to increase in the future years. China, the largest populous country in the world with a population of more than 1.3 billion individuals, is also facing this rigorous public health challenge. Owning to the large population base, China remains the largest tobacco producer and consumer in the world2. According to the report by World Health Organization (WHO) in the year of 2009, China consumed more than 2.2 trillion cigarettes, which account for 38% of the world's cigarettes and more than the other top tobacco-consuming countries combined3. Each year, more than 1.2 million people have been killed as a result of tobacco use in China and by the year 2030, the number of tobacco-related deaths will go up approximately 300%, resulting 3.0 million tobacco-related deaths annually4. Even to this day, the situation of tobacco control in China is still increasing serious, accompanying with high smoking prevalence, low and affordable price of cigarettes, poor knowledge of tobacco harms, and heavy economic burden of tobacco-related diseases etc. The WHO Framework Convention on Tobacco Control (FCTC), which covers 87.4% of the world's population and consists of more than 170 countries as signatories, is the first ever international treaty devoted to tobacco control in the world. Despite ratifying the FCTC in the year of 2005, the pace of tobacco control in China has lagged behind of most of the eligible signatories, which rank in the bottom 20% in WHO's ranking list of countries in tobacco control and FCTC compliance5,6. With an effort to assist eligible signatories to reduce tobacco use, the WHO FCTC introduced the MPOWER measures (Monitoring tobacco use and prevention policies; Protecting people from the harms of tobacco smoke; Offering help to quit tobacco use; Warning about the dangers of tobacco; Enforcing bans on tobacco advertising, promotion and sponsorship; Raising taxes on tobacco)7. However, the implementation of MPOWER measures needs to be largely improved in China at present. The health professionals also play a critical role in smoking cessation and even brief smoking cessation interventions are effective8. However, the awareness of adverse health effects of smoking in health professionals is relatively poor in China7,8. Cigarette gifting culture is another concern. Rarely seen in other cultures, the practices of gifting and sharing cigarettes are well accepted and pervasive across China. In Chinese culture, cigarette sharing or gifting is a bridge for establishing and maintaining interpersonal relationships, as well as a gesture to show respect and welcome guests. As a result, cigarette sharing or gifting is regarded as a contributing factor to smoking process, and also a major barrier to smoking cessation, especially in rural China9. In addition, it is worth noting that China's State Tobacco Monopoly Administration is not only a governmental agency responsible for all aspects of tobacco industry, including tobacco growing, processing, product manufacturing and distribution, but also material and machinery supplies, it is also in charge of tobacco control affairs in China, which presents a serious conflict of interest and is another significant obstacle for tobacco control in China10. In summary, several impediments for tobacco control in China need be overcome, including poor awareness of harm of tobacco use and high smoking prevalence among physicians, and training standard anti-tobacco skills for health professionals. Furthermore, additional cultural-specific measures also should be taken to discourage sharing or gifting cigarettes to reduce tobacco use through sharing or gifting, especially in rural China. More importantly, to separate the functions of the government from the tobacco industry may be the most critical step to eliminate the contradictions in China’s tobacco policies and to fulfill the WHO FCTC goals in China. Development of genomic analysis has reported the most frequent MPM that may change routine practice and management of patient. In 2018, a recent IASLC-EURACAN multidisciplinary meeting at an early stage when the treatment can prevent the spread of the disease. In conclusion, whilst tumour volume is clearly a prognostic factor and has showed that defactinib a focal adhesion kinase (FAK) inhibitor may have a potential action on the NF2 pathway for blocking cell survival. In consequence loss of p16 Ink4a leads to inhibition of the retinoblastoma pathway and to cell cycle arrest. CDKN2A (P16) homozygous deletion by FISH testing is a better prognosis. Another driver mutation is the CDKN2A gene located in chromosome 9p21 encoding p14 ARF and p16 Ink4a which through p14 ARF interacts with MDM2 leading to MDM2 degradation and activation of p53. In consequence loss of p14 ARF favor cell survival. On the other way loss of p16 Ink4a leads to inhibition of the retinoblastoma pathway and cell growth.

Malignant mesothelioma (MM) is a rare cancer with a natural history of 7–9 months if untreated and a 5-year survival rate of less than 5% for the epithelioid and 0% for the biphasic and sarcomatoid types. MPM aggressiveness is strongly associated with histological differentiation (2017 -MESOPATH data). Up to now there are no curable available therapeutic options but patients treated with avastin, cisplatin, (2017 -MESOPATH data). Up to now there are no curable available therapeutic options but patients treated with avastin, cisplatin, carboplatin, gemcitabine have a potential action on the NF2 pathway for blocking cell survival. The diverse molecular events are not exclusive and it should be expected that additional mutations may play a role in treatment resistance. BAP1, NF2 and NF1 are the main tumor suppressor genes involve in mesothelioma important to evaluate for diagnosis, prognostication and treatment decision. Therapeutic algorithms will be presented during the session. The European respiratory journal 2017;49: Figure 1: In the IASLC T staging database, tumour bulk was estimated by measuring the thickest tumour at the upper, middle and lower hemithorax bounded by structures shown above and below lines in (a), (b). Tumour is measured perpendicular to the chest wall or mediastinum (c).
Malignant pleural mesothelioma (MPM) has remained a therapeutically challenging condition since the establishment of cisplatin and pemetrexed chemotherapy (chemo) as the standard of care in suitably fit patients (1). Approaches to drug development in MPM as in cancer in general have traditionally focused on identifying specific cellular or biologic "targets" considered of importance in the cancer pathogenesis in the hope of obtaining large therapeutic impact. Unfortunately successful "targeted" therapy of advanced MPM has to date remained elusive. The absence of clear targets in MPM pathogenesis, characterized by alterations in multiple cellular pathways and the absence of landmark "drivers". The search for therapy by targeting fundamental pathologic processes in MPM has seen greater success. An example of this has been vascular endothelial growth factor (VEGF) signaling which has been shown to play a pivotal role in MPM pathogenesis. Targeting VEGF with the addition of the anti-VEGF monoclonal antibody bevacizumab to standard chemo in patients (pts) with advanced MPM was shown to improve survival compared with standard chemo (2). Another such approach of interest in MPM is that focusing on non-coding RNAs with their deregulation seen in MPM as in many other human cancers. MicroRNAs (miRNAs), are a subclass of non-coding RNAs with short sequences (18–24 nucleotides) that target messenger RNAs (mRNAs) through partial base pairing to sites found in their 3' untranslated region (3). They regulate gene expression post- transcriptionally by blocking the translation of target mRNAs. Over 1000 human miRNAs have been identified with roles in the control of gene and protein expression (4). In MPM several miRNA expression profiles have been identified in tissue and in blood (serum or plasma) as potential biomarkers of MPM, with possible a role in diagnosis and prognosis (5, 6). Several dysregulated miRNAs have also been associated with the pathogenesis of MPM affecting many of the hallmarks of cancer, by being downregulated and thus losing their tumour suppressor function (7). Thus, developing a therapeutic approach to MPM by targeting miRNAs has focused on restoring the levels of deficient miRNA. Therapeutic miRNA replacement to date has mainly focused on the use of synthetic miRNA mimics to replace the suppression of target expression (7). The miRNA-15/16 family specifically has been shown to be downregulated and to have a tumour suppressor function in MPM, targeting the miRNAs of BCL2, CDK1, ETS1, and JUN, which are all involved in cancer progression (7). Based on this finding Reid et al focused on developing a therapeutic strategy targeting miRNA-16 (miR-16). Firstly they showed in vivo that restoring miR-15 and -16 expression inhibited MPM cell growth and that systemic delivery of a miR-16 mimic inhibits tumour growth in vivo (8). The MPM system has to date involved restoration increasing the sensitivity of cells to gemcitabine and pemetrexed chemotherapy (8). Reid et al used an alternative to the liposomal or nanoparticle based methods frequently used to deliver miRNAs, by employing EnGeneIC DreamVectors (EDV™) nanocells (EDVs)(7, 8, 9). This is a bacterially derived delivery system developed by EnGeneIC (Sydney, Australia). It comprises nonviable minicells 400 +/- 20 nm in diameter, which were loaded with a miR-16 mimic, and coated with bispecific antibody to EGFR (panitumumab), as EGFR is known to be expressed in a high proportion of mesothelioma patients (7, 8, 9). These pre-clinical experiments were followed by a first in man open label, phase 1, dose-escalation escalation study in patients with refractory advanced MPM aimed to assess the safety, optimal dosing, and activity of TargomiRs (the aforementioned EDV minicells loaded with miR-16-based miRNA targeted to EGFR (10)). Patients were given TargomiRs via 20 min intravenous IV infusion either once or twice a week (3 days apart) in a traditional 3+3 dose-escalation design in five dose cohorts. Several dose-escalation steps were planned either once or twice weekly, but after analysis of data from the first eight pts, all subsequent patients started protocol treatment at 1 x 10⁹ TargomiRs. The primary endpoints were to establish the maximum tolerated dose (MTD), defined by dose-limiting toxicity, to define the optimal administration schedule and to explore anti-tumour activity (10). Twenty six pts received at least one TargomiR dose. Overall, 5 DLTs were noted: infusion-related inflammatory symptoms and coronary ischaemia, respectively, in 2 pts given 5 x 10⁹ TargomiRs twice weekly; anaphylaxis and cardiomyopathy, respectively, in two pts given 1 x 10¹⁰ TargomiRs once weekly; and non-cardiac pain in one pt who received reduced dexamethasone prophylaxis; and non-cardiac pain in one pt who received 5 x 10⁹ TargomiRs once weekly. MTD was 5 x 10⁹ TargomiRs once weekly. TargomiR infusions were accompanied by transient lymphopenia (25/26 pts), temporal hypophosphataemia (17/26 (65%) pts), increased aspartate aminotransferase (ALAT) (16/26 (23%) pts), altered alanine aminotransferase (ALAT) (6/26 (23%) pts), increased alkaline phosphatase blood concentrations (2/26 (8%)). Cardiac events occurred in 5 pts: 3 with ECG changes, one pt had ischaemia, one pt had Takotsubo cardiomyopathy. 2 pts were evaluable for response: one (5%) partial response, 15 (68%) stable disease, six (27%) progressive disease. The duration of response in the responding pt was 32 weeks. Median overall survival was 200 days (95% CI 94–358)(10). This phase I study demonstrated acceptable safety and signs of activity of TargomiRs acting as proof of concept supporting further development in pts with refractory MPM. The optimal next step is not to be a formal Phase II study evaluating TargomiRs in the weekly or alternative schedules or combination studies with chemo or immune checkpoint inhibitors. Another novel combination option has been suggested by the preclinical data which identified link between the fibroblast growth factor and the miR-16 family (11). 1. J Clin Oncol 2003;21: 2636–44. 2. The introduction of new cancer therapies involves Health Canada approval, a national health technology assessment (HTA) through the pan-Canadian Oncologic Drug Review (pCODR) process and national price negotiations through pan Canadian Pharmaceutical Alliance (pCPA). Once a therapy has been deemed clinically and cost effective, the individual provinces are able to negotiate local contracts and add new oncologic agents to their respective formularies. This national process, while ensuring cost effectiveness and a degree of drug price negotiation power, results in significant delays in access to new therapies. The advantage however, is that in a universal health care system, all Canadians have access to approved oncologic drugs regardless of their social status or income. The disadvantage lies with the therapies that do not meet the bar for approval due to evidence or cost effectiveness issues and that the system is nimble and responsive. In the example of immunotherapy, nivolumab was first approved by Health Canada in the post-platinum metastatic setting in February 2016. The review by pCODR was completed with approval provided that it was cost effective in June 2016. The longest aspect of the funding for nivolumab was the national price negotiations that took 9 months to reach an agreement that was agreeable to pCPA and the company in March 2017. Subsequently, nivolumab has been funded for all Canadians who meet the listed Health Canada indication. Medicaid/Medicare and private insurance decisions regarding funding of cancer therapies in the US are based on guidelines provided by the National Comprehensive Cancer Network (NCCN). Unlike Canada, the US oncology drug funding model operates on a free market basis and the price of therapy is determined by what the market will bear. Furthermore, the 2003 Medicare law prohibits Medicare from negotiating drug prices which presents significant challenges for patients who pay or those that pay fee for service. Despite the financial hurdles posed by immunotherapy, the US system is responsive to clinical trials evidence. The Food and Drug Administration (FDA) promptly approved nivolumab in the platinum treated second line setting for squamous and non squamous NSCLC in March and October 2015 respectively based on the outperformance in that year. The NCCN issued revised treatment algorithms incorporating nivolumab for squamous in May 2015 and non squamous disease in October 2015, the result being government and private insurance coverage within 1-2 months of FDA approval. In Mexico, COFEPRIS, the Comisión Federal para la Protección contra Riesgos Sanitarios, similar to Health Canada and the FDA, approved nivolumab for NSCLC in September 2016. However, as of September 2017 nivolumab was not listed on the Basicable of Drugs covered by IMSS. For Seguro Popular, the Federal Fund for Protection against Catastrophic Health Expenditures (FPCHE) covers high-cost health interventions. This program covers six types of malignant conditions; breast cancer, cervical cancer, prostate cancer, testicular cancer, non- Hodgkin’s lymphoma, and others. Unfortunately, lung cancer treatment is not covered by this plan as of 2015. While immunotherapy is approved for use in Mexico, there is no government funded mechanism to access therapy rendering it outside the reach of many of the citizens of the country. The practicalities of the transition of clinical trials data to the real world can be challenging at many levels. Depending on the national infrastructure, patients are faced with affordability and timely access issues. Navigating the health care system is the first, critical step of treatment adoption which subsequently enable an understanding of the efficacy and toxicity of providing new therapies to our real-world lung cancer patients.
and radiation therapy. Irrespective of the clinical staging approach, because of the residual inaccuracy of clinical staging even when adequately applied, thorough pathologic nodal staging is also strongly recommended as the most accurate determinant of stage in patients who undergo attempted resection. Estimated 5-year survival rates are 75%, 49%, 36% and 20%, for patients with pathologic N0, N1, N2 and N3 disease, respectively. The pathologic nodal stage also has therapeutic implications: patients with pN1-3 benefit from adjuvant chemotherapy; those with pN2 or 3 may also benefit from radiation therapy (which is harmful to patients with pN0 or pN1). Accurate pathologic nodal staging confers better survival of lymph nodes (the pathologist has no access to these nodes without surgical retrieval) and examination of all lymph nodes provided in the resection specimen (including intrapulmonary lymph nodes which are present within the anatomic resection specimen and therefore available to the pathologist, irrespective of surgical practice). Gaps in the quality of nodal staging. Although there is no universal definition of clinical or pathologic nodal staging quality, multiple organizations have made recommendations for nodal staging. The American College of Surgeons Oncology Group provided an anatomically-precise definition of ‘systematic sampling’ and ‘mediastinal lymph node dissection’ which was used in the landmark Z0030 trial. Although this trial revealed survival equivalence between the two extents of surgical nodal retrieval in patients undergoing resection for clinical T1 or T2 and N0 or non-hilar N1 NSCLC, the quality of nodal staging in ‘real world practice’ falls well short of these definitions. The use of PET/CT scans has increased in the US with greater willingness of surgeons to perform restaging, but invasion of mediastinal lymph nodes remains severely understudied, with penetration rates below 20% in many institutions. Large US database analyses reveal that up to 18% of node-negative resections have no lymph nodes (pNX); 40-60% of pN0 or pN1 resections have no mediastinal lymph nodes, and less than 70% of pN2 resections have up to 10 lymph nodes. Studies showing that a minimum of 14 to 20 lymph nodes are associated with the lowest hazard for death. In a population-based cohort of over 2300 resections within a high lung cancer mortality region of the US, only 15% of patients had the combination of preoperative PET/CT scan, invasive mediastinal nodal staging and pathologic examination of any mediastinal lymph nodes; 17% had no attempted histologic examination of mediastinal lymph nodes before, during or after surgical resection. Survival implications. The nodal staging gap has survival impact. For example, the survival of patients with pNX resections mirrors that of patients with pN1, not pN0; pN0 and pN1 patients without pathologic mediastinal nodal examination have a 5% lower 5-year survival rate than those with any mediastinal nodes; patients without attempted histologic examination of mediastinal lymph nodes (lacking both invasive preoperative biopsy and mediastinal nodal examination in the resection specimen) have 14% to 37% higher hazard for death within 5 years, compared to those who do. Unsurprisingly, eligibility for adjuvant therapy is significantly more likely when histologic examination of mediastinal lymph nodes is attempted. Furthermore, when large sets of surgically resected NSCLC patients are ordered according to stringency of pathologic nodal staging quality, a strong direct association with survival is observed. Quality improvement. The pathologic nodal staging gap is profound survival impact, and the negative impact on clinical trial eligibility, accrual, balanced randomization and accurate determination of intervention-related outcomes, suggest the need for concerted intervention. The need for such improvement is heightened by the predicted increase in the proportion of candidates for curative-intent treatment with deeper penetration of low dose CT screening and more organized management of patients with incidentally-detected nodules; the widening array of candidate novel adjuvant treatments; the opportunity to develop stage-independent biologic prognostic markers; and the intensifying interest in comparative effectiveness studies of surgical versus non-surgical treatment modalities. Sustainable quality improvement will require simple, rationally-designed and empirically-proven interventions because of the complexity of lung cancer care and the multiplicity of providers involved. We can conceptualize accurate pathologic nodal staging as involving a chain of responsibility from surgical retrieval during the operation (surgeon and scrubbed assistants), thorough examination of all material (the pathology technician), thorough examination of all material (the pathologist) and accurate reporting in a standardized format (pathologist and transcriptionist). A breach in quality at any of these steps in the chain of responsibility could, in theory, impair the accuracy of pathologic nodal staging. To be sustainably successful, corrective interventions must secure quality across all links in the chain of responsibility, which is only as strong as its weakest link.

In the AJCC/UICC 8th edition of the TNM Classification for Lung Cancer introduced in 2015, the T stage was restructured into two groups: T1 and T2. The recommendation of the IASLC Lung Cancer Staging Project was to provide guidelines for the Revisions of the T Descriptors in the Forthcoming Eighth Edition of the TNM Classification for Lung Cancer. J Thorac Oncol. 2015;10(7):990-1003. 2. Ginsberg RJ, Rubinstein LV. Randomized trial showing improved survival compared with sublobar resection (2). With improvements offered by imaging technology and advances in clinical staging, the question of whether sublobar resection, in the form of wedge resection or segmentectomy, can provide an oncologically equivalent survival benefit from lobectomy was only present for patients before 1997 and not for the newer cohorts (4). This suggests that early stage lung cancer patients of the present era are different from the era by which our current standards of care were established. Similarly, in comparing outcomes after lobectomy with sublobar resection using the T-stage the AJCC/UICC 7th edition the resection T size was no longer a predictor in survival based on the type of resection for T1a and T1b ground glass-predominant nodule groups, although there was a higher rate of lymph node metastases in the T1b group (5). Additionally, Okada et al found that there was no difference in survival between lobectomy or segmentectomy for patients with early stage adenocarcinoma using the AJCC/UICC 7th edition classification (6). Thus, even when using the prior classification of T-stage, there is evidence to suggest that these early tumors should be managed differently than larger, more advanced non–metastatic tumors. With the introduction of the AJCC/UICC 8th edition of the staging system, further studies will be able to better delineate the question of whether sublobar resection is appropriate for early stage lung cancer and whether a specific size cutoff within the T stage can guide the question of whether sublobar resection, in the form of wedge resection or segmentectomy, can provide an oncologically equivalent survival benefit from lobectomy was only present for patients before 1997 and not for the newer cohorts (4). This suggests that early stage lung cancer patients of the present era are different from the era by which our current standards of care were established. **MS28.05 COMBINING IO WITH RADIATION**

C. Faivre-Finn

Clinical Oncology, University of Manchester and the Christie NHS F’dation Trust, Manchester/GB

Lung cancer remains the leading cause of cancer-related death worldwide, with non-small cell lung cancer accounting for 85% of the disease. Over 70% of patients present with locally advanced, non-resectable or metastatic disease and despite improvements in chemo-radiography regimens and the development of molecularly targeted agents, 5 year survival rates remain poor, with acquired resistance to novel targeted therapies becoming a growing concern. Currently there remains an unmet need in effectively treating and inducing durable responses in advanced disease. Targeting the immune system has, however, recently given hope of improving therapeutic outcomes for these patients. The notion that the immune system is capable of recognising and eliminating cancer cells is now a widely accepted phenomenon and growing evidence suggests lung cancer is an attractive target for such intervention. Recent success targeting the programmed death-1/programmed death-ligand 1 (PD-1/PD-L1) axis of immune checkpoint inhibition in stage IV non-small cell lung cancer suggests a major immunotherapeutic advance in treating lung cancer and unheralded opportunity for such approaches to further improve outcome for patients. Currently there is considerable interest in combining anti-PD-1 or PD-L1 monoclonal antibodies with established standard of care therapies such as radiotherapy. Radiotherapy is known to be immunostimulatory and efforts are underway to combine and augment the efficacy of the immune checkpoint inhibitors further. The combination of radiotherapy with immunotherapy has the potential to augment anti-tumour immune responses. This talk will outline the interaction between lung cancer and the immune system, summarises current evidence supporting the use of monoclonal antibodies targeting the PD-1 axis in lung cancer (including the PACIFIC trial) and will summarise ongoing clinical trials.

**MS28.04 COMBINATION WITH TARGETED THERAPIES**

P. Soo

University Medical Center, Erasmus MC, Rotterdam/NL

Molecular targeted therapy and immunotherapy have transformed the treatment of lung cancer. In oncogene driven lung cancer such as EGFR mutant or EML4-ALK rearranged NSCLC, molecular targeted therapy is associated with high response rates but are usually not durable. Lately, the use of immune checkpoint inhibitors targeting programmed death receptor-1 (PD-1) and programmed death receptor ligand-1 (PD-L1) have generated regulatory approvals in the first line and pre-treated setting for advanced NSCLC. Single agent immune checkpoint inhibitors are associated with lower responses but responses are more durable. The combination of targeted therapy and immunotherapy can potentially deliver new opportunities to improve anti-cancer treatments. In this presentation, PD1/PDL1 inhibitors in combination with targeted therapies will be discussed with a focus on EGFR mutant/ ALK rearranged NSCLC. The areas to be reviewed include: (1) oncogene signalling pathways and PD-L1 expression, (2) the reduced effectiveness of immune checkpoint inhibitors in pre-treated EGFR/ALK +ve NSCLC, (3) mechanisms for an impaired response to immune checkpoint inhibitors, (4) the relationship between PD-L1 expression and response to targeted therapy, (5) the immunological effects of molecular targeted therapy and (6) the efficacy and toxicity outcomes in studies of combination targeted therapy and immune checkpoint inhibitors in oncogene driven tumors. In addition, the role of immunotherapy in combination with targeted agents and EGFR monoclonal antibodies in oncogene negative NSCLC will also be presented. A better understanding of the integration of targeted therapies with immunotherapies will be required to inform on the design of combination strategies and improve outcomes and reduce toxicities in patients.

**MS29 SELECTION INTO SCREENING PROGRAMS: INTERPLAY OF RISK ALGORITHMS, GENETIC MARKERS AND BIOMARKERS**

K. Ten Haaf

University Medical Center, Erasmus MC, Rotterdam/NL

Lung cancer screening guidelines generally recommend annual screening, similar to the design of the National Lung Screening Trial. However, results from European trials indicate that longer time-intervals between screenings can still yield a stage-shift. This has led to discussion on the feasibility of screening programs with longer time-intervals between screenings. Findings from trials has led to improvements in interpreting and managing nodules found on CT screens. These findings have been essential in improving nodule management protocols and reducing the number of false-positive results. But, the results of CT screens have also been shown to inform an individual’s future lung cancer risk. The NLST showed that individuals with a negative baseline screen had also been shown to inform an individual’s future lung cancer risk. Analyses of the ongoing Dutch-Belgian Lung Cancer Screening Trial (NELSON) indicate that the results of the first three screening rounds were indicative for detection of lung cancer in the fourth screening round. In addition, NELSON showed that the characteristics of screen-detected nodules can be used to estimate the two-year risk for developing lung cancer. Risk prediction models have been suggested for selecting individuals for lung cancer screening. Analyses of different risk prediction models have been shown to be superior compared to participant selection based on age and pack-years. Combining these models with the information provided by CT screens may allow the personalization of an individual’s screening regimen. This session will consider the evidence on the effects of varying time-intervals between screenings. In addition, it will discuss the potential for personalizing the screening regimen based on screening results and

Background: Genome-wide association studies uncovered multiple lung cancer susceptibility genes, and consortium efforts greatly increased our ability to investigate the genetic architecture of histological subtypes. However the clinical utility of these genomic discoveries remains unclear. Method: We therefore constructed a risk prediction model with polygenic risk score (PRS) based on 18,316 lung cancer patients and 14,025 controls from European ancestry, via grid cross-validation with elastic net penalized regression. Model calibration was assessed, and was validated with UK biobank data (N=336,911 unrelated participants with European ancestry). To evaluate its potential clinical utility, the PRS distribution was simulated in the National Lung Screening Trial (NLST, N=50,772 participants). Absolute risk was estimated based on age-specific lung cancer incidence and all-cause mortality as competing risk. Added value of PRS to the risk prediction model was assessed in VOC levels over time following ingestion of a peppermint capsule, that we will present data, including VOC washout curves monitoring changes in breath profiles pre- and post-surgery which has the advantage of allowing the patient to act as their own control. The Biology of VOCs

So why would we believe that VOC biomarkers for lung cancer could be discovered during LuCID? Cancer cells undergo profound changes of their metabolism in order to support high energetic demands of uncontrolled proliferation. Several oncogenic mutations have been shown to lead to upregulated metabolism of cancer cells by converging to common metabolic pathways linked to cell cycle and anabolic growth. The Warburg effect is among well-established cancer metabolic hallmarks and entails the activation of aerobic glycolysis as main pathway for biosynthetic purposes, as opposed to normal cells that exploit mitochondrial metabolism for their energetic needs. These changes in cellular metabolism favor survival in an oxygen deprived environment and result in altered metabolic intermediates that function as the building blocks for new cells, both enabling the growth of rapidly dividing cancer cells, and also altering the profile of VOCs in breath. As these processes are fundamental to cancer cell survival, such altered metabolism occurs as one of the earliest stages of tumorigenesis, hence VOCs are excellent candidate biomarkers for early detection of cancer. Breath Sampling: Challenges and Solutions, reviewing the inherent challenges associated with breath sampling and analysis. We will conclude by giving an update on the progress of the LuCID trial to date. The LuCID Study LuCID is an international multi-centre prospective case-control cohort study (ClinicalTrials.gov ID NCT02612532) currently in progress, evaluating breath VOCs in patients with a clinical suspicion of lung cancer. A clinical suspicion is based on symptoms and/or suspicious finding on incidental imaging. Using tidal breathing, patients breathe into the ReCIVA Breath Sampler to collect breath samples on stable sorbent tubes for later analysis by Gas Chromatography-Mass Spectrometry and Field Asymmetric Ion Mobility Spectrometry (FAIMS, Owlstone Medical Ltd). One arm of the study is focused on early detection of lung cancer, with the aim of increasing the number of cases diagnosed at Stages 1 and 2, while an additional arm is currently being initiated looking at differences in breath profiles pre- and post-surgery which has the advantage of allowing the patient to act as their own control. The Biology of VOCs

So why would we believe that VOC biomarkers for lung cancer could be discovered during LuCID? Cancer cells undergo profound changes of their metabolism in order to support high energetic demands of uncontrolled proliferation. Several oncogenic mutations have been shown to lead to upregulated metabolism of cancer cells by converging to common metabolic pathways linked to cell cycle and anabolic growth. The Warburg effect is among well-established cancer metabolic hallmarks and entails the activation of aerobic glycolysis as main pathway for biosynthetic purposes, as opposed to normal cells that exploit mitochondrial metabolism for their energetic needs. These changes in cellular metabolism favor survival in an oxygen deprived environment and result in altered metabolic intermediates that function as the building blocks for new cells, both enabling the growth of rapidly dividing cancer cells, and also altering the profile of VOCs in breath. As these processes are fundamental to cancer cell survival, such altered metabolism occurs as one of the earliest stages of tumorigenesis, hence VOCs are excellent candidate biomarkers for early detection of cancer. Breath Sampling: Challenges and Solutions The potential of using breath sampling to identify markers of disease has long been recognized, but has to date seen almost no adoption into clinical practice, with only FeNO and H. pylori breath tests in widespread use. This has largely been due to practical considerations that have made large-scale clinical trials impractical to carry out. Most previous tests have involved collecting breath in bags, which - suffer from chemical losses over time - are vulnerable to contamination from ambient air if they are reused incorrectly - are difficult to transport and store. - only allow the collection of smaller volumes, limiting the sensitivity of the analysis. In this section, we will discuss how the ReCIVA breath sampler, a key part of the Breath Biopsy platform, allows these problems to be overcome, and we will present data, including VOC washout curves monitoring changes in VOC levels over time following ingestion of a peppermint capsule, that demonstrate how the ReCIVA performs in practice.
There is a recognized need for biomarkers capable of assisting with the early diagnosis of lung cancer. We need tools to improve our ability to identify patients at risk of developing cancer; to identify patients with asymptomatic early stage lung cancer; to identify patients who are more likely to die of causes other than lung cancer; to help us characterize the nature of a patient’s lung cancer; and to improve our management of lung nodules (expedite diagnosis, reduce the risk of evaluation, reduce the cost of evaluation). To have clinical utility a biomarker result must affect a clinical decision in a manner that leads to improved patient care. Both the benefit of clinical decisions influenced by true positive and negative results and the harms of clinical decisions influenced by false positive and negative results must be considered in the screening setting. A biomarker should lead to fewer lung cancer deaths without substantially increasing harms or expense, or a similar number of lung cancer deaths with fewer harms or less expense. When used to characterize a lung nodule a biomarker should lead to earlier diagnosis of malignant nodules without substantially increasing the number of procedures performed on patients with benign nodules or fewer procedures for patients with benign nodules without substantially delaying the diagnosis of cancer in patients with malignant nodules.(1) Biomarker development moves through a series of phases. In the discovery phase, a molecule or pattern of molecules are found to be associated with the presence or absence of the condition in question. If the association appears to be strong enough the biomarker may be taken to validation stages. Technical validation refers to the assessment of the accuracy (precision, reproducibility) of the assay that will measure the biomarker. Clinical validation refers to determining the accuracy (sensitivity, specificity, AUC, NRI) of a biomarker, with a fixed threshold for result interpretation, when applied to the intended use population. Through each phase of development standard operating procedures that include pre-analytical, analytical, and post-analytical processes, must be in place. Even accurate biomarkers may not be clinically useful. Prior to clinical use, it is important that the validated biomarker move through the clinical utility phase of assessment. To determine if the accuracy of a validated biomarker is high enough to be included in a clinical utility study one must consider the potential impact of true and false positive and negative results. In a screening context true positive results may lead to individuals with lung cancer being identified at curable stages while false positive results may lead to individuals without lung cancer (or at low risk of developing lung cancer) being enrolled in screening programs where they will be exposed to the associated harms of screening. True negative results could lead to individuals without lung cancer (or at low risk of developing lung cancer) avoiding the harms associated with low-dose CT screening while false negative results could prevent individuals with (or who will develop) lung cancer from being enrolled in a low-dose CT based lung cancer screening program, and thus not have an opportunity to benefit. A judgment about an acceptable tradeoff of benefit and harm from using this biomarker will have to be made. The biomarker should be more accurate at identifying patients with (or who will develop) potentially curable lung cancer than current eligibility criteria and available clinical risk prediction calculators, alone or in combination. What is considered an acceptable tradeoff in a screening context is likely to vary based on whether the biomarker is being applied to a cohort already eligible for LDCT screening or to a cohort that is currently not eligible for LDCT screening. In the former it is most important that patients with lung cancer are not excluded from being screened (rule out test) while in the latter it may be more important not to screen individuals without lung cancer (rule in test). Calculations exist that use currently accepted benefit/harm ratios when available (e.g. the currently eligible cohort for screening had an incidence of lung cancer of 0.83% in the NLST trial) to help determine if the validated accuracy supports pursuit of clinical utility studies.(2) Biomarker-stratified, enrichment, and biomarker-strategy study designs are acceptable approaches to determine clinical utility. Ongoing research trials are moving potential biomarkers through the phases of development. A handful of biomarkers have completed discovery level work and are working on, or have published or presented clinical validation study results. Others continue discovery level work. Few have entered formal clinical utility testing. Oncimmune’s panel of autodiagnostics, the EarlyCDT-Lung test, is being assessed as part of a 12,000 person randomized controlled screening study (the ECLS study). An exciting amount of high quality discovery and clinical validation work is ongoing. Some companies are in the process of planning true clinical utility studies for early lung cancer detection (Table).
by normal tissues and toxicity in relation to overall survival. In this study the maximum grade of oesophageal toxicity and the proportion of heart receiving radiation dose were both factors associated with poorer survival [2]. The last two decades have seen many technical advances in radiotherapy delivery techniques. For treatment planning, the objective is to attain conformity of the planned dose to the target volume within margins to account for interfractional and intraplan variations of target and organ motion within the thorax and use of techniques to individualise treatment based on the motion to improve the treatment accuracy [3,4]. For radiotherapy delivery over the course of treatment, the objective is consistency between the planned and delivered dose distributions. With recent widespread availability of cone-beam computerised tomography (CBCT) it is now possible to use these images to assess the shape and position of the radiotherapy target in relation to the planned dose delivery prior to treatment, image guided radiotherapy (IGRT), to improve accuracy of treatment delivery and where necessary to use this information to adapt treatment based, image guided adaptive radiotherapy (IGART) [5]. It is hoped that emerging techniques such as proton therapy, with long range of low energy ionised particles with high linear energy transfer in bone and soft tissue, and its imaging unit with linear accelerator, will further develop IGRT and IGART delivery. Establishing the clinical benefit and cost-effectiveness of these technological advances is challenging. The improved median survival in the standard arm of recent randomised trials [1,2] compared to historical trials suggests that these technical advances may improve survival outcomes. Additionally, there are retrospective data from a large series that suggest IMRT in particular may be associated with improved outcome in stage III NSCLC with T3 and T4 tumours [6] and a recent secondary analysis of the RTOG 0617 trial suggests use of IMRT compared to 3D conformal techniques is associated with lower severe lung toxicity and lower cardiac doses [7]. Finally, it is hoped that the use of these advanced techniques will permit radiotherapy treatment intensification either through altered radiotherapy fractionation or delivery or the combination with systemic therapy.

MS30.04 PERSPECTIVE

M. Werner-Wisk
Radiation Oncology, Thomas Jefferson University Hospital, Philadelphia/US

Radiation therapy (RT) in locally advanced non-small cell lung cancer (LA-NSCLC) has not changed in its essence over many decades. The refinements in modern “so-called” RT followed general improvements applicable to many other malignancies, such as introduction of IMRT (including VMAT) and IGRT. Tumor motion appears more relevant in lung tumors than in other disease sites, and tumor-lung interface allows for a measurable and intuitively observable movement, therefore enabling motion management in the lung to be more advanced, such as 4D CT for planning and tumor tracking (CyberKnife) or gating in daily practice. Nevertheless, the median survival time (MST) for good performance status (PS) unresectable Stage III patients with NSCLC, treated with concurrent chemoradiotherapy (chemo-RT) has improved significantly over last quarter century, from MST of 17.1 mo (RTOG 9410) to MST of 28.7 mo (RTOG 0617). Since the agents used in concurrent chemotherapy are not significantly different, other causes, mostly widespread use of PET scans for staging, as well as improved RT techniques, likely play a role. Use of CT simulation is associated with improved MST, even when adjusted for other variables used in standard practice. The Phase II randomized MADACC trial of photon vs. proton-based chemoradiotherapy for patients with Stage III or oligometastatic NSCLC did not show a difference in radiation pneumonitis rates between the arms and no improvement in local control in the protons arm. However, the 5-year OS in this national registry was discovered, with lower pneumonitis rates in those patients in the proton group who were treated in the latter half of the study vs. those treated in its early phase. The ongoing NRG Oncology/RTOG 1308 Phase III randomized trial of photon vs. proton chemo-RT (70 Gy, but not lower than 60 Gy) has had a slow accrual, particularly due to the paucity of participating centers, since proton technology is not widespread yet; also, a high percentage of patients not being able to enroll due to medical insurance coverage denial for protons, as well as possible perceptions of the superiority of protons. That study’s design has been modified recently to allow for a faster study’s completion. The original primary endpoint was overall survival, in contrast to the MADACC trial, where pneumonitis and local failure rate were co-endpoints. In order to complete the RTOG 1308 trial sooner by lowering trial throughput, the current primary hypothesis is that the MST in the proton arm is non-inferior to the photon arm (i.e. 28 mo), and major cardiac toxicity and grade 4 or higher lymphopenia is better in the proton vs. photon arm. Additionally, the Qualifying Cancer Hypothesis (QCH) is that, compared with patients receiving proton therapy, patients on the proton arm will have less severe shortness of breath 6 months after the end of concurrent chemor-RT (representing late adverse response to therapy), and that the differences in symptom ratings (based on MDASI shortness of breath item) between arms will be clinically meaningful. The recent availability of Magnetic Resonance (MR)–Guided RT may open a new era in lung cancer RT, allowing for the real-time intrafractional tumor tracking and “on the fly” adaptive RT, both likely to allow smaller tumor target volumes and a better conformity of delivered dose to the normal structures, therefore lowering toxicity and potentially opening the door to reassessment of RT dose intensification. Finally, with the explosion of evidence-based applications of immunotherapy in metastatic lung cancer and the demonstration of an impressive survival prolongation in the Phase III randomized PACIFIC trial with the addition of maintenance durvalumab following chemo-RT, the role of chemotherapy may be eventually challenged and reevaluated in Stage III NSCLC, to be possibly replaced by concurrent immunotherapy or a chemo-immunotherapy combination. MS30.05 NUTRITIONAL MANAGEMENT DURING RADICAL RADIOTHERAPY

R. White
Nutrition and Dietics, Guys and St Thomas’ NHS Foundation Trust, London/GB

Curative intent fractionated external beam radiotherapy (RT) with or without chemotherapy is used to treat locally advanced non-small cell cancer (NSCLC) and common side effects include anorexia, nausea/pertitus and fatigue, all of which can all impact on nutritional status. Previous
research has shown that up to one third of lung cancer patients treated with RT experience clinically significant weight loss while one third of lung cancer patients present with malnutrition and RT. The negative impact of weight loss and malnutrition on patient and clinical outcomes is well established across all modes of cancer treatment including chemoradiotherapy. There is limited evidence available relating to effective nutritional support strategies to prevent or treat weight loss and malnutrition in lung cancer. There may be a role for enteral feeding where severe oesophageal stenosis occurs in order to support patients through radical radiotherapy and its recovery. The nutrition intervention demonstrated to be most effective in other tumours undergoing radiotherapy treatment is intensive individualised dietary counselling and the presence of dedicated dietetic services to head and neck and oesophageal cancer patients is well established in the UK with dietitians identified as core members of the multi-disciplinary team. This session will provide the clinician with an overview of the impact of nutritional status on patient outcomes and discuss the nutritional interventions that may be of benefit. It will also consider the role of a dedicated lung cancer dietitian and the impact this can have on patients with lung cancer.

Kiss, N., Krishnasamy, M. and Isenring, E. (2016) The role of nutrition intervention in lung cancer patients undergoing chemotherapy and/or radiotherapy: a systematic review. Nutr Cancer, 66: 47-56. 5. Lee, J., Leong L. and Lim, S. (2016) Nutrition and multiple alterations have been reported. The somatic BAP1 mutation is one of the molecular targets that has been identified as a novel target in this disease. The function of BAP1 is mainly regulatory, including its function as a deubiquitinating enzyme (DUB) of H2A. Through its deubiquitination activity and the effects on transcription, BAP1 functions as a tumor suppressor gene. It regulates transcription, cell cycle control, DNA damage repair and cellular differentiation [1-4]. Patients with a BAP1 germline mutation often present with skin disorders including skin tumours and uveal melanomas and are often diagnosed at an early age. BAP1 germline mutation in patients with mesothelioma was first reported in 2011 [5]. In these cases, prognosis seems to be better with a 5-year survival rate of 47%, as compared to 6% for patients who did not have the mutation [6]. Although germline mutations are rare in mesothelioma [7], somatic BAP1 aberrations are more common in mesothelioma tumors. Studies showed that 47-67% of the mesothelioma tumors contain a BAP1 genetic aberration. BAP1 somatic mutations are more frequent in the epithelial subtype than in the sarcomatoid subtype. Besides single point mutations in the BAP1 gene, copy number loss, rearrangements and multiple alterations have been reported. The somatic BAP1 mutation can easily be identified with immunohistochemistry. BAP1 as a drug target in mesothelioma The regulation of histones by BAP1 suggests the potential of BAP1 targeting with histone deacetylase inhibitors to be beneficial. In mesothelioma, the effect of HDAC inhibitors on H2A is not known, but BAP1 knockdown in mesothelioma cell lines increases the sensitivity for HDAC inhibitors leading to cell death, a process known as synthetic lethality. In the VANTAGE 014 study, a phase III trial including 661 patients, the HDAC inhibitor vorinostat did not improve overall survival in an unselected group of patients compared to placebo [8]. Enhancer of zeste homolog 2 (EZH2) is upregulated in mesothelioma and preclinical models have identified a possible role in association between BAP1 loss and EZH2 upregulation. Specifically, EZH2 inhibitors decreased cell proliferation, reduced invasion and reduced clonogenicity in mesothelioma cell lines and tumor bearing mice. Importantly, BAP1 mutant mice were more responsive to the EZH2 treatment compared to wild type mice [9]. In phase I studies with EZH2 inhibitors showed promising results [9]. Currently a study in mesothelioma patients with the EZH2 inhibitor tazemetostat is ongoing (NCT02860288). Another interaction partner of BAP1 is host cell factor 1 (HCF1). This protein has a role in cell cycle progression by activating transcription of promoters bound by the EZF (transcription family). BAP1 ubiquitinates HCF1 and recently multiple groups showed that EZF ubiquitination results in the promotion of EZF, implying BAP1 activation. Decreased activation of EZF causes problems in cell cycle progression and results in the inhibition of cell growth. Although there are no drugs yet available to inhibit EZF, these interaction partners may provide options for new therapeutic interventions. Synthetic lethality. Due to its regulatory function in DNA repair damage, it is expected that in BAP1 mutated cases the homologous recombination (HR) DNA repair system is impaired. The use of PARP1 inhibitors could therefore be promising as is shown in ovarian and mammary carcinoma. Preclinical studies of niraparib and olaparib in mesothelioma cell lines proved to inhibit the cell growth, but this effect was independent of the BAP1 mutation status [10]. Therefore it is expected that other pathways are more important in this approach. Conclusions. For the treatment of tumors with BAP1 protein loss, it is important to identify therapeutic agents that reverse the phenotypic effects. Multiple interaction partners and proteins under influence of BAP1 are reported and (pre)clinical data of new inhibitors targeting these partners is promising. Further research on the impact of these interactions in preclinical and clinical settings is required to develop a comprehensive treatment plan. Due to the many interaction partners and different functions of BAP1 the future we will probably end up with a combination of agents to reverse the phenotypic effect of BAP1 protein loss. Novel immunotherapies for pleural malignant mesothelioma (MPM) include Antibody-drug conjugates (ADCs) and Chimeric antigen receptor (CAR) T cells, both of which are in early-phase clinical trials with promising results. CAR T cells are patient T cells that are transduced with genetically engineered synthetic receptors to target a cancer cell surface antigen. The remarkable clinical response rates achieved by adoptive transfer of T cells that target CD19 in patients with B-cell leukemia and lymphoma have led to a growing number of clinical trials exploring CAR T-cell therapy for solid tumors including in MPM. Herein, I will review the evolution of ADCs and adoptive T-cell therapy; highlight advances in CAR T-cell therapy for MPM; and summarize the antigen targets being investigated in clinical trials. I will further discuss the barriers to successfully translating ADCs and CAR T-cell therapy for solid tumors and present strategies that have been investigated to overcome these hurdles.

Small cell lung cancer (SCLC) is a highly aggressive neuroendocrine lung tumor that has historically been treated as a single disease. Loss of the tumor suppressors RB1 and TP53, and amplifications of MYC family members, are frequent events in SCLC. We show that MYC expression cooperates with RB1 and TP53 loss in the mouse lung to promote aggressive, highly metastatic tumors, that are initially sensitive to chemotherapy followed by relapse, similar to human SCLC. Importantly, MYC drives a neuroendocrine–low “variant” subset of SCLC with low ASCL1 and high NEUROD1 expression corresponding to transcriptional profiles of human SCLC. Targeted drug screening reveals that SCLC with high MYC expression is vulnerable to Aurora kinase inhibition, which, combined with chemotherapy, strongly suppresses tumor progression and increases survival (Mollaoglu et al., Cancer Cell, 2017; Cardnell et al., Oncotarget, 2017). These findings were recently recapitulated in clinical trials where patients with relapsed SCLC exhibited significantly longer survival when treated with an Aurora kinase inhibitor specifically if tumors were high for MYC. More recently, our work and others suggests that MYC-high SCLC is also vulnerable to CHK1 inhibition. These data identify molecular features for patient stratification of SCLC and uncover a potential targeted treatment approach for MYC-driven SCLC. More recently, we have performed unbiased metabolic profiling of MYC-driven SCLC cell lines and murine tumors compared to MYCL and MYCN-driven samples. We find that MYC-driven SCLC is metabolically distinct in vitro and in vivo. Our findings reveal that guanine nucleotides and a potential targeted treatment approach for MYC-driven SCLC. More recently, we have performed unbiased metabolic profiling of MYC-driven SCLC cell lines and murine tumors compared to MYCL and MYCN-driven samples. We find that MYC-driven SCLC is metabolically distinct in vitro and in vivo. Our findings reveal that guanine nucleotides and biosynthetic enzyme Inosine Monophosphate Dehydrogenase-1 and -2 (IMPDH1 and IMPDH2) are elevated in MYC-high/ASCL1-low tumors in vitro and in vivo. Heterogeneity of neuroendocrine (NE) differentiation in small cell lung cancer (SCLC) determines very different molecular and phenotypic hallmarks. The work we will discuss includes validation of a 50 gene expression quantitative scoring system for NE lung tumors, consisting of both positive and negative scores [1]. Almost all carcinoid tumors have positive scores, SCLC and large cell neuroendocrine tumors have positive scores only in some locations. Methodology: We utilized the NE gene expression score to demonstrate intertumor heterogeneity of gene expression patterns and their relationship to signaling pathways and to immune and inflammatory response. We used cluster analysis to divide the SCLC samples into high and low NE subtypes. We studied two public SCLC tumor data sets (n = 140) as well as 70 cell lines established by us and a pair of high/low sublines established from a single SCLC cell line. Results: The NE score cluster analysis indicated that ~10% of cell lines and ~20% of SCLC tumors have the low NE subtype. The low NE subtype samples had RB1 mutations or low or absent RB1 expression, confirming their SCLC origin. Differences between the high and low subtypes were divided into those common to tumors and cell lines and those largely or entirely limited to tumors. Differences common to tumors and cell lines include a high mutational load in both the high and low NE subtypes. Similar differences were present in the low NE subtype involving the over 200 genes regulating the Cancer-Immunity Cycle, including the major cytokine families, toll like receptors, the inflammasome pathway, the JAK/STAT pathway, HLA antigens, CD47 antigen, perforin and granzymes. These changes were accompanied by highly significant increases in the relative number of multiple types of infiltrating immune and inflammatory cells. In addition, the low NE subtype had increased expression of PD-L1 and the interferon gamma signature, suggesting enhanced responses to immunotherapy. Conclusions: SCLC tumors and cell lines can be divided into NE high and low NE subtypes based largely on the expression of a panel of NE markers. This and other comparisons show that SCLC tumors are heterogeneous. MS32.05 TARGETING DNA DAMAGE AND REPAIR

L. Byers

Thoracic/Head & Neck Medical Oncology, UT MD Anderson Cancer Center, Houston/ TX/US

Small cell lung cancer (SCLC) remains one of the most recalcitrant cancer types, with a 5 year survival less than 10% across all stages. At the genomic level, SCLC is characterized by loss of p53 and RB1 function and frequent amplification or overexpression of MYC family members. These molecular hallmarks of SCLC contribute to high rates of replication stress and genomic instability which, in turn, may make SCLC tumors more susceptible to drugs targeting DNA damage response (DDR). Previously, we and others had found that PARP1, CHK1, and other proteins regulating DNA repair are highly expressed in SCLC, as compared to other lung cancers. Based on this finding, several DDR inhibitors have now been tested in SCLC models as single agents or in combination with other DDR inhibitors or DNA-damaging agents. Preliminary data in multiple small cell lung cancer preclinical models have shown promising activity in SCLC cell lines and mouse models, as well as some oncogenes and pathways, predicting them to respond very differently to conventional and targeted therapies. In addition, very different infiltrating cellular and gene expression patterns of immune responses were present in the low NE tumors, involving multiple aspects of innate and Adaptive immunity, and predicting that the low NE subtype tumors are more likely to respond to immunotherapy. In addition, several paradoxes of combined immunotherapy and DNA repair inhibitors have been suggested from our findings. I thank my collaborators for their invaluable contributions: Ling Cai, Tao Wang, Guanghua Xiao, Luc Girard and John Minna. 1. Zhang W, Girard L, Zhang YA, et al. Small cell lung cancer tumors and preclinical models display heterogeneity of neuroendocrine phenotypes. Transl Lung Cancer Res 2018;7(1):32-49.

**Keywords:** Small cell lung cancer, Heterogeneity, Neuroendocrine differentiation
significantly higher PFS and overall survival (OS) than biomarker-negative patients (interaction p-value 0.009). For example, SLFN11-positive patients treated with TMZ/veliparib had a median OS of 12.5 months as compared to 7.5 months in SLFN11-negative patients (p=0.014). In contrast, there was no difference in PFS or OS based on biomarker status in patients in the placebo (TMZ only) arm, supporting that the biomarker was in fact predictive of benefit from PARP inhibitor treatment. An ongoing study combining the PARP inhibitor olaparib with TMZ is further exploring this combination in relapsed SCLC patients (NCT02446704). In addition, two trials have now been conducted investigating veliparib in combination with frontline platinum-etoposide chemotherapy (NCT01642251 and NCT02289690). SLFN11 biomarker analysis from the first of these studies will be presented at this meeting. Other DDR inhibitors in clinical investigation include the Chk1 inhibitor prexasertib and the Wee1 inhibitor AZD1775 (alone or in combination with other DDR inhibitor or chemotherapy). DDR targeting may also potentiate the effect of immunotherapy. In other cancer types, recent reports describe enhanced activity of immune checkpoint inhibitors in cancers with inherent DDR deficiencies such as BRCA1 mutations. Clinical trials in multiple tumor types including lung cancer are underway investigating whether treatment with a DDR inhibitor could enhance response to immunotherapy. Emerging preclinical data suggests activity of DDR-immune targeting in SCLC. REFERENCES 1. George J, Lim JS, Jang SJ, et al. Comprehensive genomic profiles of small cell lung cancer. MS32 SCLC - FROM BENCHSIDE TO BEDSIDE - CLINICAL SCIENCE SESSION

MS32.06 EPENDICENETIC TARGETS
J. Poirier
Memorial Sloan Kettering Cancer Center, New York/NY/US

Lung cancer remains the most common cause of death in men and women, responsible for more deaths than colon, breast and prostate cancer combined. Lung adenocarcinoma (a type of NSCLC) and small cell lung cancer (SCLC) comprise two of the major subgroups within lung cancer and collectively contribute to a high degree of cancer mortality year after year. Despite recent success in developing and implementing targeted therapeutics for several prominent driver oncogenes in NSCLC, SCLC remains a critical unmet medical need in the cancer field, in part due to a relative paucity of actionable mutations and well-defined biomarker-directed therapies. New therapeutic strategies are desperately needed to improve clinical outcomes for patients with SCLC. Despite lacking known driver oncogenes, such solid tumors have been shown to have frequent inactivating mutations in epigenetic remodeling enzymes – the “reader” and “writers” of the epigenome – which collectively play a role in the regulation of transcription, cellular plasticity and the ability of cancer to avoid or resist therapeutic interventions. Known to be central to the role in regulation of gene expression are the SWI/SNF family of chromatin remodeling enzymes (also known as “BAF”); the Polycomb Repressive Complexes (PRC1/2), the p300-CBP transcriptional coactivator family, BRD4, LSD1-NuRD, MLL and others. These transcriptional rheostats have a central role in dynamic process of opening and closing chromatin to the access of transcription and elongation factors. It is increasingly appreciated that SCLC is particularly sensitive to perturbations in transcription. Small molecules now exist to target the catalytic function of many of these epigenetic targets and are proceeding to clinical testing for patients with molecularly defined cancers, offering a therapeutic opportunity in an otherwise barren space.

JCSE01.04 RISK MODELING FOR THE EARLY DETECTION OF TIN MINER LUNG CANCER IN CHINA

Y. Qiao
Department of Cancer Epidemiology, Cancer Institute/hospital, Chinese Academy of Medical Sciences, Beijing/ CN

Result of National Lung Cancer Screening Program has demonstrated a 20% reduction in lung cancer mortality with low-dose computed tomography among current or former smokers with a smoking history of 30 or more pack-years1. Selecting high risk population for LDCT screening is a key issue for lung cancer screening. Many studies have suggested that lung cancer risk model which incorporating these factors can be more accurate to identify high risk individuals suitable for LDCT screening than the NLST criteria2. Thus, more precise evaluation of association between these factors are warranted to developing lung cancer risk models. In this study, we developed and internal validated a lung cancer risk model with data of a occupational screening cohort in Yunnan, China with the aim to exploring potential improvement of yield of lung cancer screening with Chest X-ray and Sputum cytology due to the improved risk stratification. This was a prospective occupational cohort study among tin miners from Yunnan (Tin Corporation) which initiated in 19923. Participants were tin miners aged 40 or over and had at least 10 years of underground work or smoking history. Participants also had received annual lung screening from 1992 to 1999, and were annually followed up through December 31, 2007. In addition to age, educational level, smoking, occupational radon and arsenic exposure, prior chronic bronchitis were risk factors of lung cancer risk in this cohort4-6. During the study period, a total of 443 lung cancer deaths were confirmed among 9295 participants. To reduce the potential information bias, 69 lung cancer death with 1 year since enrollment were not included into the analysis. To stratified those with higher lung cancer risk, we increased the age criteria from 40 to 50 years old(model 0), then further developed three risk prediction models with multivariate logistic regression respectively, and the predicted probability of lung cancer death for each participants were also calculated based on logistic regression model respectively(model1). The goodness of fit and calibration and discrimination ability of the model performance were evaluated with -2log likelihood, area under the receiver operator characteristic curve (AUC) (C-index) and Hosmer-Lemeshow test. We found that the model incorporated age, gender, smoking, educational prior chronic bronchitis, occupational radon and arsenic had the best discrimination performance with area under ROC as of 0.821(95% CI: 0.805-0.836)(figure1a). The calibration performance of this model was also good(Hosmer-Lemeshow type x2=5.413,p=0.773)(figure1b). The areas under ROC curve of model 2 and model 3 were significantly better than those of model1 and model 0(all p<0.001), however, no difference was found between model 2 and model 3. Besides, Bootstrap techniques were used for internal validation of the model 3 to Correct for this overfit or optimism, and discrimination C-statistic from C-statistics was the same to the original data. We stratified the participants into 4 quintiles for the predicted risk of death from lung cancer. The cumulative lung cancer death rate from quintile 1 with lowest risk to quintile 4 having the highest risk increased from 11.51, 47.66, 625.41 to 1732.37 per 10^3 person-years, while only 2.5% of all lung cancer deaths were in quintile 1 and 2. Similarly, in 210 screen-detected lung cancer deaths, the proportion in quintile 1 and 2 was only 2.4%. In conclusion, we have developed and internal validated a lung cancer risk model based on personal and occupation covariates in this occupational cohort. [1] Aberle DR, Adams AM, Berg CD, et al. Keywords: lung cancer, risk model, Tin Miners.
Small cell lung cancer (SCLC) accounts for 15% of lung cancer, characterized by early dissemination and rapid development of chemoresistant disease after platinum response (60-80%). Less than 2% of extensive disease SCLC (ED-SCLC) patients survive 5 years. The bi-allelic loss or inactivation of TP53 and RB1 is common in SCLC, the poly(ADP-ribose) polymerase-1 (PARP-1), a critical DNA damage repair enzyme, is highly expressed in SCLC, and SCLC is sensitive to platinum based chemotherpay, suggesting that the defect in DNA damage repair pathways plays an important role in SCLC. ZL2306/ Niraparib is a highly selective PARP-1/2 inhibitor which was exclusively licensed for development in China by Zai laboratory from TESARO. In SCLC PDX model, niraparib demonstrated anti-tumor activities as monotherapy. In addition, niraparib demonstrated promising tumor growth inhibition in maintenance post platinum treatment in platinum sensitive SCLC PDX models. Clinically, in phase III NOVA study, niraparib demonstrated clear clinical benefit as maintenance treatment by significantly extending progression free survival in all platinum-sensitive recurrent ovarian cancer patients regardless gBRCA or HRD status which led to the approval by FDA and EMA in ovarian cancer. It is suggested that niraparib maintenance therapy could provide potential clinical benefit in platinum responsive SCLC. ZL2306-005 is a randomized double-blind multi-center phase 3 study to evaluate the efficacy and safety of niraparib versus placebo as maintenance therapy in ED-SCLC patients who have had responses to platinum based chemotherapy. Approximately 590 Chinese patients with histologically or cytologically confirmed ED-SCLC who have achieved either complete response or partial response to their platinum based chemotherapy to their newly diagnosed disease will be randomized (2:1) to 2 groups, receiving either ZL-2306 or placebo in ZL-2306-005 study. Patients need to complete 4 cycles of etoposide + platinum based chemotherapy to their newly diagnosed disease will be stratified by gender, LDH level and age. All patients will be randomized (2:1) to ZL-2306 or placebo. Patients will be stratified by gender, age, LDH level and histology of prophyllactic cranial irradiation. ZL-2306 will be started with 300mg PO QD for patients with a baseline body weight >77 kg and a baseline platelet count ≥150,000/μL, or 200 mg PO QD for patients with a baseline body weight ≤77 kg or a baseline platelet count <150,000/μL based on RADAR analysis in NOVA study. Patients will remain on treatment until disease progression or intolerable toxicity. The co-primary endpoints are PFS assessed by independent central radiologic review and OS. The secondary endpoints are PFS assessed by investigator, CFI, QoL, safety and tolerability.

Objective responses/tumor shrinkage were observed in the study: highest ORR and mPFS were observed with ceritinib, although patient numbers differed between arms. All treatments were well tolerated; no new safety signals were observed. This study demonstrated the feasibility of an umbrella trial and importance of precision medicine in the management of advNSCLC with uncommon molecular alterations.
the change of CD56+ lymphocytes was not statistical significant. 3. There were no significant difference between the changes of PD-L1 and tumor shrink rate, interval from the end of NAC to operation, pathological type, gender and smoking status. 1. NAC up-regulates the expression of PD-L1 in lung cancer tissues when the expression thresholds are 5%, 10%, and 20%. 2. NAC up-regulates the expression of CD4+, CD8+, and CD28+ lymphocytes. 3. No correlation exists between the variation of PD-L1 and tumor shrink rate, interval from the end of NAC to operation, pathological type, gender and smoking status.

JCSE01 PERSPECTIVES FOR LUNG CANCER EARLY DETECTION
SUNDAY, SEPTEMBER 23, 2018 - 07:30-11:15

JCSE01.15 MOLECULAR CHARACTERISTICS OF ALK PRIMARY POINT MUTATIONS NON-SMALL-CELL LUNG CANCER IN CHINESE PATIENTS
1Fujian Medical University Union Hospital, Fuzhou/CN, 2Zhejiang Cancer Hospital, Hangzhou/CN, 3Zhejiang Cancer Hospital, Hangzhou/CN, 4Zhejiang Rongjun Hospital, Jiaxing/CN, 5Jining Hospital, Nanjing/CN, 6Department of Respiratory Medicine, Jining Hospital, Nanjing University School of Medicine, Nanjing/CN

Anaplastic lymphoma kinase (ALK) gene rearrangements have been identified in lung cancer at 3-7% frequency, thus representing an important subset of genetic lesions that drive oncogenesis in this disease. While the genetic locus of ALK primary point mutations NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring ALK primary point mutations. A total of 339 patients with non-small-cell lung cancer were recruited and classified between July 2012 and December 2015. The status of ALK primary point mutation and other genes were detected by next generation sequencing. ALK gene primary point mutation rate was 5.55% (29/339) in non-small cell lung cancer, including V163L (3 patients), F921Cfs*16 (2 patients), K1416N (2 patients), A585T (2 patients), P1442Q (1 patient), A348T (1 patient), K1525E (1 patient), S737L (1 patient), P115L (1 patient), Q515E (1 patient), E314D (1 patient), R395H (1 patient), A348T (1 patient), G1474E (1 patient), L550F (1 patient), T1012M (1 patient), D302Y (1 patient), H755Q (1 patient), H331Q (1 patient), G1474E (1 patient) and E119D (1 patient), and median overall survival (OS) for these patients was 20.0 months. Among them, 27 patients with co-occurring mutations had a median OS of 20.0 months, and median OS of the 2 patients without complex mutations was 8.5 months. Statistically significant difference was found between the two groups (P=0.02). Briefly, patients with (n=8) or without (n=21) co-occurring EGFR mutations had a median OS of 24.0 months and 20.0 months respectively (P=0.73); patients with (n=21) or without (n=8) co-occurring TP53 mutations had a median OS of 20.0 months and 17.0 months respectively (P=0.83). EGFR and TP53 gene accompanied may have less correlation with ALK primary point mutation in NSCLC patients. Results of ongoing studies will provide a platform for further research to offer individualized therapy with the purpose of improving outcomes.

JCSE01.16 POSITIVE CORRELATION BETWEEN WHOLE GENOMIC COPY NUMBER VARIANT SCORING AND THE GRADING SYSTEM IN LUNG NON-MUCINOUS INVASIVE ADENOCARCINOMA
Z. Wang1, S. Li2, L. Zhang3, L. He4, D. Cui5, C. Liu1, Y. Gong5, B. Liu5, X. Li5, W. Wu1, D. Cram1, D. Liu1
1Beijing Hospital, Beijing/CN, 2Pathology Department, The First Affiliated Hospital of Zhengzhou University, Zhengzhou/CN, 3Berrygenomics Corporation, Beijing/CN

Grading systems of Lung adenocarcinoma have been proposed by Sica and Kadota in stage I tumors, but the predominant architectural subtype grading system is applicable for resection samples mostly. The correlation between the histological subtypes and grading with whole genomic copy number variation(WGCNV) is unknown, and was investigated in lung non-mucinous invasive adenocarcinoma (LNMA) at this study. The predominant histological subtype from 58 resection specimens of LNMA and 20 para-cancerous lung tissues were collected by laser microdissection from HE staining FrameSlides PEN-Membrane slides. 7 of 58 specimens, two predominant subtypes in one cancerous nodule were collected simultaneously. Whole genome amplification followed by high-throughput sequencing was used to detected WGCNV with the para-cancerous lung tissues as normal reference set and WGCNV was scored by a particular formula.
JCE01.17 WEEKLY NAB-PACLITAXEL PLUS CARBOPLATIN AS NEOADJUVANT THERAPY FOR IIA-N2 LUNG SQUAMOUS CELL CARCINOMA: A PROSPECTIVE PHASE II STUDY

Tianjin Medical University Cancer Institute and Hospital, Tianjin, CN

To evaluate the safety and antitumor activity of weekly nab-paclitaxel combined with carboplatin in patients with advanced stage IIA-N2 NSCLC patients with squamous histology. From April 2015 to August 2017, 36 treatment-naïve, pathologically diagnosed IIA-N2 lung squamous cell carcinoma patients were enrolled and given two cycles of weekly nab-paclitaxel (100mg/m², day1,8,15 of a 21-day cycle) plus Carboplatin (AUC = 5 at day 1, q3w) as neoadjuvant therapy. Then resectability was assessed and surgery was performed for resectable lesions. Post-operative adjuvant chemotherapy regimens is the combination of Nab-paclitaxel (100mg/m², qw x 6) and carboplatin (AUC 5, q3w x 2) for patients with PD, adjuvant chemotherapy regimen will be changed. The primary objective is the safety and efficacy, and the secondary objectives are quality of life and the role of prognostic biomarker SPARC. Of 36 patients, 3 stopped treatment due to patient decision. 33 were finally evaluated and 1 is still on treatment. Significant tumor volume shrinkage was seen in some patients after the neoadjuvant therapy. 66.7% patients achieved partial response (PR), 21.2% patients achieved stable disease (SD). Disease control (PR + SD) rate was 87.9%. Finally, 23 patients underwent surgical resection, the resectability rate was 69.7%. 12.1% occurred disease progression and failed to achieve resection, including 3 with local progress and 1 with pulmonary metastatic nodule: Among 22 PR pts, 4 failed to achieve resection, in which 1 was due to heart function, the other 3 due to personal unwillingness. 2 of 7 with stable disease failed to achieve resection; the pathological improvement in T stage and N stage before and after treatment was 81.8% (18/22) and 50% (11/22) respectively. The major adverse event was neutropenia (grade I and II) and no serious AE was found. Nab-paclitaxel in combination with Carboplatin showed promising ORR rate and resection rate in of IIA-N2 lung squamous cell carcinoma. The regimen could be a new chemo option as the neoadjuvant treatment. PFS and OS data will be reported after follow up completing.
Anlotinib is an effective multi-targeted receptor tyrosin kinase inhibitor (TKI) for refractory advanced Non-Small Cell Lung Cancer (NSCLC) therapy at 3rd line. ALTER-0303 clinical trial has been revealed that Anlotinib significantly prolongs progression free survival (PFS; Anlotinib: 5.37 months vs Placebo: 1.40 months) and overall survival (OS; Anlotinib: 9.63 months vs Placebo: 6.30 months) with the objective response rate (ORR) of 9.18% and the disease control rate (DCR) of 80.95%. Here, we sought to understand the gene mutation determinants for clinical response to Anlotinib via next generation sequencing (NGS) upon cell-free DNA (cfDNA) and circulating tumor DNA (ctDNA) at baseline. Totally 437 advanced NSCLC patients enrolled in ALTER-0303 study, and 294 patients received Anlotinib therapy. Of the 294 patients, 80 patients were analyzed in the present study. Capture-based targeted ultradepth sequencing was performed to obtain germline and somatic mutations in cfDNA and ctDNA. Response analyses upon discovery cohort (n = 62) and validation cohort (n = 80) were performed by use of germline and somatic (G+S) mutation burden, somatic mutation burden, nonsynonymous mutation burden, and unfavorable mutation score (UMS), respectively. Based on the independent biomarkers and their subtype factors, tumor mutation index (TMI) was developed, and then used for response analysis. Our data indicated that the patients harbouring less mutations are better response to Anlotinib therapy (G+S mutation burden, cutoff = 4000, Median PFS: 210 days vs 137 days, p = 0.0056; somatic mutation burden, cutoff = 800, Median PFS: 210 days vs 130 days; p = 0.0052; nonsynonymous mutation burden, cutoff = 50, Median PFS: 209 days vs 130 days; p = 0.0155; UMS, cutoff = 1, Median PFS: 210 days vs 131 days; p = 0.0016). TMI is an effective biomarker for Anlotinib responsive stratification (Median PFS: 210 days vs 126 days; p = 0.0008; AUC = 0.76, 95% CI: 0.62 to 0.89) upon discovery cohort and validation cohort (Median PFS: 210 days vs 127 days; p = 0.0006). Lastly, integrative analysis of TMI and IDH1 mutation suggested a more promising result for Anlotinib responsive stratification upon validation cohort (Median PFS: 244 days vs 87 days; p < 0.0001; AUC = 0.90, 95% CI: 0.82 to 0.97). This study provide a biomarker of TMI to stratify Anlotinib underlying responders, that may improve clinical outcome for Anlotinib therapy on refractory advanced NSCLC patients at 3rd line. Clinical trial information: NCT02388919.
different somatic alterations and clinical parameters. We first analyzed the differences in somatic alterations between AP and RP group in the primary tumors, and identified higher somatic copy number alteration (SCNA) level in DP group compared to GP group, which is significantly (p=0.016) associated with poorer progression-free survival (PFS). More specifically, patients with chromosome 18q loss in the primary tumor showed a trend (p=0.107) towards poorer PFS. PTEN (p=0.002) and GNAS (p=0.002) mutations are enriched in the primary tumors of DP group, and are associated with poorer PFS. Furthermore, pleural metastatic tumors harbor a relatively higher level of mutation burden (p=0.105) and significantly increased SCNA (p=0.035) compared to the primary tumors. NSCLC patients in the attenuated progression group have more stable genomes. High level of genomic instability, GNAS and PTEN mutations, as well as chromosome 18q loss are associated with rapid progression.

JCE01 PERSPECTIVES FOR LUNG CANCER EARLY DETECTION

JCE01.22A TISLELIZUMAB COMBINED WITH CHEMOTHERAPY AS FIRST-LINE TREATMENT IN CHINESE PATIENTS WITH ADVANCED LUNG CANCER
J. Zhao1, Z. Wang2, Z. Ma3, J. Cui4, Y. Shu5, Z. Cheng6, S. Leaw8, J. Li8, F. Xia8, J. Wang2
1Key Laboratory of Carcinogenesis and Translational Research (Ministry of Education/beijing), Department of Thoracic Medical Oncology, Peking University Cancer Hospital and Institute, Beijing/CN, 2Chinese Academy of Medical Sciences Tumor Hospital, Beijing/CN, 3The Affiliated Cancer Hospital of Zhengzhou University/henan Cancer Hospital, Zhengzhou/CN, 4The First Hospital of Jilin University, Changchun/CN, 5Jiangsu People’s Hospital, Nanjing/CN, 6Medical Oncology, Beijing Chest Hospital, capital Medical University, Beijing/CN, 7Jilin Provincial Cancer Hospital, Changchun/CN, 8Beigene (Beijing) Co., Ltd., Beijing/CN

Immune checkpoint inhibitors have shown efficacy in patients with NSCLC as monotherapy and in combination with chemotherapy. Tislelizumab is a humanized IgG4 monoclonal antibody to PD1 specifically engineered to minimize Fcϒ binding on macrophages, possibly minimizing interactions with other immune cells. In a phase 1 study, tislelizumab was generally well tolerated and showed antitumor activity; 200mg IV Q3W was established as the recommended dose.

This multi-arm phase 2 study, consisting of safety run-in and dose-extension phases, assessed tislelizumab in combination with platinum-based chemotherapy (by tumor histology) as a potential first-line treatment for Chinese patients with lung cancer. All patients received tislelizumab at 200mg Q3W in combination with 4–6 cycles of platinum-doublet until disease progression. Nonsquamous (nsq) NSCLC patients received pemetrexed + platinum Q3W for 4 cycles followed by pemetrexed maintenance, while squamous (sq) NSCLC patients received paclitaxel + platinum (A) or gemcitabine + platinum (B) Q3W, and small-cell lung cancer (SCLC) patients received etoposide + platinum Q3W. Tumor response (RECIST v1.1) and safety/tolerability were evaluated.

As of 21 Feb 2018, 48 patients (median age, 62 years [range: 36–75], 71% male, 71% current/former smokers) received tislelizumab treatment (median, 3 cycles [range: 1–7]); 44 patients remain on the study. Across the four cohorts, confirmed and unconfirmed partial responses were observed in 13 and 9 patients, respectively (Table). The most frequent AEs were chemotherapy-related hematologic toxicities. The most commonly reported grade ≥ 3 treatment-related AEs were neutropenia (20.8%) and anemia (12.5%); the most common grade 3 immune-related AEs were pyrexia (6.3%) and rash (6.3%). One sqNSCLC patient experienced a fatal myocarditis/myositis following one cycle of paclitaxel/cisplatin; all other treatment-related AEs were managed/resolved by study-drug interruption (n=15) or discontinuation (n=4) and appropriate treatment.

CT SCREENING SYMPOSIUM

S01.04 LUNG CANCER SCREENING: 1999 TO DATE – WHAT HAVE WE LEARNED?

D. Yankelevitz
Radiology, Icahn School of Medicine at Mount Sinai, New York/NY/US

In 1999, ELCAP published their initial results from baseline screening. It was found that in a cohort of 1000 participants approximately 85% of the cancers could be diagnosed as clinical Stage I, and that compared with chest radiography found many more of the cancers. In a subsequent study the expanded I-ELCAP found that the long term survival as a measure of cure rate approached 80%. The publicity associated with this initial study was quite large and led to the initiation of several other trials including the NLST. The NLST published their results in 2011 and based this, screening was endorsed by insurers in the US and now other countries are similarly following suit. However, despite the positive result of the NLST, reimbursement from insurers, screening has had extremely limited uptake in the US, with only approximately 2% of those eligible (among a restricted population) being screened. Thus, we face a situation where the most common cancer killer has been studied in the most expensive screening trial ever performed which had a positive result, insurers are reimbursing for it, and few people are having it done. With lung cancer screening being touted as a major breakthrough in the war on cancer the question naturally arises as to why it is not being performed more frequently. There have been many reasons put forth as to the poor uptake, ranging from merely a slow start but expected steady increase, lack of awareness by the clinician or potential screenee, obstacles such as the shared decision making requirement, too many potential harms, and lack of significant benefits. This lack of perceived significance of the benefit is perhaps the most important aspect, since without a substantial benefit, even if the harms were minimized, why would anyone get screened and why would a clinician recommend it. It seems that this is clearly influencing the decision not to be screened as many experts and even guideline organizations consider the benefits to not be sufficient enough so as to recommend the screening. Even CMS considered the balance of the risks and benefits so tenuous that they took the unique step of requiring a shared decision making process to be included as necessary for reimbursement so that a person could balance the risks and benefits. It is this aspect of benefit that needs to be considered more carefully when explaining it to a potential screenee. Current decision aids, which are required as part of a shared decision making process, in the US and Canada, are almost exclusively based on the NLST result and attempt to convert its findings into more visual aids. However, in translating those NLST results, it needs to be understood that they were highly dependent on the design parameters of the study itself, namely 3 rounds of screening and 6.5 years of follow-up. When these parameters change so do the benefits. In the US, current recommendations for screening include annual screening over the period of eligibility for the participant (although for Canada it is restricted to 3 years). Under the circumstance of continued annual screening, the reduction in mortality begins to approach the estimated cure rate for the cancer. It is this feature of cure rate that is really what is most important to any person interested in being screened, and it is substantially higher than the mortality reduction seen in a randomized trial where by necessity the mortality dilution is diluted by the time interval after screening has stopped and cancers are still being followed, and also by not including those cancers that are relatively slow growing and cured as a result of early treatment but not counted towards the mortality reduction because the trial has concluded before their counterpart in the control arm has died. Based on these considerations, it is possible to have a cancer that is 100% curable when screen detected, yet the trial may only show a 20% (or even lower) mortality reduction. Thus, there is inherently no incompatibility between the 80% cure rate seen in the I-ELCAP compared with the 20% mortality reduction seen in the NLST. The simple conversion of the 20% mortality reduction found in NLST into a cure rate is as so commonly done when explaining the benefit to a person interested in screening is highly misleading. The cure rate, which is the clinically relevant feature, is higher.

Keywords: mortality reduction, Screening, curability

S01.07 THE U19 PLANS FOR INTEGRATION OF BIOMARKERS INTO FUTURE LUNG CANCER SCREENING

R. Hung1, P. Brennan2, C. Amos3
1Dalla Lana School of Public Health, University of Toronto, Toronto/CA, 2Section of Genetics, International Agency for Research on Cancer, Cedex/FR, 3The Geisel School of Medicine at Dartmouth, Houston/US

We are performing a series of three integrated research projects with the unifying goal of reducing mortality from LC by applying targeted approaches to its prevention or early detection. These projects focus on (1) genetic susceptibility to nicotine dependence and lung cancer, (2) biomarkers for early detection, and (3) application of the results for LC screening. This proposal leverages an extensive collaborative framework and wealth of data from the International Lung Cancer Consortium (ILCICO), the Transdisciplinary Research in Cancer of the Lung (TRICL) Consortium and the Lung Cancer Cohort Consortium (LC3). Epidemiologic data from 60 LC studies have been harmonized within ILCICO including 71,000 cases and more than 1 million control individuals.

Aims and Results Project 1: Genomic Predictors of Smoking and Lung Cancer Risk. This project extends and augments genomic analyses that have been completed on 16,000 LC cases and 50,000 controls and extensively characterizes the contribution that genetic variation makes to LC susceptibility. The four aims are. Aim 1: To precisely characterize the contribution of common genetic variation to LC etiology. We will analyze a GWAS of LC of 47,506 genotyped LC cases and 63,687 controls. Aim 2: To investigate uncommon genetic variants using population-based approaches. Aim 3: To identify genetic effects on smoking behavior. Aim 4: To characterize joint effects of environmental and genetic interactions on LC risk. For this aim we will take advantage of novel statistical approaches (Mendelian Randomization, mediation analysis, gene by environment interactions and pathway-based analyses) developed by our team to provide a comprehensive approach to evaluating the impact of environmental factors according to genetic background. Recent findings from project 1 include identification of 10 new loci influencing lung cancer risk, the identification of 3 novel gene- gene interactions contributing to lung cancer risk, the identification and validation of two rare variants that confer an over four fold higher risk for lung cancer among carriers, and Mendelian randomization studies that show excess BMI and shorter telomere lengths increase lung cancer risk in a histology-dependent fashion. Project 2: Biomarkers of Lung Cancer Risk. Multiple preliminary studies have implicated a wide range of circulating biomarkers in risk prediction for lung cancer. In Project 2, we hypothesize that a comprehensive and extensively validated risk prediction model that incorporates such risk biomarkers has the potential to substantially improve the selection of subjects at a high risk of developing LC and that these individuals are most likely to benefit from CT screening. This project involves three aims. Aim 1: To organize the study, including identifying the study population of 2,300 smoker case and current smoking LC cases that were diagnosed within 5 years of donating their blood sample along with one smoking-matched control per case; and organize sample shipments and database preparation. Aim 2: To replicate a comprehensive panel of promising risk biomarkers and identify those that may be useful for risk prediction by assays pre-diagnostic plasma samples for immune biomarkers, protein biomarkers such as pro-surfactant protein B, micro RNAs, methylation markers, and 34 additional promising biomarkers implicated in lung cancer. We will base this initial analysis on 800 case-control pairs from three LC3 cohorts, and define a panel of replicated risk biomarkers that provide non-redundant information on disease risk. Aim 3: To extensively evaluate all replicated risk biomarkers from Aim 2, identifying a minimum set of validated risk biomarkers, and ultimately evaluate the extent to which they improve risk prediction models. This will involve performing additional assays for 1,500 additional case-control pairs selected from 16 separate LC3 cohorts. The final outcome of this work will be risk prediction models incorporating a distinct set of biomarkers that provide meaningful information on disease risk, and these biomarkers will finally be evaluated in CT screening studies in collaboration with Project 3. This project recently completed analysis of a set of 4 biomarkers that improve the classification accuracy in prediction of lung cancer risk by 14% compared with a model that included only smoking information. Project 3: Translating Molecular and Clinical Data to Population Lung Cancer Risk Assessment will evaluate radiographic models using data from the National Lung Screening Trial (NLST), lung cancer CT screening detection. The four aims are. Aim 1: Early Detection of Lung Cancer – A Pan-Canadian Study (PanCan), and the International Early Lung Cancer Action Program- Toronto (IELCAP-Toronto) along with the UK Lung Screening Trial (ULSST), and the Dutch Better Lung Cancer Care in the Netherlands (NELO). Data from Projects 1-2 will be used to improve the risk prediction model and the nodule probability models. There are 2 specific aims. Aim 1 will establish an integrated risk prediction model...
to identify individuals at high risk of lung cancer, initially analyzing epidemiological and smoking related phenotypes and then integrating targeted biomarker, genomic profile, and lung function data applied to LC CT screening populations. We will study 950 CT-detected LC patients with biosamples from 46,057 screening individuals. **Specific Aim 2 will establish a comprehensive LC probability models for individuals with LDCT-detected non-calcified pulmonary nodules.** In this aim we will (a) first establish the 2D diameter-based probability model in N. American CT programs based on 36,481 participants, and then validate it based on 9,576 participants in the European LDCT programs; (b) establish the volume 3D and radiomics-based probability model in European CT programs based on 9,576 participants in European CT programs, and then validate it in the North American CT screening populations; and (c) assess the added predictive value and clinical usefulness of targeted genomic and molecular profiles in both the 2D diameter- and 3D and radiomics volume-based LC probability models based on risk stratification table analysis and decision curve analysis. Finally we will (d) compare the model performance with the existing classification system such as Lung-RADS.

This project has developed and evaluated a polygenic risk score using data from project 1 which highly significantly improves risk prediction for lung cancer risk, but has a limited impact on prediction accuracy.

Background: To determine if prophylactic cranial irradiation (PCI) improves survival in locally advanced non-small-cell lung cancer (LA-NSCLC), we conducted a prospective randomized phase III trial. Previously we reported that compared to observation, PCI significantly increased disease-free survival and reduced brain metastases. With extended follow-up, we sought to determine whether PCI conferred an overall survival benefit. Method: Patients with stage III NSCLC without disease progression after treatment with surgery and/or radiation therapy (RT) with or without chemotherapy were eligible. Participants were stratified by stage (IIIA v IIIB), histology (h Gosquenous v squamous), and therapy (surgery v none) and were randomly assigned to PCI or observation. PCI was delivered to 30 Gy in 15 fractions. The primary end point of the study was overall survival (OS). Secondary end points were disease-free survival (DFS), neurocognitive function (NCF), and quality of life. Kaplan-Meier and log-rank analyses were used for OS and DFS. The incidence of brain metastasis (BM) was evaluated with the logistic regression model. Result: Among 356 patients entered to this study, 340 are eligible for analysis. The median follow-up time was 2.1 years for all patients, and 9.2 years for living patients. The survival estimates and hazard ratio indicate that there appears to be no improvement in survival with the use of PCI (p=0.12, HR=1.23, 95% CI: 0.95-1.59). Of note, with the current data there is only 45% power to detect the hypothesized difference HR=1.25 at 1-sided significance level of 0.025. The DFS estimates are better in the PCI arm (p=0.03, HR=1.32, 95% CI: 1.03-1.69). Patients in the observation arm were 3.3 times more likely to develop BM than those in the PCI arm (p=0.004). On multivariate analysis PCI was significantly associated with decreased BM and improved DFS, but not OS. However, among the 225 non-surgical patients, use of PCI was associated with higher OS (p=0.026, HR=1.42, 95% CI: 1.04-1.94) and DFS (p=0.014), and lower BM (p=0.003). NCF was previously published (Sun, JCO 2011 and Gondi, UROBP 2013), however, with longer follow-up, there is sufficient data for further analysis. Conclusion: In this 10-year updated analysis, use of PCI continued to significantly improve DFS and reduce brain metastases. However, the early accrual closure failed to provide adequate power to detect the hypothesized difference in OS. The survival rates are not significantly different between PCI and observation. Subgroup analyses based on stratification factors suggest that PCI may improve survival among non-surgical patients. Background: Recently, incidental dose to the heart was found to be predictive for overall survival in lung cancer patients receiving radiotherapy [McWilliam et al EJC 2017, Johnson et al Radiother Oncol 2018]. These patients often present with multiple comorbidities that should be incorporated in survival analysis. However, data on heart dose was often missing. We investigated whether calcifications, identified on the radiotherapy planning CT, can be used as a surrogate for cardiac health. In particular, we investigated the interaction between calcifications, dose and survival. Method: Data from 814 unscreened non-small cell lung cancer patients was used, all treated with 55Gy in 20 fractions. Methodology was developed to automatically segment calcifications within the heart, the aortic arch and their surroundings. The 3D planning CT scans, and the associated lung and spinal cord delineations were processed using well-established image processing algorithms, e.g., convex hull, thresholding, morphological operations, connected pixel analysis and flood filling to detect calcifications. Moreover, shape analysis was included to enhance regions that presented tubular or plate-like appearance. The detection algorithm was validated in a small subset of 10 patients, and this group was used to determine the success and error rate of the automatic segmentation. Finally, a Cox proportional hazards multivariate analysis was performed for overall survival of all patients accounting for tumour size, volume, mean dose across all identified calcifications, and interaction between calcification volume and dose. Result: The success rate of the algorithm for identifying calcifications was 81.8%, its error rate was 8.8%. The multivariate survival analysis identified tumour size (continuous, p<0.0001) and the interaction of calcification volume and their mean dose (continuous, p=0.029) as significant. Calcification volume (p=0.57) or mean calcification radiation dose alone (p=0.269) were not found to be significant. Conclusion: Multivariate analysis shows a significant interaction between volume of the identified calcification and their mean radiotherapy dose predicting survival. Further improvements to identify calcifications in the descending thoracic aorta and validation of our methodology are required. Further work linking our results with the established Agatston or Coronary Artery Calcium score is in progress. *EVO-FB share first authorship

Background: The objective response rate (ORR), progression-free survival (PFS) and overall survival (OS) were compared, as well as the safety of shrinking field and simultaneous integrated boost radiotherapy (radiological dosimetry parameters and the incidence of grade 2 or higher radiotherapy-related toxicity). T-test was utilized to compare the differences between the quantitative data of two groups, while chi-square test or Fisher exact test were utilized to compare the differences between the count data of two groups. Kaplan-Meier curve was utilized to show OS, DFS, and the log-rank test analysis was utilized to compare the survival difference between two groups. P value less than 0.05 was considered statistical difference. Result: All the patients in both two groups had completed their treatment according to the study protocol. The shrinking field and simultaneous integrated boost radiotherapy group was significantly greater than the conventional radiotherapy group in ORR (77.8% vs. 52.8%, P=0.026). The median OS and PFS in shrinking field and simultaneous integrated boost radiotherapy group was 22.0 months (95%CI:18.1-25.9) and 12.4 months (95%CI:10.4-14.3), which is significantly longer than 18.1 months (95%CI:12.4-23.8) and 8.2 months (95%CI:5.2-11.2) in the conventional radiotherapy group (P=0.045 and P=0.013). There was no significant difference between the two groups in radiological metrological parameters and organ at risk (OAR). The incidence of grade 2 or higher RILI, radiation-induced esophagitis, radiation-related myocardial damage and myelosuppression between two groups has no statistically significant difference. Conclusion: Shrinking field and simultaneous integrated boost radiotherapy guided by function imaging 18F-FDG PET/CT is a safe and operable technique in practice. It can improve ORR, OS and PFS without increasing the risk of radiotherapy-related toxicity in patients with locally advanced NSCLC.

Background: The combination of chemotherapy and immunotherapy (CT-IO) has a high response rate and longer survival in unselected patients (pts) with metastatic non-small cell lung cancer (NSCLC). There are no data about this combination in the neoadjuvant setting.

Method: A Phase II, single-arm, open-label multicenter study of local-advanced resectable stage IIIA N2-NSCLC adult pts with CT plus IO (nivolumab (N)) followed by adjuvant treatment for 1 year. Neoadjuvant treatment: Three cycles of NV Q2W IV Q3W + paclitaxel 200mg/m2 + carboplatin AUC 6 IV Q3W. After completing neoadjuvant therapy, tumor assessment is performed in patients prior to surgery. Surgery is performed in the 3rd or 4th week after day 21 of the third cycle of neoadjuvant treatment. Adjuvant treatment: NV Q2W IV Q3W for 4 months and 480mg IV Q4W for 8 months (total one year) after surgical resection. The study aims to recruit 46 pts. The primary endpoint is Progression-Free Survival (PFS) at 24 months. Efficacy is explored using objective pathologic endpoints.

Result: At the time of submission, 46 pts had been included and 20 underwent surgery. CT-IO was well-tolerated and surgery was not delayed in any patient. None of the pts was withdrawn from the study preoperatively due to progression or toxicity. Twenty surgeries had been performed and all tumors were deemed resectable. The overall clinical response rate was 5% complete (CR) and 65% PR. The pathological response evaluated after surgery: 13 cases (65.0%) achieved CR (CR) (95% CI 40.8-84.6%), and 3 (15.0%) had a major pathologic response (MPR), defined as ≥10% viable tumor cells in the resection specimen. Considering both CPR and MPR, the overall response rate was 80.0% (95% CI 56.3-94.3%) and 60% of complete responses were unsuspected

Conclusion: This is the first multicentric study testing in the neoadjuvant setting by associating chemotherapy and immunotherapy activity in locally advanced, potentially resectable NSCLC. An unexpected complete pathologic response rate. The data will be updated at the time of the congress. EuroCART Number: 2016-003732-20

OA01.06 DETERRED: PHASE II TRIAL COMBINING ATEZOLIZUMAB CONCURRENTLY WITH CHEMORADIATION THERAPY IN LOCALLY ADVANCED NSCLC - ALCAM RCT
S. Lin1, X. Lin1, D. Clay7, L. Yao1, I. Mok1, D. Gomez2, J. Kurie6, G. Simon5, G. Blumenschein3, J. Young1, S. Phan1, A. Sandler1, V. Papadimitrakopoulou2, J. Heymach5, A. Tso2
1Radiation Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US, 2Thoracic Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US, 3Genentech, Inc., South San Francisco/CA/US

Background: While consolidation immunotherapy after chemoradiation (CRT) is the current standard of care for locally advanced NSCLC (LA-NSCLC), the effectiveness of immunotherapies may be enhanced when combined concurrently with CRT. We report on the safety and preliminary efficacy of combining PD-L1 blockade using atezolizumab (atezo) and concurrent CRT followed by consolidation full dose carboplatin/ paclitaxel (CP) with atezo and maintenance atezo up to 1 year for LA-NSCLC. Method: This is a single institution phase II study in LA-NSCLC assessing the safety and feasibility of adding atezo to CRT in two parts: I) sequentially (N=10) with CP after completing CRT, or II) concurrently (N=30) with CRT followed by consolidation atezo with CP. Atezo was given at 1200 mg IV Q3 weeks for up to one year from the first dose. Radiation dose at 60-66 Gy in 30-33 fractions was combined concurrently with weekly low dose CP, followed by 2 cycles of full dose CP. Severe adverse events (AEs) ≥ grade 3 are defined within 15 weeks of start of therapy or any immune-related AEs during atezo treatment. Evaluable patients (pts) have received at least one dose of atezo. Result: From February 2016 to April 2018, we accrued 40 evaluable pts. For part 1, any grade 3+ AEs was seen in 6 pts (60%), with most common being pneumonia (2 of 10, 20%). Three grade 3+ AEs (30%) were attributed to atezo, including dyspnea, arthritis, and a grade 5 TAE (fistula). Grade 4 pneumonitis (RP) was seen in 3 pts. Four progressed with disease during atezo maintenance and have died, ranging from 0.93 to 1.86 years. Four pts completed atezo and are in follow up without recurrence. For part 2, 17 of 30 pts had any grade 3+ AEs (57%), with pneumonia being the most common (6 of 30 pts). Three (10%) were attributed to atezo (dyspnea, fatigue and heart failure). RP was seen in 3 pts, with 2 grade 2 and 1 grade 3, which led to atezo discontinuation. So far, 4 pts have progressed and 4 have died, 2 due to disease and 2 due to treatment (myelotoxic effects and grade 2 infection). PR was seen in 12 pts at 24 weeks, with 2 (16%) having ≥1 PR. Atezo maintenance and have died, ranging from 0.93 to 1.86 years. Updated efficacy results will be presented.

Conclusion: Concurrent atezo with CRT followed by consolidation and maintenance atezo appears safe without increasing toxicities compared to CRT alone followed by consolidation and maintenance atezo.

Background: Entrectinib is a central nervous system (CNS)-active, potent, and selective inhibitor of ROS1 and TRKA/B/C, with an IC50 of 0.2 nM and ≤1.7 nM, respectively, and is approximately 30 times more potent against ROS1 than crizotinib, the only agent currently approved for the treatment of patients with ROS1 fusion-positive non-small cell lung cancer (NSCLC). We previously reported interim data that demonstrated an objective response rate (ORR) by blinded independent central review (BICR) of 69% in 32 patients with ROS1 fusion-positive, ROS1 inhibitor-naive NSCLC, including 11 patients with CNS disease at baseline (Ahn MJ WCLC 2017). Entrectinib was well tolerated; the majority of treatment-related adverse events (TRAEs) were Grade ≤2 in severity and were reversible. Method: Patients with locally advanced or metastatic ROS1 fusion-positive NSCLC were enrolled across phase 1 and 2 studies of entrectinib (ALKA, STARTRK-1, STARTRK-2; EudraCT 2012-000148-88; NCT02057810; NCT02568267). Patients were screened for ROS1 gene fusions, predominately using next-generation sequencing. Entrectinib was administered orally at 600 mg once daily in 4-week cycles. Safety was assessed by monitoring adverse events, laboratory tests, and clinical visits. Tumor assessments were performed at the end of cycle 1 and every 8 weeks thereafter. All scans were read locally and by BICR using Response Evaluation Criteria in Solid Tumors v1.1. Result: Data will be available in time for final submission. We expect to present ORR, duration of response, progression-free survival, and safety data. In addition, intracranial data for patients with CNS disease at baseline will be presented. Conclusion: Section not applicable

Keywords: NSCLC, entrectinib, ROS1 gene fusion

OA02 NOVEL THERAPIES IN ROS1, HER2 AND EGFR
MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

OA02.02 SAFETY AND PRELIMINARY CLINICAL ACTIVITY OF ROPOTRECTINIB (TPX-0005), A ROS1/TRK/ALK INHIBITOR, IN ADVANCED ROS1 FUSION-POSITIVE NSCLC

1Thoracic Oncology, Massachusetts General Hospital, Boston/US, 2Department of Internal Medicine, Seoul National University Hospital, Seoul/KR, 3Memorial Sloan Kettering Cancer Center, New York/NY/US, 4Medical Oncology, University of Colorado Anschutz Medical Campus, Aurora/CO, 5Samsung Medical Center, Seoul/KR, 6Children’s Comprehensive Cancer Center, UC Irvine School of Medicine, Irvine/CA/US, 7Medicine, Samsung Medical Center Sungkyunkwan University School of Medicine, Seoul/KR, 8Oncology, TP Therapeutics, Inc., San Diego/US, 9Medical Oncology, Yonsei Cancer Center, Seoul/KR

Background: Ropotrectinib is a potent ROS1/TRK/ALK inhibitor with a ≥90-fold greater ROS1 potency than crizotinib. Preclinical studies demonstrate robust activity against all known ROS1 resistance mutations, including solvent-front mutation G2032R. Method: In this Phase I study (NCT03093116), TKI-naive and TKI-refractory (≥1 TKI) pts with advanced ALK/ROS1/TRK+ solid tumors received ropotrectinib. Asymptomatic brain metastases were allowed. Primary objectives were to determine MTD and RP2D, with safety, pharmacokinetics, and preliminary antitumor efficacy as the secondary objectives. This is a safety analysis of all pts and subgroup efficacy analysis of the ROS1+ NSCLC pts on the study. Result: As of 16-April-2018, 72 pts have been treated at 6 dose levels from 40mg QD to 200mg BID. Most AEs were grade 1-2. Common (>10%) treatment-related AEs included dizziness (49%), dysgeusia (46%), paresthesias (29%), constipation (19%), fatigue (18%), nausea (11%), and anemia (11%). 4 DLTs were observed at ≥240mg/day; 1 grade 3 (Gr3) dyspnea/hypoxia, 2 Gr3 & 1 Gr2 dizziness. 31 of 72 pts had ROS1+ NSCLC by local testing (FISH, n=20; NGS, n=11) with 1 pt determined as ROS1-negative by central NGS. Antitumor activity in ROS1+ NSCLC has been observed at ROS1+ dose levels 40mg QD-160mg BID per investigator assessment, with the best ORR 70% for TKI-naive and 11% for TKI-refractory pts (17% for 1 prior TKI crizotinib, n=12) (Table). Two crizotinib-resistant pts with G2032R achieved durable cPR and cSD, respectively. Ongoing blinded independent review identified 7 evaluable pts with target CNS lesions at baseline; the intracranial best ORR was 43% (3 cPR, 1 PR*). Updated efficacy data and ctDNA biomarker analyses will be presented.

Background: Among patients with ROS1-positive non-small cell lung cancer (NSCLC), most achieve initial benefit from crizotinib treatment but often develop resistance, and further treatment options are limited.
Lorlatinib is a potent, brain-penetrant third-generation ALK/ROS1 TKI with broad mutational coverage. It has shown compelling clinical activity in patients with ALK-positive and ROS1-positive advanced NSCLC, most of whom had CNS metastases and had received prior crizotinib.

**Method:** This ongoing Phase 2 study (NCT01970865) enrolled patients with ROS1-positive advanced NSCLC ± asymptomatic CNS metastases without restriction on the type or number of prior lines of therapy (cohorts EXP-6). Patients received lorlatinib 100 mg QD. Primary endpoints were overall and intracranial response by independent central review. Secondary endpoints included duration of response and progression-free survival. Safety was assessed in all treated patients (cohorts EXP-1–6); molecular profiling is ongoing. **Result:** As of the data cut-off (02 Feb 2018), 47 patients with ROS1+ NSCLC were treated; 25 had baseline CNS metastases; 34 had received prior crizotinib and 13 were crizotinib-naive. Treatment with lorlatinib led to rapid and durable responses in both crizotinib-naive and crizotinib-pre-exposed patients (Table).

The most common treatment-related adverse events (TRAEs) in EXP-6 were hypercholesterolemia (83%) and hypertriglyceridemia (60%). In EXP-6, 36% and 23% of patients had TRAEs leading to dose interruptions and dose reductions, respectively. No permanent treatment discontinuations due to TRAEs or treatment-related deaths occurred.

**Conclusion:** Lorlatinib showed clinically meaningful benefit in patients with ROS1-positive NSCLC, including those who had received prior crizotinib or were crizotinib-naive, as demonstrated by rapid and durable responses. These findings further suggest that the activity of lorlatinib differs depending on prior exposure to crizotinib. The safety profile of lorlatinib in ROS1 patients was comparable to that previously reported in the overall ALK/ROS1 population.

**Keywords:** lorlatinib, NSCLC, ROS1

**OA02.05 CK-101 (RX518), A THIRD GENERATION MUTANT-SELECTIVE INHIBITOR OF EGFR IN NSCLC: RESULTS OF AN ONGOING PHASE II TRIAL**

M. Johnson1, J. Karliki1, H. Burris3, S. Jones1, D. Harris3, K. O’Byrne3, V. Srinapanong1, C. Charoentum1, N. Prasongsook2, W. Jitpeawng3, K. Wirasorn4, J. Wang6, S. Waqa7, J. Olivierio1, L. Gorelik1, X. Qian12

**Background:** CK-101 (also known as RX518) is a novel, oral, third-generation, irreversible epidermal growth factor receptor tyrosine kinase inhibitor (EGFR-TKI) that selectively inhibits EGFR-TKI-sensitizing and resistance mutations, with minimal activity on wild-type EGFR. CK-101 is being studied in an ongoing first-in-human, multicenter, Phase I/II trial in advanced non-small cell lung cancer (NSCLC) patients (pts) with EGFR mutations and other advanced malignancies in the US, Australia, New Zealand and Thailand (NCT02926768). Following dose escalation in which 18 pts received CK-101 in dose groups ranging from 100 mg to 1200 mg/day, a first dose-expansion cohort was enrolled at 400 mg bid.

**Method:** Eligible pts in dose escalation had a confirmed diagnosis of NSCLC or any advanced solid tumor where targeting EGFR was reasonable. Eligible pts in dose-expansion had a confirmed diagnosis of either (1) EGFR mutation-positive advanced or metastatic NSCLC without prior exposure to EGFR-TKI therapy, or (2) T790M-positive, EGFR mutation-positive or metastatic NSCLC with disease progression on previous EGFR-TKI therapy, with no limit on number of prior lines of systemic therapy.

**Result:** As of 25 June 2018, 37 pts were treated in dose escalation and expansion and evaluable for safety; median age 59 years, 51% male, 51% Asian, 84% ECOG PS 1. No DLTs or treatment-related SAEs were reported. Most common treatment-emergent adverse events: nausea (16%), diarrhea (14%), lacrimation increased (14%) and vomiting (11%), all grade 1/2 except one grade 3 diarrhea; no grade 4. In dose-expansion, 19 pts were treated with CK-101 at a dose of 400 mg bid and evaluable for response; 8/19 (42%) pts were treatment-naive, 6/19 (32%) pts had brain metastases; 16/19 (84%) pts remained on treatment. Disease control rate was 100% (19/19), with 16/19 (84%) experiencing target lesion reduction versus baseline and 8 pts achieving a partial response (7 confirmed, 1 pending confirmation). In treatment-naive pts, 6/8 (75%) pts achieved a partial response. In pts with brain metastases, 3/6 (50%) pts achieved a partial response. Higher drug exposures were associated with higher response rate with a confirmed ORR of 55% (6/11) in pts achieving Cmax >400 ng/mL. Median duration of response and progression-free survival were not reached as of the data cutoff. **Conclusion:** CK-101 was well tolerated with a manageable safety profile. Durable anti-tumor activity was observed, particularly in treatment-naive pts. Further study is ongoing to establish the optimal dose to maximize therapeutic effect in a planned Phase 3 study in treatment-naive EGFR-mutant NSCLC pts.

The most common treatment-related adverse events (TRAEs) in EXP-6 were hypercholesterolemia (83%) and hypertriglyceridemia (60%). In EXP-6, 36% and 23% of patients had TRAEs leading to dose interruptions and dose reductions, respectively. No permanent treatment discontinuations due to TRAEs or treatment-related deaths occurred.

**Conclusion:** Lorlatinib showed clinically meaningful benefit in patients with ROS1-positive NSCLC, including those who had received prior crizotinib or were crizotinib-naive, as demonstrated by rapid and durable responses. These findings further suggest that the activity of lorlatinib differs depending on prior exposure to crizotinib. The safety profile of lorlatinib in ROS1 patients was comparable to that previously reported in the overall ALK/ROS1 population.

**Keywords:** lorlatinib, NSCLC, ROS1
**Basic background:**

Insertions/mutations in exon 20 of EGFR or HER2 occur in 3% of all lung adenocarcinomas. These alterations are characterized by point mutations in tyrosine kinase inhibitors (TKIs) with response rates of <12%. We previously showed that exon 20 inserts restrict the size of drug-binding pocket, limiting binding of most available TKIs. However, poziotinib can potentially circumvent these steric changes due to its smaller, flexible structure and is a potent inhibitor of EGFR and HER2 exon 20 mutants (Robichaux et al. Nat Med, 2018). Herein, we report the results of an investigator-initiated study of poziotinib in EGFR and HER2 exon 20 mutant NSCLC (NCT03066206). Method: Patients with ≥18 years metastatic NSCLC harboring mutations/insertions in EGFR or HER2 exon 20 (except EGFR T790M) were eligible. Unlimited prior systemic and targeted therapies were permitted. Poziotinib 16mg PO daily was administered until progression, death, or withdrawal. The primary endpoint was objective response rate (ORR) based on RECIST v1.1. This study was prospectively planned every eight weeks. A Bayesian design was used with a plan to enroll patients in cohorts of 10 and to terminate the study if ORR was ≤20%. Secondary endpoints included DCR, PFS, OS and safety. Result: Of May 3, 2018, the planned EGFR cohort of 50 patients was fully enrolled, and 40 patients were evaluated for response. 65.1% of patients had received at least two prior lines of therapy for metastatic disease. 60% of patients had >grade 3 adverse events; most common were skin-rash (27.5%) and diarrhea (12.5%). 45.0% of patients required dose reduction to 12mg, while 17% required dose reduction to 8mg. One patient stopped treatment due to grade 3 skin rash. ORR at eight weeks was 58% (95%-CI 40.9-73.0) and the DCR was 90% (95%-CI 76.3-97.2). Among 23 patients who achieved partial response, 15 responses were confirmed. Ten of the 15 frequent scan responses were unconfirmed, and three patients are pending confirmation. Responses were observed in 8/13 (62%) patients that were previously treated with TKI. Median PFS was 5.6mo (95%-CI 5.06-NA). Furthermore, 13 patients were enrolled in HER2 cohort. Toxicities were similar to EGFR cohort except one case of grade 5 pneumonitis. assessed to be possibly drug related. Twelve patients were evaluated for response with ORR of 50% (95% CI 21.1-78.9) at eight weeks and DCR of 83%. Conclusion: In heavily pre-treated population with EGFR and HER2 exon 20 mutant NSCLC, poziotinib demonstrated encouraging antitumor activity in both TKI-naive and -refractory patients, and manageable toxicity profile.

in SP142, according to the manufacturer instruction. We calculated Spearman’s correlation coefficient and kappa value among TC proportion and PD-L1 score of each tumour specimen from 36 resected primary lung cancers. Discordant rate among assays was examined. Result: 486 patients (438 nonsmall, 48 small cell carcinoma) completed IHC study analysis from February to December 2017. Compared to 22C3, TC-score of 28-8 (kappa value 0.896) were higher compared to SP263 (0.729) showed good, and SP142 resulted slight (0.159) correlations. SP142-tc+ic score showed fair correlation with 22C3/28-8/SP263 TC-scores (kappa = 0.213/0.241/0.291, respectively). Our results showed substantial reproducibility of TC score among observers across different assays (range of kappa: 0.65-0.857). Inter-observer concordance of the SP142-IC score was also acceptable (kappa 0.591-0.779). Of note, within 22C3 positive group (>1%), 4.5/15.6/67.7/55.0% of 28-8/SP263/SP142-tc+22C3-tc+ (rc) resulted in negative, respectively, indicating a risk of lower category switching for SP263 and SP142 compared to 22C3/28-8. A subset of 22C3-negative cases resulted in SP142-positive and all such discrepancy was due to IC-positivity. There was no significant association between each PD-L1 expression and TMB by WES and OCA. Out of 77 patients treated with ICI, none of them showed PD-L1-positivity. A subset of lung cancer showed IC-only PD-L1-positivity, Inter-observer reproducibility was substantial for IC and moderate for TC. The scoring algorithm affected the concordance trend in a modest way. For harmonization, we should aware of each assay properties. PD-L1 IHC is not a perfect but a feasible biomarker for patients’ selection of ICI therapy.

OA03.03 PHASE 2B OF BLUEPRINT PD-L1 IMMUNOHISTOCHEMISTRY ASSAY COMPARABILITY STUDY

1Aberdeen Royal Infirmary, Aberdeen University Medical School, Aberdeen, Scotland
2University Health Network, Princess Margaret Cancer Centre and University of Toronto, Toronto/ON/CA, 3Aichi Cancer Center, Nagoya, JP, 4U University Medical Center, Amsterdam/NL, 5Royal Brompton, Imperial College, London, London/GB, 6New York University Langone Health, New York/US, 7Taipei Veterans General Hospital, Taipei/TW, 8Weill Cornell Medicine, New York/US, 9Universitätsspitäl Basel, Pathologie, Basel/CH, 10Massachusetts General Hospital and Harvard Medical School, Boston/US, 11Uppsala University, Uppsala/SE, 12Mount Sinai Medical Center, New York/NY/US, 13Bingham and Women's Hospital and Harvard Medical School, Boston, US, 14University of Pittsburgh, Pittsburgh/PA/US, 15Centre Léon Bérard, Lyon/FR, 16University of Milan, and Inter-Hospital Pathology Division, IRCCS Policlinico, Milan/IT, 17Seoul National University Bundang Hospital, Seoul/KR, 18University of Colorado Anschutz Medical Campus, Aurora/US, 19Faculty of Medicine, University of Tsukuba, Tsukuba-Shi/JP, 20MD Anderson Cancer Center, Houston/US, 21Princess Margaret Cancer Centre, Toronto/CA, 22International Association for the Study of Lung Cancer, Aurora/CO/US

Background: PD-L1 immunohistochecmistry (IHC) has been established as companion or complementary diagnostic assays, each developed as predictive biomarker for specific anti PD1/PD-L1 immunotherapies. The Blueprint (BP) phase 1 comparability study demonstrated that three PD-L1 assays (28–8, 22C3, SP263) showed comparable analytical performance for assessment of PD-L1 expression on tumor cells, while the SP-142 PD-L1 assay appeared to stain a lower percentage of tumor cells when compared to the other assays. The first part of BP phase 2 (BP2A) re-affirmed these findings in a larger cohort of ‘real life’ specimen scores by 25 experienced pulmonary pathologists, and also showed that the 73-10 assay developed for Avelumab showed greater sensitivity than all other assays to detect PD-L1 on tumor cells. BP2A also demonstrated generally excellent inter-observer agreement for tumor cell PD-L1 staining using both glass slides and digital images, with slightly lesser agreement for the B cytology samples included in the study cohort. Inter-observer agreement for immune cell scoring on glass or digital slides was poor. Phase 2B of Blueprint will complete comparative study including large tumour resection blocks, small biopsy samples and fine needle aspirate cell blocks prepared from the same tumor.

Method: Triplet samples of large resected tumor block, small biopsy sample and fine needle aspirate cell block (the latter two taken from the same tissue). Each sample was gathered from 36 resected primary lung cancers (15 adenocarcinomas, 15 squamous cell carcinomas). Sections from all ninety blocks were stained with the pharmDx 28-8 and 22C3, the FDA-approved SP142 and SP263, or clinical trial associated 73-10 PD-L1 assays. A subset of PD-L1 IHC slides were scanned and digital images were used to score all cases by the same 25 pathologists involved in BP2A. As before, tumor cells PD-L1 staining were scored as continuous variable and into 7 cut-off-defined categories, as used in various immune checkpoint inhibitor trials. All assays were scored for immune cell PD-L1 staining based on the scoring system developed for the SP-142 assay.

Result: The inter-assay concordance of PD-L1 staining on tumor cells and tumor infiltrating immune cells will again be assessed using the mean scores from all pathologists. Score concordance will also be assessed between the different samples types (large block, small biopsy and cytology FNA) from the same tumors. Given the pre-arranged agreement is expected to be high, and the performance of the various assays is well characterized, the results should provide some insight into the relative performance of small biopsy and cytology tumor aspirate samples replicating in the PD-1L scores assessed on large tumour blocks with large block (in a late-breaking abstract placeholder).

Background: Recurrence of non-small cell lung carcinoma (NSCLC) is associated with genetic and epigenetic intra-tumor heterogeneity (ITH). The interaction between malignant cells, stromal cells, and tumor-associated immune-cells (TAICS), such as T-cell lymphocytes (TCLs) and tumor-associated macrophages (TAMs), is important for progression of NSCLC and the characterization of the immunologic ITH might be relevant to predict recurrence in surgically treated patients at early stages of NSCLC. The aim of this study was to characterize the immunologic ITH of primary NSCLC tumors at early stages using image analysis and multiplex immunofluorescence (mIF) approaches.

Method: Eight cases of stage IA and 8 cases of stage IB surgically resected NSCLC (11 adenocarcinomas, ADCs; and 5 squamous-cell carcinomas, SCCs) with a history of early recurrence were selected for this preliminary analysis: FFPE blocks were obtained and consecutive sections were stained with two panels of mIF for immune profiling, panel 1: pan-cytokterin (AE1/AE3), PD-L1, PD-1, CD3, CD8, and CD68; panel 2: AE1/AE3, CD3, CD8, granocyte-macrophage (G-M) (CD15), and FOXP3. Three non-small (2, intra-tumor regions) and 3 small (1 mm2 each) sections were randomly selected after grading the whole tumor section. A total of 41 intra-tumor regions were scanned by Vectra multispectral-microscope and analyzed using InForm-software. TAICS were quantified in epithelial and stromal compartments from each tumor region. G-Cross AUC (area under the curve) was computed for specified inter-tumor regions, such as TAICS and malignant cells. Median distance between TAICS and malignant cells within each region was calculated. Result: The median density of TCLs and TAMs were 1527 cells/mm2 and 635 cells/mm2, respectively, with significant differences between histologic subtypes. ADCs and SCCs were predominantly concentrated in stromal compartment (median, 2222 cells/mm2) compared with epithelial compartment (median, 332 cells/ mm2). Percentage and density of TCLs and TAMs varied 4 and 8 times, respectively, between cancer types. Non-cancerous regions, inactive cytotoxic T-cells were the most prevalent phenotypes. Higher density of TAMs and antigen-experienced TCLs were observed in stage IB than stage IA. Conclusion: Characterization of immunologic ITH of NSCLC is able by mIF and image analysis with FFPE tissue sample.
variability of TAICs densities between regions from the same tumor and different subpopulations were observed. TAMs and exhausted T-cells were more prominent in stage IB (tumor ≥3cm) suggesting these cells may play an important role in recurrence. Ongoing studies with a larger cohort and comparison with non-recurrent surgically treated patients are warranted. Supported by CPRITRP160668 and UT LungSPORE grants

OA03.05 EXTRACTION OF RADIOMIC VALUES FROM LUNG ADENOCARCINOMA WITH NEAR-PURE HISTOLOGICAL SUBTYPES
M. Lin1, S. Yang2, L. Chen3, H. Wang4, L. Chen2, K. Lor5, Y. Chen6, M. Hsieh4, J. Chen7, Y. Chang3, C. Chen2
1Department of Surgery, National Taiwan University Hospital, Taipei/TW, 2Institute of Biomedical Engineering, College of Medicine and College of Engineering, National Taiwan University, Taipei/TW, 3Department of Pathology, National Taiwan University Hospital, Taipei/TW, 4Department of Medical Imaging, National Taiwan University Hospital, Taipei/TW

Background: Histological subtypes of lung adenocarcinomas classified by the International Association for the Study of Lung Cancer/American Thoracic Society/European Respiratory Society (IASLC/ATS/ERS) system have been investigated using radiomic approaches. However, the results have had limitations since of invasive lung adenocarcinomas may be heterogeneous, with two or more subtypes. To reduce the influence of heterogeneity during radiomic analysis, computed tomography (CT) images of lung adenocarcinomas with near-pure adenocarcinoma subtypes were analyzed to extract representative radiomic features of different subtypes.

Method: We enrolled 95 patients who underwent complete resection for lung adenocarcinoma and a pathological diagnosis of a “near-pure” (≥70%) IASLC/ATS/ERS histological subtype. Conventional histogram/morphological features and complex radiomic features (grey-level-based statistical features and component variance-based features) of thin-cut CT data of tumor regions were analyzed. A prediction model based on leave-one-out cross-validation (LOOCV) and logistic regression (LR) was used to classify all five subtypes and three pathologic grades (lepidic, acinar/papillary, micropapillary/solid) of adenocarcinomas. The validation was performed using 36 near-pure adenocarcinomas in a later cohort.

Result: A total of 31 lepidic, 14 papillary, 32 acinar, 10 micropapillary, and 8 solid adenocarcinomas were analyzed. With 23 conventional and complex radiomic features, for 5 subtypes and 3 pathological grades, the prediction models achieved accuracy rates of 84.2% (80/95) and 91.6% (87/95), respectively, while accuracy was 71.6% and 85.3%, respectively, if only conventional features were used. The accuracy rate for the validation set (n=36) was 83.3% (30/36) and 94.4% (34/36) in 5 subtypes and 3 pathological grades, respectively, using conventional and complex features, while it was 66.7% and 77.8% only using conventional features, respectively.

Conclusion: Lung adenocarcinoma with high purity histological subtypes demonstrates strong stratification of radiomic values, which provide basic information for accurate pathological subtyping and image parcellation of tumor sub-regions.

Keywords: pathological stratification, lung adenocarcinoma, computed tomography

Result: A total of 31 lepidic, 14 papillary, 32 acinar, 10 micropapillary, and 8 solid adenocarcinomas were analyzed. With 23 conventional and complex radiomic features, for 5 subtypes and 3 pathological grades, the prediction models achieved accuracy rates of 84.2% (80/95) and 91.6% (87/95), respectively, while accuracy was 71.6% and 85.3%, respectively, if only conventional features were used. The accuracy rate for the validation set (n=36) was 83.3% (30/36) and 94.4% (34/36) in 5 subtypes and 3 pathological grades, respectively, using conventional and complex features, while it was 66.7% and 77.8% only using conventional features, respectively.

Conclusion: Lung adenocarcinoma with high purity histological subtypes demonstrates strong stratification of radiomic values, which provide basic information for accurate pathological subtyping and image parcellation of tumor sub-regions.

Keywords: pathological stratification, lung adenocarcinoma, computed tomography

OA03 ADVANCES IN LUNG CANCER PATHOLOGY
MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

OA03.07 THREE-DIMENSIONAL IMMUNOFLUORESCENCE ANALYSIS OF DYNAMIC VESSEL CO-OPTION OF SPREAD THROUGH AIR SPACES (STAS) IN LUNG CANCER
Y. Yagi1, R. Aly2, K. Tabata1, N. Rekhtman1, T. Eguchi3, J. Montecalvo1, K. Manova4, P. Adusumilli2, M. Hamed2, W. Travis1
1Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Thoracic Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York/NY/US, 3Thoracic Service, Memorial Sloan Kettering Cancer Center, New York/NY/US, 4Molecular Cytology, Sloan Kettering Institute, New York/NY/US

Background: STAS was identified, by the 2015 WHO classification, as a new method of invasion in lung adenocarcinoma, with poor prognosis. Blood vessel co-option is a mechanism by which spreading intraalveolar tumor cells connect to the surrounding vasculature to survive. The aim of this study was to visualize the dynamic mechanism of blood vessel co-option using a high resolution and high-quality 3D reconstruction, and multiplex immunofluorescence (IF). Method: A 3D reconstruction image of a case of invasive lung adenocarcinoma with extensive STAS was performed on the formalin fixed paraffin-embedded (FFPE) block. 150 serial sections were obtained by the automated sectioning system AS410 (DNS, Ltd, Japan), and stained with H&E (100 slides), and multiplex IF (30 slides) for CD31, type IV collagen, TTF-1 and E-Cadherin to assess the relation between STAS and the surrounding lung parenchyma and vasculature. The IF stained sections were scanned with 0.33um/pixel by Panoramic P250 Flash (3D Histech Ltd, Hungary) Whole Slide Imaging Scanner (WSI). The WSIs were reconstructed into 3D exported to Imaris 8.0 (Bitplane, MA, US) for signal assessment. Result: Serial 3D image analysis identifies the presence of STAS mainly in the form of micropapillary clusters. The multiplex IF staining highlighted the
co-option which was determined by the spread and then attachment of STAS (TTF-1 and E-Cadherin positive) to distant alveolar wall capillaries (CD31 positive) with preservation of the alveolar wall (figure). This relation between STAS and the surrounding lung parenchyma was visualized in all serial sections of the whole FFPE block thickness.

**Conclusion:** The survival of STAS, beyond the tumor edge, in lung adenocarcinoma is a viable mechanism for tumor recurrence. The combination of the high resolution and high-quality 3D reconstruction and multiplex immunofluorescence in our study, supports the concept that dynamic blood vessel co-option is a mechanism for STAS survival.

**Keywords:** Co-option, STAS, 3D immunofluorescence analysis

**Conclusion:** Studies funded by pharmaceutical industry had stronger evidence, tested more innovative therapies, and were more accessible to the readers compared with studies developed with other sources of funding. These findings may alert oncology cooperative groups to the need of more studies with more evidence strength.

**Keywords:** clinical trials, Evidence-Based Medicine, lung cancer

---

**Background:** Evidence-based medicine was developed to guide medical decisions based upon the strongest scientific evidence available in the literature. However, large randomized clinical trials are expensive. In addition, new antineoplastic drugs development is also extremely expensive. Therefore, we hypothesized that the strongest evidence available nowadays comes from studies developed by the pharmaceutical industry. **Method:** We carried out a search on network databases for studies published between 2014 and 2017. We included only experimental studies that assessed the treatment for advanced or metastatic non-small cell lung cancer. All included studies were divided into two groups: studies funded by pharmaceutical industry and studies funded by other sources. The primary end point was to compare the evidence strength of each group. Secondary end points were to compare other aspects, such as the number of patients included by each group of studies and the number of innovative drugs studied by each group of studies. **Result:** We found 1,502 studies and included 299 studies (154 sponsored by pharmaceutical industry and 145 funded by other sources). 52,988 patients were included in all studies (36,455 in studies sponsored by industry and 16,533 in studies with other funding sources; p < 0.001). The studies funded by pharmaceutical industry had the stronger evidence compared with studies with other sources of funding (p = 0.005). Moreover, studies sponsored by pharmaceutical industry studied more innovative therapies (72.4% versus 48.9%; p < 0.001) and had a higher proportion of open access manuscript (60.8% versus 43.9%; p = 0.004). Results are summarized in the table.

associations with cancer screenings and knowledge of the lung cancer screening recommendation. **Result:** Participants’ mean age was 51.7 years (SD 13.6); the group was largely African American (77.3%) and male (67.9%). Despite higher cancer risk behaviors, knowledge of lung cancer screening and general participation rates for cancer screenings were below national benchmarks. Among women, the breast and cervical cancer screening rates were 46.5% and 85.1%. Among men, the prostate cancer screening rate was 34.2%. Among all participants, the colon cancer-screening rate was 44%. Cancer risk behaviors were higher than national rates and lung cancer screening knowledge was low (23.6%). Smoking behavior was associated with age, income, health status, obesity, tobacco use, and physical activity level. **Conclusion:** The associations of screening with modifiable risk factors such as smoking, physical activity and obesity suggests that relevant behavior change interventions are necessary among this high-risk population. Given the barriers to screening of poverty-stricken individuals, such as lack of transportation and access, nurses must not only educate patients on lung cancer screening, they must assist with identifying payment resources and care navigation. Moreover, nurses must be educated on the ambiguity and inconsistency among evidenced-based screening guidelines and be prepared to engage patients in shared decision-making that weighs the recommendations with the patient’s individual cancer risks. To improve cancer survival among disparate populations, sustained community outreach is necessary to increase awareness of screening recommendations, identify high-risk individuals, and navigate them to resources. It is imperative that resources are provided to support relevant behavior change interventions, such as tobacco cessation in this high-risk population.

**OA04.03 THE ROLE OF COMPREHENSIVE GENOMIC PROFILING IN THE COMMUNITY SETTING**

K. Rohan

This abstract is under embargo until September 24 at 10:30 Eastern Time.

**OA04.05 AN EARLY REHABILITATION INTERVENTION FOR ENHANCING OXYGENATION FROM LUNG CANCER SURGERY**

W.L. Hsiao

National Taiwan University Hospital, Taipei/TW

**Background:** The purpose of this study is to test the effects of an early rehabilitation intervention on oxygenation, postoperative complications, and recovery from lung cancer surgery. **Method:** The study uses an experimental design. Ninety patients scheduled for lung cancer surgeries was recruited from thoracic surgery units of a medical center in Taiwan. Patients were randomly assigned to the intervention or the control group. The intervention includes a 5-day postoperative in-hospital rehabilitation from post op day 1. The main components of the rehabilitation were aerobic and strength exercises as well as breathing training by using an incentive spirometry. Peripheral capillary oxygen saturation (SpO2/FiO2) was measured in the morning of the preoperative day and of the 4 consecutive days from postoperative day one to four by using the Nellcor™ OxiMax N-65 Portable Pulse Oximeter. The SpO2/FiO2 (S/F) ratio was then calculated to assess patients’ oxygenation. Data on postoperative pulmonary complications and durations of chest tube drainage were collected from the patients’ charts. **Result:** The patients’ demographics and baseline measures were equivalent between groups. Results of GEE showed a significant group by time interaction effect on S/F ratio. As for the parameter estimates, from postoperative day 1 to day 4, the S/F ratio improvement in the intervention group was 74.49 (Wald X2 = 46.42, p < 0.001) more than in the control group. Result of Chi-square test showed that the number of postoperative lung complications in the intervention group (n = 1) was significantly less (X2 = 8.39, p = 0.004) than it in the control group (n = 10). Result of t-test showed that the duration of chest tube drainage in the intervention group (2.00±1.00 days) was significantly shorter (t = -2.32, p = 0.022) than it in the control group (2.56±1.25 days). **Conclusion:** The study results support the effectiveness of early rehabilitation intervention on enhancing oxygenation, preventing complications, and promoting recovery from lung cancer surgery as indicated by shortened the duration of chest tube drainage. Surgery to remove the cancer is one of the primary treatment options for non-small cell lung cancer. However, lung cancer surgery may result in decreasing lung capacity and expansion; therefore, increasing risk for postoperative pulmonary complications. Pulmonary rehabilitation designed to enhance lung expansion and ventilation may help to reduce postoperative lung complications and promote patients’ recovery from lung cancer surgery.

**Keywords:** pulmonary rehabilitation, lung cancer surgery, oxygenation

**OA04.06 PERCEPTIONS OF NON-PARTICIPATION IN A REHABILITATION INTERVENTION AFTER SURGERY FOR NON-SMALL CELL LUNG CANCER**

M. Schoena1, M. Missel2

1Department of Thoracic Surgery, University Hospital of Copenhagen, Rigshospitalet, Copenhagen/DK. 2Department of Thoracic Surgery, University Hospital of Copenhagen, Copenhagen/DK

**Background:** Patients with non-small lung cancer (NSCLC) are difficult to engage in clinical trials. Few studies have examined in-depth why these patients refuse to participate. In a Danish randomized clinical trial; ‘Postoperative rehabilitation in operable lung cancer patients (PROLUCA)’ only 32% of eligible participants consented to participate in the trial. The purpose of this qualitative study was therefore to explore perceptions, considerations and barriers of non-participation in PROLUCA. **Method:** This study was inspired by Reflective Life Research as developed by Dahlberg et al. as a descriptive and interpretive phenomenological research approach. Participants are patients who declined to participate in PROLUCA (non-participants). They were purposefully sampled and recruited from the group of patients who were found to be eligible for the exercise intervention but who declined to participate. Data were collected though telephone interviews. Openness, curiosity and sensitivity played an important role in carrying out the interviews. Analysis was performed according to Reflective Life Research. **Result:** Fifteen non-participants consented to participate in qualitative interviews. Nine men and six women with a mean age of 68 years (range 48–84) were included. Mean time since surgery was 21 month (range 12-28). Five patients were working and ten were retired, eleven patients lived with a partner. The analysis revealed three essential themes referred to the patients’ experiences of being ‘Between healthy life and good life’. ‘Under the influence of society’ and their experiences of ‘Health and rehabilitation as a personal responsibility’. Perceptions of non-participation in rehabilitation after surgery for lung cancer are moderated between freedom and necessity. Patients experience ambivalence between a wish to participate in rehabilitation and not having the energy to participate. Patients refused to participate due to daily life priorities and lack of motivation which furthermore is related to social and interpersonal relationships. The patients exercise history is also essential in declining participation. Additionally the patients are under influence of norms and health perceptions from the society. **Conclusion:** Patients’ perception of “the good life” was fundamental for accepting or declining participation in a rehabilitation intervention study. Consideration and barriers of non-participation was influenced by norms from the society, motivation, priorities, exercise history, social and interpersonal relationships. This study has contributed with a sensitive awareness of why patients following lung cancer surgery might refuse participating in rehabilitation. This knowledge can be taken into consideration in the planning of future clinical trials with lung cancer patients.

**OA04.07 EARLY INITIATED POSTOPERATIVE REHABILITATION REDUCES FATIGUE IN PATIENTS WITH OPERABLE LUNG CANCER: A RANDOMIZED TRIAL**

M. Pedersen1, M.S. Summerson2, J. Vibe-Petersen3, M. Stærkend Bohibro1, S. Langer4, K. Larsen5, K. Trier2, M. Christensen6, P. Clementsen6, M. Missel2, C. Henriksen7, P. Poulsen2, H. Langberg2, J. Pedersen8

1University Hospitals Centre for Health Research, Department 9701, Rigshospitalet, University of Copenhagen, Copenhagen/DK. 2Copenhagen Centre for Cancer and Health, Copenhagen Municipality, Copenhagen/DK. 3Dept. of Oncology, Rigshospitalet, Copenhagen Ø/DK. 4Dept. of Respiratory Medicine, Bispebjerg University Hospital, Copenhagen Nv/DK. 5Dept. of Thoracic Surgery, University Hospital of Copenhagen, Copenhagen/DK. 6Medicine, Zealand University.
**Background:** Surgical tolerability and perioperative risk of complications are correlated with high age, smoking history, comorbidities, low cardiorespiratory fitness (VO2peak) and low functional capacity, which paradoxically are characteristics describing the average patient with lung cancer. Little is known about the optimal amount and timing of exercise such as prehabilitation in order to improve functional capacity, muscle strength and quality of life (QOL). On this background, we decided to investigate the effect of early vs. late initiated postoperative rehabilitation in patients with operable lung cancer on exercise capacity, functional capacity, muscle strength and QOL.

**Method:** The study was designed as a two-armed randomized controlled trial with randomization to either early initiated postoperative rehabilitation (14 days after surgery (ERG)) or a control arm with late initiated postoperative rehabilitation (14 weeks after surgery (LRG)). The primary endpoint was a change in preoperative oxygen consumption (VO2peak) from baseline to post intervention 26 weeks following lung resection. Fatigue was measured with EORTC QLQ C30 LC13.

**Result:** From April 2013 to June 2016, 582 patients with operable NSCLC were screened for eligibility. With 119 patients randomized in the early rehabilitation group (ERG) (68 females, 51 males; median age 65), and 116 randomized to late rehabilitation group (LRG) (62 females, 54 males; median age 65), the recruitment rate was 1 patient. Additional correlative analyses to identify biomarkers of response, including whole exome sequencing and RNAseq, are in progress.

**Conclusion:** EN + PEMBRO demonstrated anti-tumor activity and acceptable safety in patients with NSCLC who have progressed on prior PD-(L)1 blockade. Ongoing analysis of immune correlates may identify strategies for effective patient selection.

**Keywords:** Entinostat, pembrolizumab, Monocytes

**OA05 CLINICAL TRIALS IN IO**

**MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00**

**OA05.01 EFFICACY & SAFETY OF EN Tinostat (ENT) AND PEMBROLIZUMAB (PEMBRO) IN NSCLC PATIENTS PREVIOUSLY TREATED WITH ANTI-PD-(L)1 THERAPY**

**Background:** Treatment options are limited for lung cancer patients whose disease has progressed on anti-PD-(L)1 therapy. HDAC inhibitors may synergize with PD-L1 inhibition to overcome resistance. We report the interim results of a Phase 2 trial of entinostat (ENT), a class I selective histone deacetylase (HDAC) inhibitor, plus pembrolizumab (PEMBRO) in patients with NSCLC previously treated with anti-PD-(L)1 therapy.

**Method:** ENCORE-603 is an open label study evaluating the combination of ENT + PEMBRO in patients with recurrent or metastatic NSCLC and prior progression on anti-PD-1/PD-L1 therapy. Patients were eligible irrespective of histology or baseline PD-L1 expression. Patients were treated with 4 mg PO QD ENT + PEMBRO 200 mg IV QW. The primary endpoint was ORR as assessed by irRECIST. Tumor biopsies and blood samples for immune correlates were taken prior to and during treatment in a subset of patients. A total of 70 patients will be enrolled.

**Result:** 57 patients with anti-PD-(L)1 resistant/refractory NSCLC, the confirmed objective response rate with ENT + PEMBRO was 11% (6 of 57, 95% CI: 4-21%). Of 49 patients with post-baseline tumor measurements, 47% had at least some reduction in tumor. Anti-PD-(L)1 therapy was the most recent line of therapy in 38 of 57 patients, and the median time from last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest over 14 months. Of the 6 responders, four were PD-L1 negative at study entry. Response was associated with a higher median baseline level of peripheral blood mononuclear cells (PBMC) (CD14+CD16-NKDRhi) with 16.4% of total live PBMCs in responders (n=6) compared to 8.2% in non-responders (n=45). 5 patients (8.8%) experienced Grade 3/4related adverse events (AEs) (2 events each of pneumonitis and colitis, 1 event of hyperthyroidism), in addition, 19 patients (33.3%) experienced other Grade 3/4 related AEs with organ toxicity, anaemia, hypothyroidism, or hyponatremia occurring in more than 1 patient. Additional correlative analyses to identify biomarkers of response, including whole exome sequencing and RNAseq, are in progress.

**Conclusion:** EN + PEMBRO demonstrated anti-tumor activity and acceptable safety in patients with NSCLC who have progressed on prior PD-(L)1 blockade. Ongoing analysis of immune correlates may identify strategies for effective patient selection.

**Keywords:** Entinostat, pembrolizumab, Monocytes

**MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00**

**OA05.02 EPACADOSTAT PLUS PEMBROLIZUMAB IN PATIENTS WITH NON-SMALL CELL LUNG CANCER: PHASE 1/2 RESULTS FROM ECHO-202/KEYNOTE-037**

**Background:** Epacadostat (E) is a potent, highly selective inhibitor of the indoleamine 2,3-dioxygenase 1 (IDO1) enzyme. ECHO-202/KEYNOTE-037 is an open-label, phase 1/2 study of E + pembrolizumab (P) in patients with advanced tumors (NCT02178722). We report updated efficacy and safety data for the phase 1 and 2 non-small cell lung cancer (NSCLC) cohort as of 8 Jan 2018 data cutoff. **Method:** Adult pts with prior platinum-based therapy (tx), no prior immune checkpoint inhibitors, and those intolerant to EGFR-targeted therapy were eligible. Pts could receive E (25, 50, 100, or 300 mg twice daily [BID]) + P (2 mg/kg or 200 mg every 3 weeks [Q3W]) during phase 1; maximum tolerated dose was not achieved. E (100 mg BID) + P (200 mg Q3W) tx doses were selected for phase 2 evaluation. Efficacy was assessed by RECIST 1.1 criteria. Programmed death-ligand 1 (PD-L1) tumor proportion score (TPS) was evaluated using the 22C3 pharmDx assay. IDO1 status was measured by RNASeq. Safety was assessed in pts receiving ≥1 + E + P dose. Result: A total of 70 pts (phase 1, n=12; phase 2, n=58) were included. Grade 3/4 treatment-related adverse events (TRAEs) were reported in 10% (22/208) pts. Additional correlative analyses to identify biomarkers of response, including whole exome sequencing and RNAseq, are in progress.

**Result:** Of 57 patients with anti-PD-(L)1 resistant/refractory NSCLC, the confirmed objective response rate with ENT + PEMBRO was 5 months, with the longest last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest last dose of prior anti-PD-(L)1 to study entry was 67 days. The median duration of response with ENT + PEMBRO was 5 months, with the longest
Background: Adoptive transfer of tumor infiltrating lymphocytes (TIL) can cause durable regression by recognition of neoantigens unique to the patient. NSCLC TIL has synergistic preclinical activity with nivolumab, and we hypothesized it may induce remissions in anti-PD1-refractory patients. We initiated a phase I trial with the primary objective to characterize the safety and preliminary activity of the combination. Method: Metastases from patients with Stage 4 NSCLC were resected, morselized, cultured, and tested for autologous reactivity. Reactive TIL fragments were pooled and cryopreserved. Patients received nivolumab over 8 weeks. Patients with progressive disease (PD) proceeded to lymphodepletion cyclophosphamide/fludarabine (Cy/Flu), TIL, and IL-2. Tumor whole exome sequencing, transcriptomics, and LC-MS/MS peptide sequencing was performed. TCR-Vß rearrangements were analyzed from tumor, TIL, and pre-/post-infusion peripheral lymphocytes. Result: Of 14 patients enrolled to date, 13 had successful ex vivo TIL expansion from resected metastases. TIL had high proliferative capacity, expanding to median 81 billion CD3+ cells infused per patient (range 27–138 billion) and median 27% of fragments were autologously reactive (range 0–67%). Demographics: median age 54 (range 44–74), median TMB 4 mutations/MB (range 0.9–25), median PD-L1 proportion-score 0% (range 0–100%), and 4 had LKB1 allelic inactivation. Predicted neoantigens correlated with variants on proteomic sequencing. Outcomes: 9 patients had confirmed PD on nivolumab, and proceeded to receive Cy/Flu/TIL/IL-2. No unexpected serious adverse reactions (SUSARs) were identified. Of these 9 patients, 7 had reduction in sum of target lesions at Day+28 CT scan (Figure 1). Peripheral lymphocytes expanded at Days 2-7 in the majority of patients. In patients tested to date, TIL clonotypes persisted through Day+100, and CCR7+ CD95 + CD45RA + stem cell-like memory (TSCM) cells were increased at post-infusion timepoints.

Conclusion: Adoptive cell transfer with TIL and nivolumab for NSCLC had acceptable toxicity and preliminary activity in this ongoing trial.

Keywords: Tumor-specific neoantigen testing, Phase I NSCLC trials, Adoptive cell transfer of tumor infiltrating lymphocytes (TIL)
Avelumab showed increasing clinical activity in patients who had platinum-treated NSCLC with higher tumor PD-L1 expression; however, the trial did not meet its primary objective of improving OS vs docetaxel in PD-L1+ tumors (≥1% cutoff). OS findings may have been confounded by subsequent checkpoint inhibitor therapy in the docetaxel arm.

Keywords: Phase 3, avelumab, docetaxel

## OA05.06 CHECKMATE 227: PATIENT-REPORTED OUTCOMES OF FIRST-LINE NIVOLUMAB + IPILIMUMAB IN HIGH TUMOR MUTATIONAL BURDEN ADVANCED NSCLC

OA06.02 VIDEO-ASSISTED THORACOSCOPIC SURGERY VS. THORACOTOMY FOR NON-SMALL CELL LUNG CANCER: ONCOLOGIC OUTCOME OF A RANDOMIZED TRIAL

D. Situ1, H. Long1, Q. Tan2, Q. Luo3, Z. Wang3, G. Jiang3, T. Rong4

1Lung Cancer Research Institute, Sun Yat-Sen University, Guangzhou/ CN, 2Thoracic Surgery, Daping Hospital of the Third Military Medical University, Chongqing/ CN, 3Thoracic Surgery, Shanghai Chest Hospital, Shanghai Jiao tong University, Shanghai/CN, 4Thoracic Surgery, Shenzhen People’s Hospital, Jina University, Shenzhen/CN, 5Thoracic Surgery, Shanghai Pulmonary Hospital, Tongji University, Shanghai/CN, 6Thoracic Surgery, Sun Yat-Sen University Cancer Center, Guangzhou/ CN

Background: Video-assisted thoracoscopic surgery (VATS) has been widely used in the treatment of early-stage non–small cell lung cancer (NSCLC). However, there has not been a robust randomized control trial (RCT) to conclude VATS has similar oncologic efficacy to open surgery. Therefore, a large multicenter RCT in China was designed and initiated in order to verify the role of VATS. Method: A non-inferiority phase 3 RCT was undertaken at five thoracic surgical centers in China. Patients aged 18-75 years who were diagnosed of clinically early-stage NSCLCs were randomized in a 1:1 ratio into VATS and thoracotomy groups. Radical lobectomy plus hilar and mediastinal lymph node dissection was the standard surgical intervention as per protocol. The long-term oncologic outcomes including 3-year locoregional recurrence rate, overall survival (OS) and disease-free survival (DFS) would be analyzed and reported here. This study is registered with the ClinicalTrials.gov, number NCT01102517. Result: A total of 508 patients were recruited in the trial between January 2008 and March 2014. And 433 patients were eligible for final analysis (222 cases in VATS group and 211 cases in thoracotomy group). At 3 years, the locoregional recurrence rates were 4.5% in VATS group and 5.7% in thoracotomy group respectively (P=0.664). Patients who received VATS procedures had a similar DFS rate to those who underwent open surgery (66% versus 69%, P=0.925; Fig 1A). Again, the 3-year OS rates were of no significant difference between VATS and thoracotomy groups (74% versus 73%, P=0.382; Fig 1B).

Conclusion: VATS in the treatment of clinically early-stage NSCLCs was associated with equivalent oncologic efficacy when compared to open surgery.

Keywords: Video-assisted thoracoscopic surgery, non-small cell lung cancer, thoracotomy

OA06.03 SUBLOBAR RESECTION IS EQUIVALENT TO LOBECTOMY FOR SCREEN DETECTED LUNG CANCER

B. Stiles, M. Hussein, M. Rahouma, B. Lee, S. Harrison, J. Port, N. Altorki

Cardiothoracic Surgery, Weill Cornell Medicine, New York/NY/US

Background: Despite the lack of survival data from modern, ongoing randomized clinical trials (CALGB 140503, JCOG 0802), sublobar resection (SLR) is increasingly offered to patients with small, peripheral lung cancers. In particular, SLR may be an attractive surgical strategy for screen detected lung cancers, some of which may be less biologically aggressive than cancers detected by other means. Utilizing prospective data collected from patients undergoing surgery in the National Lung Screening Trial (NLST), we sought to determine whether the extent of resection affected survival for patients with screen detected lung cancer.

Method: The NLST database was queried for patients who underwent surgical resection for confirmed lung cancer. Numerical variables were compared using Mann-Whitney U test. Categorical variables were compared using Chi-square test. Overall survival was estimated using the Kaplan-Meier method.

Keyword: Sublobar resection, Lung cancer, Survival
compared using Chi-squared test. Propensity score matching analysis (lobectomy versus sublobar resection) controlling for age, gender, race, tumor size, and stage was performed (nearest neighbor, 3:1 matching with no replacement, caliper 0.2). Overall survival (OS) and cancer specific survival (CSS) were compared using log rank test in Kaplan Meier curves. **Result:** Among 1,029 patients who underwent resection for lung cancer, we identified 821 patients (80%) who had lobectomy and 166 patients (16%) who had SLR, among whom the majority (n=114, 69%) had wedge resection. Patients who underwent SLR were older (64 vs. 61, p=0.66), more likely to be female (53% vs. 41%, p=0.004), had smaller tumors (2 cm vs. 4.5 cm, p=0.001), and were more likely to be stage I (80% vs. 75%, p=0.001). At five years, for stage I patients undergoing SLR (n=1299) there was no difference in OS (77% vs. 77%, p=0.889) or CSS (83% vs. 83%, p=0.959) compared to patients undergoing lobectomy (n=613). In order to more accurately compare surgical outcomes, we propensity matched 134 patients from each group undergoing SLR and lobectomy. Among these matched groups, there were no differences in age, gender, histology, or stage. Postoperatively, patients undergoing SLR had less total complications (22% vs. 32%, p=0.05) than those undergoing lobectomy (HR 0.59, CI 0.38-0.94). In matched patients at five years, there was no difference in OS (67% vs. 70%, p=0.629) or CSS (74% vs. 74%, p=0.980) for patients undergoing SLR compared to those undergoing lobectomy. **Conclusion:** For patients with screen detected lung cancer, SLR conferred equivalent survival to lobectomy. By decreasing perioperative complications and potentially preserving lung function, SLR may provide distinct advantages in a screen detected lung cancer patient cohort.

**Keywords:** surgery, sublobar resection, screening

## OA06 EARLY STAGE LUNG CANCER: OUTCOMES AND INTERVENTIONS
**MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00**

### OA06.05 DO SBRT PLANNING AND DELIVERY FACTORS INFLUENCE LOCAL CONTROL FOR EARLY STAGE NON-SMALL CELL LUNG CANCER (E-NSCLC)?
G. Videtic, C. Reddy, A. Juloori, B. Manyam, N. Woody, K. Stephens. Radiation Oncology, Cleveland Clinic, Cleveland, OH/US

**Background:** Stereotactic Body Radiation (SBRT) utilizes a variety of techniques to deliver very high-dose radiation to moving targets in the lung. We investigated the impact of dose-delivery factors on local failure (LF) by surveying our 12 year experience with e-NSCLC from our prospective database. **Method:** Curative SBRT was administered to 1,085 patients (pts) between 2005 and 2016 and planned with either pencil beam (PB) or collapsed cone convolution (CCC) dose calculation algorithms (DCA), using open (dynamic arcs) or modulated beams (IMRT or VMAT), immobilized by abdominal compression or automatic breathing control (ABC), and treated with/without available CBCT (aligned to external fiducial) or KV x-rays to bone or if CBCT, PTV margins were not altered based on availability of CBCT). We limited our analysis to standard radiation fractionation regimens, [60 Gy/3, 48 Gy/4, 50 Gy/5, & 30-34 Gy/1] chosen per the treating physician in a risk-adapted approach relative to tumor size and location. The interplay of technical variables with known patient and tumor factors on LF was analyzed using Fine and Gray univariate regression, with significant predictors selected for a forward step-wise multivariable regression model. **Result:** At mean follow-up time of 25.6 months the cumulative incidence of LF at 1, 2, 5 years was 3.0, 8.3, and 9.8% respectively. Overall survival (1, 2, 5 years) was 83, 62, and 51% respectively. Nine patients (0.9%) had grade 3 or 4 toxicities, most commonly pulmonary in nature (Grade 4: atelectasis and respiratory failure [n=1]; Grade 3: pneumonia/pneumonitis [n=2]; bronchopleural fistula [n=1]). In the patients receiving surgery, 2-year outcomes were: overall survival 77%, local control 100%, regional control 53% and distant control 66%. There were 25 (2%) grade 2, 5 (0.5%) grade 3, and 1 (0.1%) grade 4 perioperative mortalities. **Conclusion:** Overall LF and survival outcomes were favorable, compared to historical series of surgery alone, and there was no perioperative mortality. Larger studies are needed to determine the clinical role of this combined treatment approach.

**Keywords:** Early-stage lung cancer, stereotactic radiation, Surgery

## OA06 EARLY STAGE LUNG CANCER: OUTCOMES AND INTERVENTIONS
**MONDAY, SEPTEMBER 24, 2018 - 13:30-15:00**

### OA06.07 PREDICTORS AND CONSEQUENCES OF REFUSING SURGERY FOR CLINICAL STAGE I NSCLC: A NATIONAL CANCER DATABASE ANALYSIS

**Background:** Given perceived morbidity of lung cancer surgery, patients may instead pursue other treatment options, particularly in the current era of shared decision-making. We sought to determine predictors of refusal of surgery for clinical stage I non-small cell lung cancer (NSCLC) patients and to determine associated outcomes. **Method:** The NCDB (2004-2014) was queried for clinical stage I NSCLC patients who underwent or were recommended to undergo surgery. A unique field in the NCDB allows identification of those patients who were recommended to have surgery, but refused. We only included cases in which surgery was refused “by the patient, patient’s family member or guardian”. We excluded patients with multiple primary tumors, unknown treatment modality/sequence, those who did not undergo recommended surgery for unknown reasons, and those initially not recommended to have surgery. Survival was compared using log rank test in Kaplan Meier curves. Logistic regression was performed to identify predictors of refusing surgery. **Result:** We identified 118,0217 patients undergoing surgery and 3,210 (2.6%) who were recommended, but refused surgery. By multivariate analysis older age (HR=1.09, CI=1.08-1.09), non-white race (HR=2.18, CI=1.97-2.42), low income (HR=1.28, CI=1.16-1.41),
**OA07.01 PHASE II STUDY OF PEMBROLIZUMAB FOR OLIGOMETASTATIC NON- SMALL CELL LUNG CANCER (NSCLC) FOLLOWING COMPLETION OF LOCALLY ABLATIVE THERAPY (LAT)**

J. Bauml1, R. Mick1, C. Ciunci2, C. Aggarwal2, C. Davis1, T. Evans2, C. Deshpande1, R. Patel1, E. Alley1, C. Clepney1, F. Mutale1, R. Cohen1, C. Langer1

1Perelman School of Medicine at the University of Pennsylvania, Philadelphia/PA/US, 2Perelman Center for Advanced Medicine, South Pavilion, 10Th Floor, University of Pennsylvania, Philadelphia/PA/US, 3Lankenau Medical Center, Wynnewood/PA/US

**Background:** Patients (pts) with oligometastatic NSCLC may benefit from LAT (e.g., surgery, stereotactic radiation (SRT)). It is unclear if systemic therapy can provide benefit after LAT. We completed a Phase II study evaluating the efficacy of pembrolizumab after LAT, hypothesizing that immunotherapy would be effective in the setting of a minimal disease burden.

**Method:** Eligibility stipulated oligometastatic NSCLC (up to 4 sites) with completion of LAT to all known sites of disease. Within 4-12 weeks of completing LAT, pts began pembrolizumab 200 mg every 21 days for 6 mos, with a provision to continue for up to a year in the absence of progression (PD) or toxicity. Progression-free survival (PFS) and overall survival (OS) were measured from the start of LAT. A sample size of 42 pts would provide 80% power for a test at 5% 1-sided type I error to increase PFS to >10 mos compared to a historical control PFS of 6.6 mos.

**Result:** Since January 2015, 45 pts have been enrolled. Median age is 64 years; 53% male; 89% Caucasian; 89% current and former smokers. Most common metastatic sites are lung (16 pts), brain (18), liver (9), and bone (9). LAT included surgery (30 pts), SRT (30), and chemoradiotherapy (23). Adverse events have been mostly mild.

There were two episodes of Grade 3 pneumonitis, two episodes of Grade 3 colitis, and one episode of Grade 3 adrenal insufficiency. Median follow-up from start of LAT is 20.1 mos. To date, 19 pts have had PD or died. Median PFS was 25 mos. PFS rates (+ SE) at 12, 18 and 24 mos are 72%±7%, 54%±9% and 50%±9%, with 10 Tee of PD/death beyond 24 mos. To date, 10 pts have died. Median OS has not yet been reached. OS rates (+ SE) at 12, 18 and 24 mos are 91%±4%, 82%±7% and 73%±8% with 14 pts alive beyond 24 mos. Median PFS was 16.9 mos for pts with metastatic disease (n=33), not yet reached for pts with synchronous disease (n=12). Median OS has not yet been reached in either group.

**Conclusion:** Pembrolizumab after LAT for oligometastatic NSCLC is feasible and well tolerated. PFS appears quite favorable, preliminarily Final analysis will be performed September 2018. Updated survival estimates and biomarker data will be presented.

**Keywords:** Oligometastatic, pembrolizumab, locally ablative therapy

**OA07.03 ADDITION OF LOCAL THERAPY TO EGFR TKI SHOWED SURVIVAL BENEFIT IN EGFR-MUTANT NSCLC PTS WITH OLIGOMETASTATIC OR OLIGOPROGRESSIVE LIVER METASTASES**

T. Jiang1, C. Zhou1, H. Wang2, Q. Chu3

1Department of Medical Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN, 2Medical, Henan Cancer Hospital, Zhengzhou/China, 3Department of Oncology, Tongji Hospital of Tongji Medical College, Huazhong University of Science and Technology, Wuhan/CN

**Background:** Our previous study demonstrated that EGFR-mutant NSCLC patients (pts) with liver metastases (LM) showed poor response to EGFR-TKIs than those without LM, suggesting that additional treatment is warranted. Recently, several clinical studies indicated that local therapy (e.g. surgery and radiotherapy) could significantly improve progression-free survival (PFS) in NSCLC pts with oligometastatic or oligoprogressive disease. This study aimed to investigate whether addition of local therapy to EGFR-TKIs could provide a better survival benefit than TKIs alone in EGFR-mutant NSCLC Pts with oligometastatic or oligoprogressive LM.

**Method:** Pts with EGFR-mutant NSCLC and LM were randomized to either the control arm (TKI) or the treatment arm (TKI + radiotherapy) and followed until death. Oligometastatic LM was defined as ≤ 5 sites in liver without extrahepatic metastases at initial diagnosis. Oligoprogressive LM was defined as ≤ 5 sites in liver without extrahepatic metastases during TKIs therapy. For oligoprogressive cohort, PFS was calculated from time of initiation of TKI therapy to first RECIST 1.1 defined progression disease (PD) or death. PFS2 was calculated from time of initiation of TKI therapy to off-TKI PD.

**Result:**
Totally, 135 cases with EGFR-mutant NSCLC and LM were eligible (64 with oligometastatic LM and 71 with oligoprogressive LM). In oligometastatic cohort, 20 Pts received EGFR-TKIs (E) and 23 Pts received EGFR-TKIs plus local therapy (E+LT) as first-line treatment. The addition of local therapy showed a significantly longer PFS (12.9 vs. 7.9 m, P = 0.041) and OS (36.8 vs. 21.3 m, P = 0.034) than EGFR-TKIs alone. In oligoprogressive cohort, 24 Pts received continuation of EGFR-TKIs plus local therapy (E+LT) and 25 Pts received switched therapy (ST). Median PFS1 was similar. Median PFS2 (13.9 vs. 9.2 m, P = 0.007) and OS (28.3 vs. 17.1 m, P = 0.011) was significantly longer in E+LT group than in ST group. Multivariate analysis revealed that addition of local therapy was independently associated with prolonged PFS (HR = 0.435, P = 0.028) and OS (HR = 0.434, P = 0.071) in Pts with oligometastatic LM. Distant metastatic sites were the major pattern of failure in EGFR-TKI plus local therapy group while locoregional recurrence including primary lesions and LM was the major reason in TKI alone group. Conclusion: The current study suggested that EGFR-TKIs plus local therapy demonstrated the prolonged survival benefit than EGFR-TKIs alone in EGFR-mutant NSCLC Pts with oligometastatic or oligoprogressive LM. These findings suggest that local therapy should be further explored in large-scale, strictly designed clinical trials as a standard treatment option in this clinical scenario.

OA07.05 LOCAL ABLATIVE THERAPY IMPROVES SURVIVAL IN PATIENTS WITH SYNCHRONOUS OLIGOMETASTATIC NSCLC HARBORING EGFR MUTATION TREATED WITH EGFR-TKIS

Q. Xu1, F. Zhou2, H. Liu3, Y. Xu1, C. Zhou4
1Department of Radiation Oncology, Shanghai Pulmonary Hospital, School of Medicine, Tongji University, Shanghai, Shanghai/CN; 2Department of Medical Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai,CN; 3Department of Radiation Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN; 4Department of Medical Oncology, Shanghai Pulmonary Hospital, Shanghai Pulmonary Hospital, Shanghai/ CN

Background: Non-small-cell lung cancer (NSCLC) is the most common cause of cancer deaths worldwide. Patients with oligometastatic disease can represent an indolent phenotype that could benefit from local ablative therapy(LAT). However, whether first-line continual EGFR-TKIs plus LAT could have potential benefit in EGFR-mutant NSCLC patients with oligometastatic disease remains undetermined. Method: Patients with stage IV EGFR-mutant NSCLC and no more than five metastases at diagnosis in 2 months were enrolled. All patients were treated with first-line EGFR-TKIs. Consolidation LAT included radiotherapy or surgery. Overall survival (OS) and progression-free survival (PFS) were estimated by Kaplan-Meier curves. Result: From October 2010 to May 2016, 145 patients were enrolled, including 51 (35.2%) who received consolidation LAT to all oligometastatic sites (All-LAT group), 55 (37.9%) who received consolidation LAT to either primary tumor or oligometastatic sites (Part-LAT group), and 39 (26.9%) who did not receive any consolidation LAT (Part-LAT group). The median OS in All-LAT, Part-LAT, and None-LAT group were 20.6 months, 15.6 months, and 13.9 months, respectively (p<0.001). The median PFS in All-LAT, Part-LAT, and None-LAT group were 20.6 months, 15.6 months, and 13.9 months, respectively (p<0.001). The difference was significant between All-LAT group and Part-LAT group but was not significant between Part-LAT and None-LAT group. The median OS was significantly improved with consolidation LAT for primary tumor (40.5 versus 31.5 months, P<0.001), brain metastases (38.2 versus 29.2 months, P=0.002), adrenal metastases (37.1 versus 29.2 months, P=0.032). Adverse events (Grade≥3) due to radiotherapy included pneumonitis (7.7%) and esophagitis (16.9%). Conclusion: The current study demonstrated that consolidation LAT to all sites was a feasible option among patients with EGFR-mutant oligometastatic NSCLC during first-line EGFR-TKI treatment, with significantly improved PFS and OS compared with consolidation LAT to partial sites or observation alone.

OA07.06 EFFICACY OF LOCAL CONSOLIDATIVE THERAPY FOR OLIGOMETASTATIC LUNG ADENOCARCINOMA PATIENTS HARBORING EGFR MUTATIONS

F. Hu, J. Xu, B. Zhang, C. Li, W. Nie, P. Gu, P. Hu, H. Wang, Y. Zhang, Y. Shen, S. Wang, B. Han, X. Zhang
Shanghai Chest Hospital, Shanghai/CN

Background: For oligometastatic lung adenocarcinoma patients with sensitive EGFR mutations, the role of local consolidative therapy (LCT) remains debatable. The purpose of this study was to investigate the efficacy of LCT in these patients. Method: Advanced stage patients with oligometastatic lung adenocarcinoma who harboring EGFR mutation were identified at the Shanghai Chest Hospital from 2010 to 2016. Result: A total of 253 patients (149 patients who received LCT plus EGFR-TKIs [combination group] and 104 patients who received EGFR-TKIs [TKI monotherapy group]) were included. The median PFS time in the combination group was 14 months versus 9 months in the TKI monotherapy group (HR=0.57, 95% [CI] 0.44, 0.79, p<0.01, Figure 1 A). The median OS time in the combination group was 33 months versus 20 months in the TKI monotherapy group (HR=0.56, 95% [CI] 0.41, 0.75, p=0.01, Figure 1D). Survival benefit was independent of EGFR mutation type (PFS: 19del, p=0.02, Figure 1B; 21L858R, p<0.01, Figure 1C; OS: 19del, p=0.0189, Figure 1E; 21L858R, p<0.01, Figure 1F) and metastatic sites.

(See next page)
Conclusion: LCT combined with TKI therapy was feasible and significantly improved PFS and OS among oligometastatic lung adenocarcinoma patients with sensitive EGFR mutations, and thus, should be considered as an important medical treatment during clinical management.

3Pulmonology, Maastricht University Medical Centre, Maastricht/NL
4Zuyderland Mc, Heerlen/NL
5Department of Respiratory Diseases, Grow School for Oncology & Developmental Biology, Maastricht University Medical Centre, Maastricht/NL

Background: There is increasing interest in the treatment of synchronous oligometastases of NSCLC. Two randomized studies demonstrated an increased PFS by adding a radical local treatment to systemic therapy in responding patients, but long-term data are lacking. We previously reported a median PFS of 12 months and a median OS of 13.5 months in 39 radically treated patients with synchronous oligometastases in a prospective study (De Ruyscher J Thorac Oncol 2012). As the minimal follow-up is now exceeding 6 years, we here report the long-term PFS and OS. Method: Prospective single-arm phase II trial. The main inclusion criteria were pathologically proven NSCLC stage IV with less than five metastases at primary diagnosis, amendable for radical local treatment (surgery or radiotherapy). No previous response to systemic treatment was required. Result: Forty patients were enrolled, 39 of whom were evaluable (18 men, 21 women); mean age was 62.1 ± 9.2 years (range, 44-81). Twenty-nine (74%) had local stage III; 17 (44%) brain, seven (18%) bone, and four (10%) adrenal gland metastases. Thirty-five (87%) had a single metastatic lesion. Thirty-seven (95%) of the patients received chemotherapy as part of their primary treatment. Median overall survival (OS) was 13.5 months (95% CI 7.6-19.4); 1-, 2-, 3-, 4-, 5, 6-year OS was 56.4%, 23.3%, 12.8 %, 10.3 %, 7.7 %, 5.1 % (2 patients), respectively. Median progression-free survival (PFS) was 12.1 months (95% CI 9.6 - 14.3); 1-, 2-, 3-, 4-, 5, 6-year PFS was 51.3 %, 36.6 %, 25.4 %, 13.6 %, 12.8 %, 10.3 %, 7.7 %, 7.7 %, 2.5 % (1 patient); respectively. Of the 3 patients with a PFS after 5 years, 1 had a squamous cell cancer T2N2 with a single pathologically proven bone metastasis in the sternum, 1 had a NSCLC-NOS T4N0 with a single adrenal metastasis, and 1 a T1N2 adenocarcinoma with a pathologically proven contralateral lung metastasis. The latter patient is still free of disease. Two patients developed a second primary cancer: 1 tongue carcinoma after 70 months and 1 an adenocarcinoma in the contralateral lung after 71 months. Both patients died of their second cancer. Three patients (7.7 %) had a local recurrence, all in the PTV of their primary tumor. Only one patient was treated with a TKI (gefitinib) at progression. Conclusion: After radical treatment of oligometastases, approximately 8 % of the patients achieve a PFS after 5 years. Entering patients in trials combining local therapy with novel systemic agents (e.g. chemo-immunotherapy) remains mandatory.

15Niigata Cancer Center Hospital, Niigata/JP
16National Cancer Center Hospital, Tokyo/JP

Background: Malignant Pleural Mesothelioma (MPM) is a rare and highly aggressive malignancy with poor prognosis and no treatment is approved for patients (pts) progressing after 1st line pemetrexed-platinum doublet. Here, we report latest analysis of MERIT study in previously treated Japanese MPM pts to update the previous report (WCLC 2017, Goto Y, et al). Method: This open-label study enrolled advanced or metastatic MPM pts previously treated with up to two regimens of chemotherapy.
A 21-month follow-up showed that 40 patients had a partial response (PR), 12 had stable disease (SD), and 3 had progressive disease (PD). The median time to progression (TTP) was 12.6 months (95% CI: 9.8–16.6), and the median overall survival (OS) was 24.2 months (95% CI: 18.0–30.3). The 1- and 2-year OS rates were 76.3% (95% CI: 65.9–84.1) and 50.7% (95% CI: 38.5–61.8), respectively. Immune-related adverse events (irAEs) occurred in 17% of patients, with 9% experiencing grade 3–4 irAEs. The most common grade 3–4 irAEs were rash (3%), colitis (1%), and hypothyroidism (1%). No deaths were attributed to irAEs.

Conclusion: Pembrolizumab showed promising antitumor activity in previously-treated MM patients, with a manageable toxicity profile. Further studies are needed to confirm these results and to investigate the role of pembrolizumab in combination with other therapies.

**OA08.06 TUMOUR SUPPRESSOR MICRORNAS MODULATE DRUG RESISTANCE BY TARGETING ANTI-APOPTOTIC PATHWAYS IN MALIGNANT PLEURAL MESOTHELIOMA (MPM)**

M. Williams1, Y.Y. Cheng1, M. Phimmachanh1, P. Winata1, G. Reid2
1Asbestos Diseases Research Institute, Sydney/NSW/AU, 2University of Sydney, Sydney/AU

**Background:** Malignant pleural mesothelioma (MPM) is an aggressive thoracic malignancy with limited treatment options. MPM has a poor prognosis, predominately due to its inherent drug resistance and its limited response to current therapies. Aberrant microRNA expression is a common event in neoplasms with many implicated in chemoresistance, however their role in MPM drug resistance is largely unexplored.

**Method:** To investigate the role of microRNAs in MPM drug resistance, we generated MPM cell lines with acquired drug resistance to cisplatin, gemcitabine and vinorelbine by periodontal treatment with the ICSO of each chemotherapeutic agent. Expression levels of mature microRNAs were compared between parental MPM cell lines and cell lines with acquired drug resistance using RT-qPCR. BCL2 is an anti-apoptotic gene and a known target of miR-15a/16-1 and miR-34a. To determine if microRNAs potentiate drug sensitization via a BCL2-mediated anti-apoptotic pathway, drug sensitivity assays were carried out following reverse-transfection with microRNA mimics and BCL2 siRNAs combined with cisplatin, gemcitabine and vinorelbine treatment. Following microRNA mimic transfection in 6-well plates, levels of apoptosis and necrosis were determined by PI and annexin V staining while Bcl-2 mRNA and protein expression was determined by RT-qPCR and Western blotting respectively.

**Result:** Expression of miR-15a/16-1 and miR-34a was downregulated in MPM cells with acquired resistance to cisplatin, gemcitabine and vinorelbine, compared to the parental counterpart. Transfection with mimics corresponding to miR-15a/16-1 were most effective in improving sensitivity to all chemotherapeutics tested in drug resistant cell lines. In parental cell lines, miR-15a/16-1 mimic induced sensitization was also observed but restoration of miR-34a and miR-34b was also capable of improving response in cisplatin and vinorelbine resistant MPM. Forced miR-15/16 and miR-34a expression also sensitized both parental and resistant cell lines to cisplatin, gemcitabine and vinorelbine via induction of apoptosis; their ability to increase levels of drug-induced apoptosis suggest they may sensitize cells to chemotherapeutics via an anti-apoptotic mechanism involving Bcl-2. miR-15a/16-1 and miR-34a transfection caused Bcl-2 mRNA and protein reduction, confirming their regulation of Bcl-2 in MPM. Furthermore, siRNA induced knockdown of Bcl-2 also induced a modest improvement in drug sensitivity. Conclusion: Restoration of microRNA expression sensitized both drug resistant and parental cell lines to chemotherapeutic agents and increased levels of drug-induced apoptosis. Taken together, this data suggests that miR-15a/16-1 and miR-34a are involved in the acquired and intrinsic drug resistance phenotype of MPM cells in part by modulation of apoptotic mechanisms via targeting Bcl-2.

**OA08.07 IN SILICO DISCOVERY OF UNANNOTATED MIRNAS IN MALIGNANT PLEURAL MESOTHELIOMA REVEALS NOVEL TISSUE-OF-ORIGIN MARKERS**

B. Minatel1, E. Marshall1, C. Anderson1, K. Ng2, K. Enfield1, A. Sage1, Z. Xu1, W. Lam1, V. Martinez2
1Integrative Oncology, British Columbia Cancer Research Centre, Vancouver/BC/CA, 2Dalhousie University, Halifax/CA

**Background:** Malignant pleural mesothelioma (MPM) is an aggressive disease. One of the major clinical challenges associated with MPM is the lack of biomarkers capable of distinguishing primary MPM from cancers that have metastasized to the pleura. The current gold standard consists of a panel of positive and negative protein markers to confirm tissue-of-origin; however, many cases remain indistinguishable from other thoracic cancers. Recent studies have suggested that the human genome encodes more microRNAs (miRNAs) than currently annotated. These undescribed sequences have been shown to display enhanced tissue and lineage specificity. Therefore, we hypothesize that MPM tumors express a specific set of previously unannotated miRNA sequences with tissue-specific expression capable of distinguishing MPM from other thoracic diseases.

**Method:** Novel miRNA candidates were detected from small RNA-sequencing data generated by The Cancer Genome Atlas (TCGA) (n=87 MPM) using the miRDeep2 algorithm, a well-established novel-miRNA prediction algorithm. The possible biological roles of these miRNA candidates were investigated by performing a genome-wide 3’UTR target prediction analysis. Additionally, their tissue-specificity was assessed using expression profiles of 1,093 lung tumors from four independent cohorts of adenocarcinoma (LUAD) and squamous cell carcinoma (LUSC). Finally, we developed a miRNA-based classifier model using the weighted voting class prediction method to distinguish MPM from other thoracic cancers.

**Result:** Our initial analysis revealed 424 miRNA candidates, which were subsequently filtered by RNA structure, abundance of sequencing reads, and genomic location, resulting in 154 previously unannotated miRNA sequences. Interestingly, the novel miRNAs were predicted to target protein-coding genes involved in MPM biology, including the Atrxia Telengiectasia Mutated (ATM) gene, a tumor suppressor gene frequently mutated in MPM. Likewise BRCA1 Associated Protein 1 (BAP1), involved in the DNA damage response pathway, was also a predicted target. Principal component analyses revealed that novel-miRNA expression was able to distinguish MPM from LUAD and LUSC. Furthermore, our miRNA-based classifier model revealed 10 novel miRNAs capable of successfully identifying 86 out of the 87 MPM cases (98.80%) and 100% of LUAD cases (true positive rate = 98.85%, false positive rate = 1.15%). Conclusion: Here, we provide evidence for the potential of 154 previously unannotated miRNA species relevant to MPM. These miRNAs not only significantly expand the miRNA repertoire but also unveil specific roles in MPM biology. Most importantly, the strikingly high sensitivity and specificity of the novel miRNA-based classifier in distinguishing MPM from LUAD illustrates the potential of using these novel miRNAs to supplement current clinical markers to define MPM.

**OA09 PREVENTION AND CESSATION**

**MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45**

**OA09.01 5AS TO 3AS: EVOLUTION OF THE SYSTEMATIC APPROACH TO SMOKELESS LIQUIDATION IN ONTARIO’S REGIONAL CANCER CENTRES**

E. Cameron1, M. Haque1, N. Schwartz2, S. Khan1, R. Truscott1, W. Evans2
1Cancer Care Ontario, Toronto/ON/CA, 2Department of Oncology, McMaster University, Hamilton/ON/CA

**Background:** Smoking is responsible for approximately 30% of all cancer deaths in Canada, and more than 85% of all lung cancer cases. Cancer patients who continue to smoke experience decreased treatment efficacy and safety, increased toxicities, greater risk of cancer recurrence and secondary primaries, poorer quality of life, and decreased survival. Evidence suggests that quitting smoking after diagnosis can significantly reduce these adverse effects. In 2012, Cancer Care Ontario (CCO) introduced a Framework for Smoking Cessation to be implemented across the
province's 14 Regional Cancer Centres (RCCs). In 2017, the Framework was revised from a 5As (Ask, Advise, Assess, Assist, Arrange) to a 3As (Ask, Advise, Act) model. The intervention modified a 3As model based on emerging evidence, feedback from CCO's Smoking Cessation Advisory Committee and Regional Smoking Cessation Champions, as well as learnings from a preliminary program evaluation. The revised Framework recommended an “opt-out” approach to referring smokers to cessation services. Following an environmental scan and site visit with each RCC to assess the current state, site-specific action plans were developed to promote alignment with the revised Framework. Action steps were given priority ratings in the areas of data capture, referrals, and resources. Two phone calls were held with each RCC to monitor progress on action plan implementation. Knowledge translation resources were created to support healthcare providers’ uptake of the 3As model. Result: Smoking cessation interventions are often perceived by healthcare providers as time-consuming; the 3As model made the intervention briefer but no less effective. Over 3,000 knowledge translation resources were distributed to support healthcare providers working directly with cancer patients, including pocket cards and posters with suggested scripts. While the revised Framework officially launched in April 2018, early adopters of the 3As model and opt-out approach have seen improved performance on the Accepted a Referral Indicator (proportion of smokers who accepted a referral to cessation services). In 2017, one RCC’s rate tripled from 10.1% to 30.6% in 6 months, while another improved from 13.2% to 36.9% in the same period. Conclusion: To improve program effectiveness, CCO’s smoking cessation initiative transitioned from a 5As to a 3As model and an opt-out referral process. Frontline staff have indicated a willingness to adopt the simplified approach, and early results show a promising increase in the number of smokers who are connected to smoking cessation services.

Background: The current scientific evidence on the effectiveness of e-cigarettes for smoking cessation is limited, but shows e-cigarettes may be at least as effective as nicotine replacement therapy (NRT), which is a standard treatment for cessation and broadly recommended by health professionals (HPs). E-cigarettes are now more popular for cessation than e-cigarettes for smoking cessation is limited, but shows e-cigarettes may be a less-harmful alternative to smoking. More research is urgently needed to assess whether e-cigarettes are a viable alternative to cigarettes for people with lung disease to help them stop smoking and prevent further lung deterioration.

OA09.05 POTENTIAL REDUCTION IN LUNG CANCER MORTALITY IN THE US FROM 2015-2065: A COMPARATIVE MODELING APPROACH

J. Jeon1, T. Hoflord3, B. Levy1, E. Feuer4, P. Caoli5, J. Tam6, L. Clarke7, J. Clarke8, C.Y. Kong9, R. Meza1

1Epidemiology, University of Michigan, Ann Arbor/MI/US, 2Biostatistics, Yale University, New Haven/CT/US, 3Georgetown University, Washington/DC/US, 4National Institute on Drug Abuse, Bethesda/MD/US, 5Health Law and Policy, University of Michigan, Ann Arbor/MI/US, 6Cornerstone Systems Northwest Inc, Lynden/WA/US, 7Massachusetts General Hospital, Boston/MA/US

Background: Tobacco control efforts implemented since the 1960s in the US have led to considerable reductions in smoking and smoking-related diseases including lung cancer. It is, however, unclear to what extent tobacco use and lung cancer mortality will be further reduced during the next half century due to control efforts that have already been implemented until 2015. To address this question, we developed simulation models that explicitly relate smoking temporal patterns to future lung cancer rates. Method: Four independent lung cancer natural history models were developed using US smoking (1964-2015) and lung cancer mortality (1969-2010) data. Each model projected lung cancer mortality by smoking status (ages 30-84) from 2015 to 2065 under a status quo scenario, in which current smoking patterns are assumed to continue into the future. Sensitivity analyses were conducted comparing optimistic and pessimistic assumptions relative to the status quo. Result: Models validated well to observed lung cancer mortality. Under the status quo scenario, age-adjusted lung cancer mortality is projected to drop 79% from 2015 to 2065. Concomitantly, the annual number of lung cancer deaths is projected to decrease from 135,000 to 50,000 (63% reduction). Despite these decreases, 4.4 millions deaths from lung cancer are projected to occur in the US from 2015-2065. Conclusion: Tobacco control efforts since the 1960s will continue to lead to reductions in lung cancer rates well into the next half century. Nonetheless, additional prevention efforts are required to sustain and expand these gains, and further reduce the lung cancer burden in the US.

OA09.06 MOLECULAR ALTERATIONS AND ESTIMATED INDOOR RADON IN NSCLC PATIENTS FROM THE FRENCH NATIONAL CANCER INSTITUTE REGISTRY: RADON FRANCE STUDY

Nonetheless, additional prevention efforts are required to sustain and expand these gains, and further reduce the lung cancer burden in the US.
Background: Radon is a radioactive gas, considered the leading cause of lung cancer in non-smokers. We assessed the correlation between the radon exposure areas in France and the molecular alterations nationally registered in non-small cell lung cancer (NSCLC) patients. Method: We retrospectively collected all NSCLC tested for EGFR, BRAF, HER2 and KRAS mutations (m) and ALK and ROS1 rearrangements (r) on the 28 French Platform led by INCa (French National Cancer Institute). The prevalence of molecular alterations by region was correlated to the indoor radon risk area based on the official French (Institut de Radioprotection et de Sûreté Nucléaire, IRSN, France). Paris and its region Ile-de-France were not included in this analysis due to its high rate of patients that are native from other regions. Result: 116,424 NSCLC were included. Overall, KRAS was positive in 27.7% (27,314/98,522), EGFR in 11.27% (13,125/116,424), ALK in 3.2% (2,928/91,291), BRAF in 2.3% (2,419/105,919), ROS1 in 1.12% (373/33,222) and HER2 in 0.8% (816/97,749) of all cases. We stratified the French regions in 3 areas based on their exposure to radon: high (Auvegrenne-Rhône-Alpes, Bretagne, Normandie, Pays de la Loire), intermediate (Bourgogne-Franche-Comté, Nouvelle Aquitaine, Occitanie, Provence-Alpes-Cote-d’Azur) and low exposure (Centre Val-de-Loire, Grand Est, Hauts de France). The prevalence of driver alterations (EGFR, BRAF, HER2 and ROS1) were significantly higher in high exposure area. KRAS mutations were significantly higher in low exposure area.

OA10.01 PATIENT PREFERENCES FOR TYROSINE KINASE INHIBITOR TREATMENTS FOR EGFR MUTATION POSITIVE METASTATIC NSCLC
J. Bridges1, M. De La Cruz2, M. Pavlikiv3, E. Flood4, E. Janssen5, N. Dabbagh6, A. Fernandez1
1Department of Biomedical Informatics, the Ohio State University College of Medicine, Columbus/OH/US, 2Icon, Gaithersburg/MD/US, 3Medical Affairs Oncology, Astrazeneca, Gaithersburg/MD/US

Background: EGFR mutation positive (EGFRm) NSCLC respondents to EGFR-tyrosine kinase inhibitors (TKIs). First-, second-, and third-generation EGFR-TKI treatment attributes vary in efficacy, side effects, and dosing regimen. We used two different methods to explore treatment preferences among patients with EGFRm metastatic NSCLC. Method: Patients with EGFRm metastatic NSCLC were recruited in the US to participate in an online survey containing two complimentary preference elicitation methods. First, preferences were assessed through direct elicitation exercises where participants chose between competing treatment profiles. The first exercise compared two profiles with a large difference in progression-free survival (PFS) (6 vs 18 months). The second exercise compared two profiles with a smaller difference (10 vs 18 months). Both exercises compared the same side effect risks (0-1% vs 2-16%). Second, a discrete choice experiment (DCE) was used to assess preferences for variation in treatments in terms of PFS, severity of side effects (mild/moderate/severe), and mode of administration. These attributes and levels were varied based on a D-efficient design. Participants completed 10 DCE choice tasks where they saw pairs of hypothetical treatments with different attribute levels and selected their preferred treatment. A choice model was estimated using conditional logit regression. Result: Between 10/2017 and 03/2018, 90 patients with EGFRm metastatic NSCLC were recruited and completed the survey: 42% female; 79% white; 76% taking first-line or second-line EGFR-TKIs at time of survey. Median time since diagnosis: 2.1 years (inter-quartile range: 1.1–2.7). In the direct elicitation exercise, participants opted for shorter PFS in exchange for more favorable side effects, but were less likely to do so for a large difference in PFS (52% of participants) vs a smaller difference (66%; p<0.001). Participants who chose shorter PFS when difference in PFS was large were more likely to be taking EGFR-TKIs (odds ratio: 21.4; 95% confidence interval: 2.24, 204.88). No relationship between choice and treatment characteristic was observed when difference in PFS was small. In the DCE, conditional logit regression indicated that to avoid severe levels of nausea/vomiting, diarrhea, rash, or fatigue, participants on average would accept reductions in PFS of 13, 11, 9, and 8 months, respectively. Participants would accept reduction in PFS of 7 months for oral treatment taken with/out food vs IV. Conclusion: In this online survey of patients with EGFRm metastatic NSCLC, some patients were willing to accept shorter PFS for a better safety profile and dosing convenience; however, PFS remained an important attribute in treatment choice.

OA10 RIGHT PATIENT, RIGHT TARGET & RIGHT DRUG - NOVEL TREATMENTS AND RESEARCH PARTNERSHIPS
TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

OA10.02 ONCOGENE-DRIVEN PATIENT GROUPS: A NEW ERA FOR RESEARCH PARTNERSHIPS
J. Freeman-Daly1, I. Elkins2, L. Greco3, M. Horn4, B. Addario5, D. Leduc6, R. Doebel6, C. Lovly6

This abstract is under embargo until September 25 at 10:30 Eastern Time.
Background: Several EGFR tyrosine kinase inhibitors (TKIs) are used for the treatment of EGFR-mutant non-small cell lung cancer (NSCLC), however resistance inevitably develops. The combination of the irreversible ErbB family TKI afatinib and the EGFR monoclonal antibody cetuximab was previously shown to overcome resistance to first-line EGFR TKIs. To attempt to delay resistance, we conducted a randomized trial of afatinib plus cetuximab versus afatinib alone in treatment-naive patients with advanced EGFR-mutant NSCLC (NCT02438722). Method: Patients with previously-untreated EGFR-mutant NSCLC were randomized to afatinib 40mg PO daily plus cetuximab 500mg/m2 IV every 2 weeks or afatinib 40mg PO daily. The study was designed to accrue a total of 212 patients, comparing progression-free survival (PFS) between the arms at the 1-sided 0.025 level when 134 PFS events had been observed. Secondary objectives included comparison of overall survival (OS) time to treatment discontinuation (TTD), and toxicity. An interim analysis evaluating early stopping for futility occurred when at least 64 PFS events were reported. Result: Between March 26, 2015 and April 23, 2018, 170 eligible patients were accrued: 86 to afatinib/cetuximab and 84 to afatinib. Median age was 66.4 years, 66% were female, 64% had an EGFR exon 19 deletion mutation and 36% had an L858R point mutation. With 109 events observed, there was no improvement in PFS with the combination compared to single-agent (HR 1.37, 95% CI 0.80-1.51, P = 0.74, median 12.5 months vs 12.3 months). Grade ≥3 treatment-related adverse events (AEs) were more common among patients treated with afatinib/cetuximab, and more patients in the combination arm required at least 1 dose reduction of afatinib (57% vs 26%). However, treatment discontinuations due to AEs were similar between the two groups (HR 0.95, 95% CI 0.64-1.39, P = 0.79, median 12.5 months vs 12.2 months). Conclusion: There was no difference in PFS, OS or TTD with the addition of cetuximab to afatinib for treatment-naive patients with EGFR-mutant NSCLC. The trial was closed to accrual at the interim analysis having met the criteria for futility. Correlative analysis of tumor tissue and blood from patients is ongoing.

Background: Approximately 10% of EGFR mutants harbor uncommon mutations, which represent a heterogeneous group of rare molecular alterations within exons 18-21 and the sensitivity to EGFR TKIs is variable. Osimertinib is a potent irreversible inhibitor of both sensitizing EGFR mutation and T790M. In preclinical data, osimertinib was found to be active against most uncommon EGFR mutants, apart from the exon 20 insertion variant. Here we present the efficacy and safety of osimertinib in patients with uncommon EGFR mutation positive NSCLC.

Method: Patients with histologically confirmed metastatic or recurrent NSCLC with activating EGFR mutation other than exon 19 deletion, L858R, T790M and insertion in exon 20 were eligible. Patients received 80mg of osimertinib orally, once daily until progression or unacceptable toxicity. Response was assessed every 6 weeks by investigator. The trial was registered with ClinicalTrials.gov, number NCT03424759. Result: Between Mar 2016 and Oct 2017, 35 patients were enrolled. Median age was 59, 63% male, 43% never smoker, 97% adenocarcinoma. 63% of patients were treated as first-line therapy. The mutations identified were G719A/C/D/S/X (9, 54.3%) followed by L861Q (9, 25.7%), S768I (8, 22.9%), and others (3, 8.6%). The overall response rate was 50.0% (95% CI 32.8-67.2) and DCR was 88.9% (95% CI 78.1-91.9). Seven patients (77%) with L861Q mutation achieved partial response; 10/19 (52.6%) with G719A/C/D/S/X mutation; 3/14 (21.4%) with S768I mutation. At data cutoff (Apr, 2018), the median PFS was 8.2 months (95% CI 1.9-14.4) and median duration of response was 9.8 months (95% CI 7.6-12.0). The most common adverse events were rash (n=11, 31.4%), anorexia (n=8, 22.9%), and diarrhoea (n=7, 20%). Grade 3 or 4 AEs were reported in 8 of 35 patients (23%), but all of AEs were manageable. Conclusion: Osimertinib showed highly active in NSCLC patients harboring uncommon EGFR mutation with manageable safety profile, consistent with previous reports. Further analysis will be provided.

Keywords: non-small cell lung cancer, osimertinib, uncommon EGFR mutation

OA10.06 A FIRST-IN-HUMAN PHASE 1 TRIAL OF THE EGFR-CMET BISPECIFIC ANTIBODY JNJ-6186372 IN PATIENTS WITH ADVANCED NON-SMALL CELL LUNG CANCER (NSCLC)

K. Park 1, M. Ahn 2, S. Lee 1, H.R. Kim 3, M. Millington 3, M. Curtis 3, T. Triantos 1, S. Chaplan 1, N. Haddish-Berhane 1, R. Knoblauch 3, Z. Aupaur 1, J. Laquerre 3, L. Leonard 4

Background: JNJ-6186372 (JNJ-372) is a bispecific antibody targeting both EGFR and cMET. In preclinical studies, JNJ-372 demonstrated efficacy in EGFR and cMET driven tumor xenograft models (including EGFR T790M and MET-amplified/HGF-secreting), consistent with inhibition of ligand binding, receptor degradation, and ADCC activity. The goal of Part 1 of this study (reported here) was to assess the safety, pharmacokinetics (PK), and preliminary efficacy of JNJ-372 and to identify the recommended phase 2 dose(s) to be explored in Part 2.

Method: Patients with previously treated, advanced NSCLC were enrolled at two sites and treated with escalating doses of JNJ-372 administered IV weekly for the first 4-week cycle, then biweekly for each subsequent cycle. PK sampling was taken at multiple time points within cycle 1 and 2. Disease assessments were performed every 8 weeks. Tumors were characterized at baseline through next-generation sequencing of circulating tumor DNA (Guardant360). Result: 25 patients were treated with JNJ-372 during dose escalation: 140mg (n=3), 350mg (n=3), 700mg (n=9), 1050mg (n=7), 1400mg (n=3). Median age was 63y, 48% were male, 100% were Asian, 84%/12%/4% had adenocarcinoma/squamous/other histology, and median prior therapies was 4. No dose-limiting toxicities were observed at any dose level tested. The most frequent treatment-emergent AEs were infusion-related reactions (76%), rash/ acniform dermatitis (40%), dyspnea (24%), paronychia (24%), pruritus (20%), fatigue, (20%), nausea (20%); incidence of peripheral edema (cMET-related toxicity) was 12%. Infusion-related reactions were grade 1/2 in 3/8 patients with the first dose, and grade 3/4 in 1/8 with the second dose. The incidence of rash/acniform dermatitis was grade 2 (16%). One treatment-related AE of grade ≥3 severity was reported (neutropenia grade 3, possibly related). JNJ-372 demonstrated linear PK at doses levels 350 mg and above with non-linear PK at lower concentrations, suggesting concentration-dependent drug disposition. Doses ≥700mg resulted in average steady-state concentrations at or above the preclinically established therapeutic target level. Preliminary evidence of efficacy (maximum change from baseline in sum of target lesion diameters) was observed in a patient with squamous cell carcinoma (n=1), a patient with WEGFR adenocarcinoma (n=2), and 4 patients with EGFR-mutant adenocarcinoma (≥30%). Conclusion: JNJ-372 is a novel EGFR-cMET bispecific antibody. The manageable safety profile and preliminary evidence of clinical activity support active accrual of patients with previously treated EGFR-mutant NSCLC. The first recommended dose of 1050mg is being evaluated in Part 2.

Keywords: cMET, NSCLC, EGFR

Background: Osimertinib is approved for metastatic NSCLC patients with EGFR T790M mutation after progression from TKI therapy. Despite impressive tumor responses, drug resistance usually develops. The resistance mechanisms of osimertinib are emerging but studies with large cohorts of Chinese patients and association with clinical outcomes are lacking. Here we report a biomarker study of osimertinib using plasma samples from 107 Chinese patients who had progressed by 24 months after LSFD (Oct. 2017) of AURA17 (NCT02442349), the 2nd-line pivotal cohorts of Chinese patients and association with clinical outcomes are also associated with favorable ORR (80.0% vs. 9.6%). Aberrations in bypass tracks including AKT2, ALK, DDR2, ERBB2/3, G796S/D, T854I mutations, or amplification were found in 11 patients. EGFR C797S, all Ex19Del (6 and 9, respectively). The median time of C797S detection from EGFR C797S, all patients and urged for new drug discovery or combination strategies to reveal the diverse mechanisms to osimertinib in Chinese NSCLC patients and urged for new drug discovery or combination strategies to overcome this clinical challenge.

Keywords: non-small cell lung cancer, osimertinib, resistance mechanisms
radiation: HR 0.15 (95% CI 0.06 to 0.36). Chemotherapy and radiation was also associated with improved CSS in regional disease (HR=0.22 (95% CI 0.07 to 0.63) and remote disease (5.16 [0.37, 71.94]), though the latter was not statistically significant. **Conclusion:** This is a population-based study of TMs from the CCR that identifies baseline variables significantly associated with CSS. TM incidence appears to be increasing over time. Advanced stage and thymic carcinoma were found to be associated with worsened CSS, which is consistent with previous studies. Treatment incorporating surgery was associated with improved CSS in local and regional disease, as was chemoradiation in regional disease. Immunohistochemical assay trended towards significance in patients with remote thymic neoplasms treated with chemoradiation. These findings provide a more contemporary database for future TM outcomes research.

**OAI1.04 A COMPARATIVE STUDY OF PD-L1 IMMUNOHISTOCHEMICAL ASSAYS WITH FOUR RELIABLE ANTIBODIES IN THYMIC CARCINOMA**

1Department of Oncology, Immunology and Surgery, Nagoya City University Graduate School of Medical Sciences, Nagoya/JP, 2Department of Chest Surgery, Toyota Memorial Hospital, Toyota/JP, 3Department of Thoracic Surgery, Kanya Toyota General Hospital, Kariya/JP

**Background:** Currently, programmed death 1 (PD-1)/programmed death ligand 1 (PD-L1) targeted therapy has not been established for thymic carcinoma (TC) yet and limited information is available regarding the expression pattern of PD-L1 in TC. Four immunohistochemical assays are registered with the US Food and Drug Administration to detect the expression of PD-L1. We investigated the PD-L1 expression in thymic carcinoma using these four diagnostic assays. **Method:** The clinicopathological data of 53 TC patients were reviewed and their specimens were subjected to four PD-L1 assays with different antibodies (22C3, 28-8, SP142, and SP263). We examined tumor proportion scores (TPS) in each sample and the cutoff values were settled at 1% for 22C3, 1% for 28-8, 1% for SP142, and 25% for SP263. Date were correlated to clinicopathologic parameters and outcomes. **Result:** The study population included 32 male patients and 21 female patients (median age, 61 years). In the TPS, the four assays showed similar scores in each case. Pairwise analyses of the TPS for the four assays showed high concordance among the four assays (the Spearman's rank correlation coefficients were all >0.9). Histopathologically, high TPS was observed in squamous cell carcinomas (SqCCs). Using cutoffs, 34 cases (64.2% with 22C3, 41 cases (77.4%) with 28-8, 43 cases (81.1%) with SP142, and 26 cases (49.1%) with SP263 were detected as PD-L1 positive. In SqCCs, the high expression of PD-L1 was associated with early stage cancer when evaluated with 22C3 (p=0.0205), 28-8 (p=0.0448), and SP263 (p=0.0486), respectively. However, the high expression of PD-L1 were not associated with sex, age, tumor size, and curability. The SqCC patients with high expression of PD-L1 tended to show longer overall survival; p=0.0250 in 22C3, p=0.0719 in 28-8, p=0.1064 in SP142, and p=0.0675 in SP263. **Conclusion:** The present study revealed that the TC patients, especially SqCC patients, showed high PD-L1 positivity and that the staining pattern showed high concordance among the four assays. High expression of PD-L1 might be a prognostic predictor, though observed effect was independent on the assay. Our results suggest that the PD-L1/ PD-L1 pathway is a potential immunotherapeutic target in TC.

**OAI1.06 TWO BRM PROMOTER POLYMORPHISMS DO NOT PREDICT SUSCEPTIBILITY OR PROGNOSIS OF THYMOHYMA**

1University of Toronto Faculty of Medicine; Princess Margaret Cancer Centre, Toronto/ON/CA, 2Princess Margaret Cancer Centre, Toronto/ON/CA, 3Dept of Medical Oncology and Haematology, Princess Margaret Cancer Centre, Toronto/ON/CA, 4Radiation Oncology, Princess Margaret Cancer Centre, Toronto/ON/CA, 5Division of Thoracic Surgery, Toronto General Hospital, University Health Network, Toronto, Ontario/CA, 6Division of Hematology & Oncology, University of Florida, Gainesville/US

**Background:** Braham (BRM) is a critical protein subunit in chromatin remodeling, and insertions/deletions at its two polymorphic promoters in lung, head and neck, esophageal, pancreatic, and liver cancers. There is also evidence of potential association with immune-related diseases such as ulcerative colitis and rheumatoid arthritis. As epigenetic silencing of BRM can be pharmacologically reversed, BRM polymorphisms in cancer might have therapeutic implications. Thymoma is a unique cancer in that it has immunological disease associations. We evaluated whether BRM-741 and BRM-1321 polymorphisms influence overall risk, survival, and time-to-progression of thymoma. **Method:** Thymoma cases and matched healthy controls were recruited in a prospective case-control study. Peripheral blood samples were collected and genotyped for BRM promoter polymorphisms. Multivariable logistic regression assessed risk of thymoma in case-control analyses. Association of BRM variants with overall survival (OS) and time-to-progression or recurrence (TTP) was assessed by multivariable Cox regression. **Result:** Of 237 cases of histologically diagnosed thymoma and 948 age- and gender-matched healthy controls, thymoma patients had median age of 53 (range: 17-84) years; 121 (51%) were male; 76 (32%) had a history of smoking. Median follow-up time was 7 years. 79% of patients were recurrence- and progression-free at 10-year follow-up (95% CI: 74-86%), and 81% of patients were alive at 10 years post-diagnosis (95% CI: 75-87%). Frequency of homzygous variants for either gene was not significantly different between cases and controls. **Conclusion:** homzygous BRM-741 genotype (OR=1.0; 95% CI:0.6-1.8; P=0.95), homzygous BRM-1321 (OR=0.59; 95% CI:0.3-1.0; P=0.07) or double homzygous variants in both loci (OR=0.69; 95% CI:0.3-1.4; P=0.29). No association between BRM-741/BRM-1321 and OS and TTP was detected.
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

**OA12.01 PHASE II DATA FOR THE MET INHIBITOR TEPOTINIB IN PATIENTS WITH ADVANCED NSCLC AND MET EXON 14-SKIPPING MUTATIONS**

1Vall d’Hebron Institute of Oncology (VHIO). Vall d’Hebron University Hospital, Barcelona/ES, 2Saïtama Cancer Center, Saitama/JP, 3Section of Pulmonary Medicine, Bruns, J. Scheele, 7, P. Paik

**Method:** Recruitment of 120 adult patients with advanced METex14+ NSCLC without EGF-R-activating mutations or ALK rearrangements is ongoing. METex14+ mutations are identified in FPE tumor (T) material and/or plasma (L; 60 patients each, overlap anticipated) by a central laboratory. Patients receive tepotinib 500mg QD until disease progression, intolerable toxicity, or withdrawal. Primary endpoint: objective response rate (ORR). Secondary endpoints include duration of response (DR), duration of treatment (DT), safety.

**Result:** Forty-one patients have been treated to date; data are available for 34 (median age 73.5 years; 23 male: 24/8 Caucasian/Asian; prior lines of therapy: 0, n=12; 1, n=11; 2, n=10; 3, n=1; stage IVA, n=4; stage IV, n=29; stage IIIb, n=1). Treatment is ongoing in 24 patients. Based on investigator assessment, 13/22 (59.1%) evaluable patients responded: 1 had a confirmed complete response; 12 had a confirmed partial response (PR); 3 (13.6%) had stable disease for ≥12 weeks (SD). Based on independent review, 9/22 (40.9%) had a confirmed PR; 5 (22.7%) had SD. Duration of response >12 months in 2 patients. Twenty (88.8%) patients have experienced tepotinib-related adverse events (TRAEAEs), including serious TRAEAEs in 3 (8.8%); pneumonia=1, generalized edema=1, interstitial lung disease=1, and grade ≥3 TRAEAEs in 6 (17.6%); generalized edema=1, pneumonia=1, ALT increased=1, AST increased=1, amylase increased=2, gamma GT increased=1, lipase increased=1, hyperkalemia=1; no TRAEAEs were grade ≥4 or led to death. Five (14.7%) patients have died.

**Figure:** Time on treatment and duration of response for tepotinib-treated patients (investigator assessment; median response duration: 10.5 months).

**Conclusion:** Tepotinib 500mg QD has promising activity in METex14+ NSCLC, with a favorable safety profile.

**Keywords:** tepotinib, MET inhibitor, non-small cell lung cancer

**OA12.02 UPDATED ANTITUMOR ACTIVITY OF CRIZOTINIB IN PATIENTS WITH MET EXON 14-ALTERED ADVANCED NON-SMALL CELL LUNG CANCER**

A. Drilon, J. Clark, J. Weiss, S. Ou, D.R. Camidge, B. Solomon, G. Otterson, L. Villaruz, G. Rieley, R. Heist, G. Shapiro, D. Murphy, S. Wang, T. Usari, S. Li, K. Wilner, P. Paik

1Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Massachusetts General Hospital, Boston/MA/US, 3University of North Carolina at Chapel Hill, Chapel Hill/NC/US, 4University of California Irvine, Irvine/CA/US, 5University of Colorado Denver/CO/US, 6Peter MacCallum Cancer Centre, Melbourne/VIC/AU, 7Ohio State University, Columbus/OH/US, 8University of Pittsburgh Medical Center and Cancer Institute, Pittsburgh/PA/US, 9Dana Farber Cancer Institute, Boston/MA/US, 10Pfizer Oncology, La Jolla/CA/US, 11Pfizer Oncology, Milan/IT

**Background:** MET exon 14 alterations occur in ~3% of non-squamous non-small cell lung cancer (NSCLCs) and 20–30% of sarcomatoid lung carcinomas. Here we present updated antitumor activity for crizotinib in patients with advanced NSCLC whose tumors are positive for MET exon 14 alterations (hereafter MET exon 14-positive NSCLC), including updated biomarker analyses in circulating tumor DNA (ctDNA).

**Method:** Patients with MET exon 14-positive NSCLC by local molecular profiling were treated with 250 mg crizotinib BID in an expansion cohort of the ongoing PROFILE 1001 study (NCT00585195). Responses were based on derived investigator assessment per RECIST v1.0. Prospective plasma profiling for MET exon 14 alterations in plasma ctDNA was performed (PlasmaSELECT-R64); Personal Genome Diagnostics, Boston, MA.

**Result:** As of Jan 31, 2018, 69 patients (65 response-evaluable) with MET exon 14-positive NSCLC had been treated. Median age was 72 y (range: 34, 91). Tumor histology was: 84% adenocarcinoma, 9% sarcomatoid adenocarcinoma, 4% squamous cell carcinoma and 3% adenosquamous carcinoma. 61% were former-smokers, 38% never-smokers and 1% a current smoker. Median duration of treatment was 7.4 mo (95% CI: 5.5, 9.1), with 29% of patients ongoing. Confirmed responses were 3 CRs and 18 PRs; (ORR, 32%; [95% CI: 21, 43]); 29 patients had SD as their best overall response (Figure).

Median time to response was 7.6 weeks (range: 3.7, 16.3). Median DOR was 9.1 mo (95% CI: 6.4, 12.7). Median PFS was 7.3 mo (95% CI: 5.4, 9.1). MET exon 14 alterations were detected in ctDNA from 18/37 (49%) patients with analyzable samples. **Conclusion:** In patients with MET exon 14-positive advanced NSCLC, crizotinib treatment led to objective responses that were rapid and durable, with CRs in some cases. Plasma ctDNA profiling detected MET exon 14 alterations in a subset of patients who harbor MET exon 14 alterations by tumor testing.

Background: BRAF mutations are found in 2-3% of NSCLC. BRAF inhibitors reportedly have antitumor activity. The French National Cancer Institute (INCa) launched a program giving nationwide access to vemurafenib for cancer patients with BRAF-mutated tumors and supported molecular screening. We herein report the NSCLC cohort results.

Method: BRAF mutational status was assessed on INCa molecular genetic centers by direct sequencing or NGS. Patients with mutated BRAF (V600E and others mutations) progressing after ≥1 standard treatment were proposed vemurafenib 960 mg BID. Objective Response Rate (ORR) was assessed using RECIST v1.1 every 8 weeks. A sequential Bayesian approach was planned to allow early stopping using an inefficacy bound for ORR of 10%. If no early stopping occurred, the treatment was considered worthy for further evaluation if there was a 90% probability that the estimated ORR is ≥30%, the efficacy bound. Result: From 10/2014 to 10/2017, 118 NSCLC patients were enrolled: 101 with BRAF V600E and 17 with other potentially activating mutations (4 G466, 4 G469, 1 G596, 1 K601, and 3 NS81). Median age was 68 years (range 34–85), 71% smokers, 48% females, 100% non-squamous histology, and 20% with ECOG PS 2. Most frequent grade ≥3 adverse events (AEs) were asthenia (9% of patients), epidermoid carcinoma (6%), dermatitis (5%), and increased GGT (5%). Three toxic deaths were reported: 1 nausea and vomiting leading to dehydration, 1 pneumonia, and 1 neutropenic sepsis.

Conclusion: Vemurafenib provided reasonable response rate and extended PFS in pretreated NSCLC patients with BRAF V600E mutations but was not effective in those with other BRAF mutations. These results emphasize the need of integrating BRAF V600E in routine biomarkers screening.

Keywords: NSCLC, Vemurafenib, BRAF mutation

Nine patients were still on treatment at the cut-off date. 106 had stopped vemurafenib (65 PD, 26 AEs, 3 deaths, 1 doctor’s decision, 11 patient’s decisions). Conclusion: Vemurafenib provided reasonable response rate and extended PFS in pretreated NSCLC patients with BRAF V600E mutations but was not effective in those with other BRAF mutations. These results emphasize the need of integrating BRAF V600E in routine biomarkers screening.

Keywords: NSCLC, Vemurafenib, BRAF mutation
Background: BRAF V600E mutation is identified as molecular drivers in 1-2% of lung adenocarcinomas and predicts response to combination BRAF and MEK inhibitors. Little is known about molecular mechanisms of acquired resistance to these therapies for lung cancer patients with BRAF V600E mutations, partially due to a lack of representative cancer models.

Method: We identified patients with BRAF V600E mutated lung cancer who were progressing after initial response to a BRAF/MEK inhibitor combination in 5 academic institutions in the US. Potential molecular mechanisms of resistance were explored by comparing pre- and post-therapy results from comprehensive tissue and/or the Guardant360 FoundationACT plasma-based next generation sequencing assays.

Result: We identified 6 patients. Prior to treatment with a BRAF/MEK inhibitor combination, four patients had received at least one line of chemotherapy and immune checkpoint inhibitor monotherapy, one had received chemotherapy only and one was treatment naïve. Five patients received dabrafenib/trametinib and one vemurafenib/cobimetinib combination. All 6 patients achieved a partial response. Progression free survival (PFS) ranged from 3 to 15 months (median 9.5 months). At the time of progression, all patients had the BRAF V600E mutation re-identified in their samples. Additionally, there was one patient with a new AKT1 E17K mutation at the time of progression. Another two patients had AKT1 E17K mutations that were present prior to BRAF/MEK inhibitor therapy. They both had oligoprogression, one in lymph nodes and one in the brain after 5.2 and 3 months, respectively; both continued on dabrafenib and trametinib combination therapy after radiation treatment to the progressing sites. Interestingly, co-occurrence of AKT1 E17K and BRAF V600E mutations is rare in the TCGA data, but was identified in three of six patients in our case series. Finally, we have established a BRAF V600E positive lung adenocarcinoma cell line from a TKI naïve patient for further functional studies of drug resistance.

Conclusion: Comprehensive molecular testing can identify potential resistance mechanisms following progression of BRAF V600E positive lung cancer to TKI therapy. AKT1 mutations were common as co-alterations in BRAF V600E mutated lung adenocarcinoma before and after targeted therapy and may contribute to drug resistance. The development of patient-derived cell line models may assist in the identification and validation of drug resistance mechanisms, and may help devise strategies to overcome drug resistance.

Keywords: BRAF V600E, AKT1 E17K, drug resistance
Patients who were also staged with 18F-FDG PET/CT (n=309) had smaller n=309) had smaller outcomes were not different in LS-SCLC patients staged with or without outcomes were not different in LS-SCLC patients staged with or without parameters were also not prognostic.

Conclusion: CONVERT is an international multi-centre phase III trial that randomly assigned fit patients to receive either twice-daily (45Gy in 30 fractions) or once-daily (66Gy in 33 fractions) radiotherapy starting on day 22 of chemotherapy (NCT00433563). Chemotherapy consisted of a modified RECIST 1.1 criteria, and adequate organ function. The study will later enroll patients with extended disease SCLC with ongoing clinical benefit following no more than 6 cycles of first-line platinum-based chemotherapy. AMG 757 will be administered as an intravenous infusion once every 2 weeks.

Both of these studies are currently enrolling patients. For more information, please contact Amgen Medical Information: medinfo@amgen.com.
anlotinib arm (71.6% vs 13.2%, p<0.0001). Treatment-related adverse events (TRAEs) occurred more frequently in anlotinib arm than that in placebo (72.4% vs 44.0%, p=0.03). The most common TRAEs were hypertension, anorexia, fatigue, and hand-foot syndrome. Grade ≥3 TRAEs occurred in 29 (35.8%) of patients in anlotinib arm and 6 (15.4%) in placebo arm, respectively.

**Conclusion:** ALTER 1202 study demonstrates anlotinib should be considered a treatment option for patients with relapsed SCLC who have experienced treatment failure with two lines of chemotherapy. The safety profile was consistent with the previous report and no newly adverse events were identified.

**Keywords:** Anlotinib, 3rd line, relapsed SCLC

**OA13 THERAPEUTICS AND RADIATION FOR SMALL CELL LUNG CANCER WEDNESDAY, SEPTEMBER 26, 2018 - 10:30-12:00**

**OA13.05 PROPHYLACTIC CRANIAL IRRADIATION (PCI) FOR LIMITED-STANCE SMALL-CELL LUNG CANCER: RESULTS FROM THE PHASE 3 CONVERT TRIAL**

**Background:** PCI is considered standard of care in limited-stage small-cell lung cancer (LS-SCLC) patients. However the impact of the dose and fractionation of thoracic radiotherapy (RT) on the risk of developing brain metastasis (BM) has not been evaluated prospectively. **Method:** CONVERT is an international, phase 3 trial that randomly assigned patients to receive twice-daily (BD) 45 Gy in 30 fractions) or once-daily (OD 66 Gy in 33 fractions) RT starting on day 22 of chemotherapy (CT) cycle 1 (NCT00433563). PCI was offered, if indicated. Data on thoracic (OD 66Gy in 33 fractions) RT starting on day 22 of chemotherapy (CT) and fractionation of thoracic radiotherapy (RT) on the risk of developing BM and overall survival (OS) was collected. **Result:** 1547 patients were randomized to either group. The median PCI dose was 25 Gy in both OD and BD groups (p=0.74). PCI was delivered after CT in the OD group compared to the BD group (median days post CT 37 vs. 35 days, respectively; p=0.04). In patients who received PCI, 75 (17%) developed BM (35% of patients in the BD group and 25% in the OD group; p=0.2). In the univariate analysis, GTV was associated with OS. In the multivariate analysis, only thoracic GTV was associated with OS. Delay between end of CT and PCI was not associated with OS (p=0.1). Conclusion: Patients receiving OD or BD thoracic RT did not have the same risk of developing BM. Larger tumours are associated with a higher risk of BM.

**OA13 THERAPEUTICS AND RADIATION FOR SMALL CELL LUNG CANCER WEDNESDAY, SEPTEMBER 26, 2018 - 10:30-12:00**

**OA13.07 SURVIVAL OUTCOMES AFTER WHOLE BRAIN RADIOTHERAPY FOR BRAIN METASTASES IN ELDERLY PATIENTS WITH NEWLY DIAGNOSED METASTATIC SMALL CELL CARCINOMA.**

P. Renz, S. Hasan, A. Turrisi, A. Colonias, R. Wegner

**Background:** Small cell lung cancer (SCLC) is an aggressive malignancy with a tendency to affect the elderly and to metastasize to the brain. However, elderly patients tolerate whole brain radiotherapy (WBRT) poorly with potentially detrimental effects on quality of life. Accordingly, the survival benefit of WBRT in this population is unclear. We utilized the national cancer database (NCDB) to evaluate the survival outcomes following WBRT in elderly patients with SCLC and brain metastases.

**Method:** We analyzed 1615 patients >75 years old diagnosed with SCLC and brain metastases at diagnosis. Patients were categorized by type of therapy: chemotherapy + WBRT (n=576), chemotherapy alone (n=238), WBRT alone (n=360) and no chemotherapy or WBRT (n=441). Clinical and demographic characteristics were reported for each treatment cohort with a subsequent multivariable regression analysis for survival. Propensity score–matching analysis was used for balance between comparison groups. **Result:** Median patient age was 79 years. 51% had brain-only metastatic disease. Whole brain radiotherapy median dose delivered was 30 Gy (1.8-40 Gy). Median follow up was 2.8 months (0.03-68.01) for all patients. Of the patients included in this study, 1530 had died at time of analysis yielding a median OS of 2.9 months versus 6 months and 1 year survivals of 31% and 12%, respectively. For patients without chemotheraphy, median OS with WBRT was 1.9 months compared to 1.2 months without WBRT (p=0.0001). For patients receiving chemotherapy with, and without WBRT, median OS was 5.6 months and 6.4 months, respectively (p=0.43). Multivariable cox regression revealed age >80, extracranial disease, male sex, and rural location as predictors of increased risk of death.

*(See next page)*
Conclusion: In elderly patients 75 years old or greater with SCLC brain metastasis, WBRT was associated with a modest increase in survival in patients not fit for chemotherapy, and there was no association with increased survival over chemotherapy alone.

MA01 EARLY STAGE LUNG CANCER: QUESTIONS AND CONTROVERSIES
MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MA01.01 PROPOSAL ON INCORPORATING LYMPHOVASCULAR INVASION AS A T-DESCRIPTOR FOR STAGE I NON-SMALL CELL LUNG CANCER
S. Wang, B. Zhang, J. Xu, R. Qiao, B. Han, B. Yan, Y. Dong
Department of Pulmonary Medicine, Shanghai Chest Hospital, Shanghai/CN

Background: Lymphovascular invasion (LVI) and Pleural Visceral Invasion (PVI) have been reported to be risk factors for stage I Non-Small Cell Lung Cancer (NSCLC). However, only LVI was incorporated into the current 8th TNM staging. We hypothesize that the recurrence hazard following lung resection for stage I NSCLC patients in the Shanghai Chest Hospital (2008-2012). By using the Kaplan-Meier method and Cox proportional hazard regression model, we identified the correlations between LVI, PVI and clinical outcomes in p-stage I NSCLC. Result: Of all p-stage I NSCLC 2600 patients, 221 were pathologically diagnosed with LVI and 815 pathologically with PVI, respectively. We observed that patients with LVI had an unfavorable lung cancer specific survival (LCSS) (hazard ratio [HR]: 1.883; 95% confidence interval [CI]: 1.351-2.625; P < 0.001) and recurrence-free survival (RFS) (HR: 2.025; 95% CI: 1.570-4.098; P < 0.001) compared with that of PVI in pN0 non-small-cell lung cancer and a tumor diameter of 3cm or smaller. When tumor size was between 3-4cm, patients with LVI and PVI were associated with inferior prognosis than those with only LVI or PVI (P < 0.001). Conclusion: The presence of LVI independently and significantly affects LCSS and RFS in patients with stage I NSCLC. Our results suggest that stage IA(Ia) patients with LVI should be upstaged to T2a(Ib), meanwhile, stage T2(aIb) patients coexist with LVI and PVI should be upstaged again in the TNM classification.

Keywords: TNM classification, lymphovascular invasion, visceral pleura invasion

MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MA01.02 HISTOLOGIC SUBTYPING IN PATHOLOGIC STAGE I LUNG ADENOCARCINOMA PROVIDES RISK-BASED STRATIFICATION FOR SURVEILLANCE
Y. Takahashi1, T. Eguchi1, K. Kameda1, S. Lu2, R. Vaghjiani3, K.S. Tan2, D. Jones2, W. Travis3, P. Adusumilli3
1Thoracic Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Zhongshan Hospital Fudan University, Shanghai/CN, 3Epidemiology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 4Department of Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US

Background: Current national practice guidelines (NCCN, ACCP, ESMO) recommend a uniform follow-up protocol with intensive surveillance within the first two years following lung resection for stage I NSCLC. We hypothesize that the recurrence hazard following lung resection for stage I lung adenocarcinoma (ADC) varies according to histologic subtype. Method: A total of 1572 patients with resected pathologic stage I lung ADC were investigated. Two thoracic pathologists reviewed all tumor H&E slides (range 1-8, median 3) for histologic subtyping and percentage of each subtype. Recurrence hazard was estimated using the Kernel-Epanechnikov smoothing procedure. Association between recurrence hazard and high-grade histologic subtypes (micropapillary [MIP] and solid [SOL]) was assessed. Result: Presence (≥5%) of these high-grade subtypes (MIP and/or SOL) was associated with significant increase of recurrence hazard compared to high-grade pattern negative (<5%) tumors (Figure 1): 1) patients with presence of either MIP or SOL had significant recurrence hazard peaks within two years after surgery; 2) SOL was associated with early hazard peak at the first year after surgery especially in distant recurrence hazard; 4) one-third of patients (515/1572, 33%) had no high-grade subtypes, in which the recurrence hazard was consistently very low (<2% risk each year) during the 10-year period after surgery without any hazard peak (red arrow).

Conclusion: Our data suggest the utility of histologic subtyping for identifying patients with very low recurrence hazard, and provide foundation for establishing risk-based follow-up protocols. A potential option for low-risk patients may be omission of intensive follow-up during the first two years after surgery.

MA01.03 AN EXTERNALLY VALIDATED NOMOGRAM FOR PREDICTING DISTANT METASTASIS AFTERSBRT FOR EARLY STAGE NON-SMALL CELL LUNG CANCER
A. Juloori1, A. Zajichek1, M. Kattan2, D. Mullen2, P. Samson2, N. Woody2, M. Roach2, J. Bradley4, G. Videtic5, C. Robinson5, K. Stephens5
1Department of Radiation Oncology, Cleveland Clinic, Cleveland/OH/US, 2Cleveland Clinic, Cleveland/US, 3Department of Radiation Oncology, Washington University in St. Louis, St. Louis/US, 4Radiation Oncology, Washington University School of Medicine, St. Louis/MO/US, 5Radiation Oncology, Cleveland Clinic, Cleveland/OH/US

Background: SBRT is a standard option for patients with early stage NSCLC who are medically inoperable. While SBRT is associated with excellent local control, distant metastases (DM) represent the primary pattern of failure. Adjuvant systemic therapy has not traditionally been used in this patient population due to medical comorbidities. With the advent of immunotherapy that may be better tolerated, there has been a renewed interest in identifying patients that may derive benefit. We developed and internally validated a nomogram to predict the likelihood of DM after SBRT for early stage NSCLC which was then externally validated. Method: Our lung SBRT registry was queried for patients with early stage NSCLC treated with definitive intent from 2003-2017 and 1002 patients were identified for analysis to develop the model. A dataset from an external institution was used to similarly identify patients and 737 were used for the validation cohort. Random Survival Forest was used to assess importance, interactivity, and overall predictive ability with respect to DM for 14 variables. A Fine-Gray competing-risks regression model was formulated where apparent interactions were examined with likelihood-ratio tests. Backward variable selection was implemented to reduce to a parsimonious model. The concordance probability (C-index) of the model was internally validated with 10-fold cross validation.

Result: The median overall survival was 1.71 years internally and 1.92 years externally. Median follow-up was 18.3 months and 21.1 months. 1-year incidence of DM was 16% and 12.1% in the internal and external cohorts, respectively. Random Forest analysis suggested that tumor size and PET SUV are the most important predictors of distant failure. The 1-year cumulative incidence (CI) of DM was 18.5% for PET SUV ≥4.1 vs 8.4% for <4.1. 1-year CI for tumor size ≥3 cm was 26% vs 12.6% for <3 cm. The median time to DM was 0.6 years internally and 1.1 years externally. The final nomogram included tumor size, histology, PET SUV, age, KPS, and active smoking status, and had a cross-validated C-index of 0.62. The nomogram provides predictive value for probability of DM at 1-year between 30% and 70%. Conclusion: This novel nomogram with external validation can be used to predict the 1-year DM risk after SBRT for patients with early-stage NSCLC, accounting for the competing risk of death. This nomogram may help define patient subsets for stratification in future clinical trials to help identify who may benefit from adjuvant systemic therapy after SBRT to reduce the incidence of DM and disease-related death.

**MA01.05 OPIOIDS AND SLEEP MEDICATION USE AFTER SURGERY FOR EARLY STAGE LUNG CANCER: A SEER-MEDICARE ANALYSIS**

S. Tuminello1, J. Wisnivesky2, R. Schwartz3, B. Liu4, G. Mangloa5, R. Flores2, E. Taioli6

1Population Health Science and Policy and Institute for Translational Epidemiology, Icahn School of Medicine at Mount Sinai, New York/US; 2Division of General Internal Medicine and Pulmonary and Critical Care Medicine, Icahn School of Medicine at Mount Sinai, New York/US; 3Department of Population Health Science and Policy and Institute for Translational Epidemiology, Icahn School of Medicine at Mount Sinai, New York/US; 4Department of Thoracic Surgery, Icahn School of Medicine at Mount Sinai, New York/US; 5Department of General Thoracic Surgery, Dokkyo Medical University, Tochigi/JP; 6Department of Thoracic and Cardiovascular Surgery, Osaka University Graduate School of Medicine, Osaka/JP

**Background:** More than 50% of patients undergoing surgery for early stage lung cancer experience persistent post-operative pain, which can prevent their returning to normal daily activities and cause disruptions in sleep. Whether Video-Assisted Thoracoscopic Surgery (VATS), a minimally invasive surgical technique, reduces long-term opioid and sleep medication use compared to traditional open surgery has not yet been established.

**Method:** The Surveillance, Epidemiology, and End Results (SEER) data linked to Medicare data (SEER-Medicare) database was queried to identify patients with stage I primary non-small cell lung cancer (NSCLC) who had VATS or open resection between 2007 to 2013, and had no record of opioid or sleep medication use in the 30 days before surgery. Long-term opioid and sleep medication use were defined as having fulfilled one or more prescriptions in the first 90 days after surgery as well another prescription in the 90–180 days post-surgery. Logistic regression was used to investigate the associations between surgical type and long-term opioid and sleep medication use. Models were adjusted for relevant clinical and socioeconomic covariates.

**Results:** There were 3,900 NSCLC patients included in this analysis; 1,987 (51.0%) VATS and 1,913 (49.0%) open surgery patients. 15.9% of patients met the criteria for 90 days of opioid or sleep medication use after the 30 days before surgery. The adjusted odds ratio (OR) of opioid sleep medication use was 1.95, 95% CI: 1.61, respectively) through univariate and multivariate analyses. A 5-fold cross validation was performed as an internal validation to reconfirm these five predictive factors (average AUC: 0.70). We developed a simplified risk system as follows: RS = male + 2 (CGA75: memory: yes) + 2 (Alb: <3.8 ng/ml) + 1 (%VC: <50) + 1 (NVC: ≤90) + 1 (SCS: Diabetes mellitus: yes). Conclusion: The current study shows that octogenarians can be successfully treated for lung cancer with surgical resection with an acceptable rate of severe complications and mortality. We propose a simplified risk system to predict severe complications in octogenarian patients with medically operable lung cancer.

**Keywords:** Octogenarian, lung cancer, Surgery

**MA01.07 VALIDATION OF RTOG 0813 NORMAL TISSUE CONSIDERATIONS FOR PULMONARY TOXICITY IN SBRT FOR CENTRAL NON-SMALL CELL LUNG CANCER**

K. Verdeccchia, B. Manyam, G. Videtic, T. Zhuang, N. Woody, K. Stephens

Radiation Oncology, 10201 Carnegie Avenue, Cleveland/OH/US

**Background:** Stereotactic body radiation therapy (SBRT) yields excellent local control rates for medically inoperable early stage “central” non-small cell lung cancer. Normal tissue constraints provided in RT0813, which tested safety and efficacy of lung SBRT for central tumors, were largely based on expert estimates, and clinical validation of constraints is limited. We sought to identify the sensitivity and specificity of the current RT0813 constraints for predicting pulmonary toxicity in a large institutional data set. Method: We identified 136 lesions within 2 cm of the proximal bronchial tree (PBT), treated from 2005 to 2014 from a prospective registry of 1,462 patients. Dose was 50 or 60 Gy given in 5 fractions. Pulmonary toxicity was categorized as pneumonitis or non-pneumonitis (fistula, bronchial stenosis or necrosis, atelectasis, hemoptysis, or clinically significant pleural effusion). A series of dose endpoints for the PBT was generated based on dose volume histograms, where dose levels ranged from 0 Gy to 80 Gy in increments of 0.1 Gy, and volumes ranged from 0.03 cc to 50 cc in increments of 0.03 cc. A total of 333,600 dosimetric endpoints were analyzed. The sensitivity and specificity of these endpoints in predicting pulmonary toxicity was calculated. The optimal dosimetric endpoint was chosen by identifying the highest F-score. Result: We observed nine grade 2 pneumonitis and 10 grade ≥2 non-pneumonitis toxicities, of which three were grade 5 (broncheo-pleural fistula, left mainstem bronchus necrosis, and bronchial stenosis). The optimal dosimetric endpoint to avoid Grade 2-5 non-pneumonitis toxicity was D0.03cc=50 Gy to the PBT, with 90% sensitivity and 77% specificity. The optimal point dose to avoid Grade 3-5 non-pneumonitis toxicity was D0.3cc=46.5 Gy, with 100% sensitivity and 85% specificity. Applying PBT RT0813 constraints to our dataset achieved 18% sensitivity and 91% specificity for D4cc=18 Gy and 29% sensitivity and 93% specificity for D0.03cc=52.5 Gy. Conclusion: Clinical results from this large institutional data set validate current RT0813 constraints for PBT as predictive for pulmonary toxicity. The results also suggest that RT0813 constraints D4cc=18 Gy and D0.03cc=52.5 Gy to PBT have moderate sensitivity but excellent specificity for pulmonary toxicity. We identified D0.03cc=50 Gy to PBT as having the largest sensitivity and specificity for toxicity prediction, and this value parallels current RT0813 constraint of D0.03cc≤52.5 Gy. This analysis suggests that an additional volume/dosimetric constraint of D0.3cc≤46.5 Gy may be considered for avoidance of Grade 3-5 non-pneumonitis pulmonary toxicity.

**Keywords:** toxicity, SBRT, central
MA01 EARLY STAGE LUNG CANCER: QUESTIONS AND CONTROVERSIES
MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MA01.09 RISK FACTORS OF RADIATION-INDUCED LYMPHOPENIA (RIL) AND ITS PROGNOSTIC SIGNIFICANCE IN SMALL LUNG CANCER PATIENTS TREATED WITH STEREOTACTIC BODY RADIATION THERAPY
Q. Zhao, J. He
Department of Radiation Oncology, Zhongshan Hospital, Fudan University, Shanghai/CN

Background: The decrease in peripheral blood lymphocytes induced by radiation lessens the antitumor effect of the immune response, which might cause immunosuppression. This reduction might be affected by fractionation scheme. The purpose of this study was to assess the effect of fractionation scheme (consecutive daily fractions or nonconsecutive fractions) of SBRT on clinical outcomes in early-stage peripheral non-small cell lung cancer (NSCLC). We also analyzed the different effect of these two fractionation schemes in reducing peripheral blood lymphocytes during SBRT treatment period. Method: Data from a total of 61 early-stage peripheral NSCLC patients who had received SBRT were retrospectively analyzed. A total dose of 50 Gy in 5 fractions over 5-7 days was delivered for all patients. Peripheral blood lymphocytes were measured before and after SBRT. We used the Kaplan-Meier method, the log-rank test, and Cox proportional hazards regression to determine whether radiation treatment schedule associated with clinical outcomes. Result: Figure 1 showed Kaplan–Meier estimates for progression free survival (PFS) (Figure A) and overall survival (OS) (Figure B) for entire cohort stratifying for fractionation regimen. Multivariate analysis showed that nonconsecutive fractionation was an independent predictor of a longer PFS (P = 0.002). OS trended toward improvement in the non-consecutive group, but this was not statistically significant (P = 0.181). Development of any grade 3 or higher toxicity was not significantly different between the two groups (P = 0.813). The average circulating lymphocyte counts of consecutive group patients significantly declined after RT (1977.27 versus 1368.18 cells/μl, P < 0.001) while the nonconsecutive group patients did not (1700.00 versus 1450.00 cells/μl, P = 0.155).

Conclusion: Five-fraction SBRT delivered over non-consecutive days achieved superior clinical outcomes and similar toxicity compared to consecutive fractionation. Consecutive daily fractions of SBRT might cause worse immunosuppression by the more severe damage of peripheral lymphocytes.

MA01.10 TOXICITY AND LOCAL CONTROL IN “ULTRA-CENTRAL” LUNG TUMORS TREATED WITH SBRT OR HIGH-DOSE HYPOFRACTIONATED RT
Radiation Oncology, Memorial Sloan Kettering Cancer Center, New York/US

Background: Stereotactic body radiation therapy (SBRT) for central lung tumors has been associated with higher rates of severe toxicity. Data suggests that tumors with specific high-risk features, namely GTV abutting proximal bronchial tree (PBT), trachea or PTV intersecting esophagus (“ultra-central” tumors), are at risk of severe complications. We sought to evaluate toxicity and efficacy for high-risk tumors abutting PBT or esophagus. Method: For the interval 2004-2017, 50 (3.4%) pts, of a total of 1,461 lung SBRT cases, met criteria for analysis. Pre-sSBRT surgical resection of lung tumors has been associated with higher rates of severe toxicity. Development of any grade 3+ toxicity was not significantly different between the two groups (P = 0.181). Eight patients (9.1%), all abutting the PBT, experienced fatal complications related to RT. Four patients developed fatal pulmonary hemorrhage. Maximum point doses to PBT were 54.9Gy, 51.4Gy, 49.4Gy (in 5 fractions) and 63.8Gy (8 fractions) and 2 of them had received bevacizumab in close proximity to RT. Four patients developed fatal pneumonia/radiation pneumonitis (all had pre-existing COPD). No Grade 4 toxicity was identified. Grade 3 overall toxicity rate was 12.5%. Only 3 of 22 (13.6%) patients whose PTV overlapped with esophagus had Grade 3 toxicity. The 1-year and 2-year LC for the whole cohort were 87.5% and 79.1%, respectively. The 1, 2-year OS for primary NSCLC patients were 77.8% and 62.6%, respectively. Conclusion: To our knowledge, this is the largest reported series of patients who received SBRT for ultra-central tumors. RT achieves high rates of local control in these patients, but the rate of severe or fatal toxicity is substantial. Further studies are needed to establish the relationship between SBRT and toxicity in these patients.

MA01 EARLY STAGE LUNG CANCER: QUESTIONS AND CONTROVERSIES
MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MA01.11 SALVAGE SBRT FOR LOCAL RECURRENCE AFTER PRIMARY SURGICAL RESECTION OF EARLY STAGE NON-SMALL CELL LUNG CANCER
S. Sittenfeld, A. Juloori, C. Reddy, K. Stephans, G. Videtic
Department of Radiation Oncology, Cleveland Clinic, Cleveland/Ohio/US

Background: To report on the patient, tumor and treatment characteristics of patients treated with salvage lung SBRT (sSBRT) for non-metastatic NSCLC that has relapsed after previous surgical resection, and the resulting clinical outcomes. Method: We surveyed our IRB-approved prospective lung SBRT registry for patients who received sSBRT for local recurrence after previous resection of an early stage NSCLC. Following sSBRT, outcomes of interest included local control (LC), overall survival (OS), and treatment-related toxicity graded per CTCAE version 4.0. Result: For the interval 2004-2017, 50 (3.4%) pts, of a total of 1,461 lung SBRT cases, met criteria for analysis. Pre-sSBRT surgical approaches were: 23 (46%) wedge resection, 2 (4%) segmentectomy, 20 (40%) lobectomy, 2 (4%) bilobectomy, 1 (2%) pneumonectomy and 1 (2%) with unspecified surgery. At the time of resection, disease stage...
was: 34 (68%) stage I, 4 (8%) stage II, 5 (10%) stage III and for 3 (6%) pts, pre-operative stage was unknown. Median time to local recurrence after surgery was 27.45 months. At sSBRT, 38 (76%) pts had biopsy-proven recurrence while 12 (24%) had recurrence diagnosed only by radiographic findings. Forty seven (9%) pts could not have surgical salvage due to pulmonary (60%), cardiac (2%), technical unacceptability (4%), poor KPS (2%), or multifactorial reasons (26%), with 3 (6%) refusing re-resection. Median age and KPS at salvage treatment was 74 years (range 50–89) and 80 (range 60–100) respectively. The most common sSBRT schedule was 50Gy in 5 fractions (68%), with all schedules having a BED of at least 100 Gy. Median follow up after sSBRT was 22.2 months (3.8–108.8 months). Eight pts subsequently experienced local or lobar failure (16%), and 9 patients had nodal failure (18%). Median time to local failure after sSBRT was 12.5 months (2.66.1 months). At analysis, 11 (22%) pts remain alive and free from disease progression. At 24 months, LC and OS were 83.6% (95% CI 71.1-96) and 66.7% (95% CI 53.3-80.1). Median OS after sSBRT was 29.3 months. Twenty one (42%) pts failed distantly at a median time of 11.4 months and 12 (24%) pts received systemic therapy following distant failure. 74% of pts experienced no toxicity after sSBRT as a control group within +/- 90 days of diagnosis. Secondary endpoints was the incidence of TEE in ROS1+ compared to KRAS+ NSCLC with the adoption of end-of-life resources. We aimed to determine the utilization of OPC services in stage IV NSCLC patients within our multistate, community-based healthcare network. Method: We reviewed 4,298 stage IV NSCLC patients diagnosed between 1/2013-12/2017, in a community-based healthcare network encompassing 34 centers in California, Montana, Oregon and Washington. We excluded 899 patients managed at 9 sites without OPC services, and 92 patients who received inpatient palliative care only. Eligible patients were stratified by whether or not they received OPC; then further by early OPC, which was defined as within 11 weeks of diagnosis. Survival was compared using Kaplan-Meier with log rank tests. Result: Of the 3,307 patients reviewed, only 8% (252/3,307) received OPC and 6% (182/3,307) early OPC. Kaplan-Meier from diagnosis to death was significantly longer for OPC patients (347 days, 95% CI 273–421) versus no PC (151 days, 95% CI 138–164), p<0.001; and similarly for early OPC (216 days, 95% CI 167–265) versus no PC, p=0.008. Documentation of advance directive/living will/power of attorney was low in all categories, with rates of documentation at 32%, 31% and 27% for patients receiving OPC, early OPC and no OPC, respectively. (See next page)
Background: Osimertinib is a third-generation, CNS-active EGFR-TKI that potently and selectively inhibits both EGFR-TKI sensitizing and EGFR T790M resistance mutations. We report results from a second planned protocol, optimal interim analysis of the ongoing ASTRI S study (NCT02474355). Method: Eligible patients receive osimertinib 80 mg once daily. Inclusion criteria: stage IIIB/IV, T790M-positive non-small cell lung cancer (NSCLC); T790M status confirmed locally by validated test, not restricted by sample type; prior EGFR-TKI therapy received; WHO performance status (PS) 0–2; acceptable organ and bone marrow function and no history of interstitial lung disease (ILD) or QTc prolongation. Asymptomatic, stable CNS metastases are permitted. The primary efficacy outcome is overall survival (OS). Result: From Sept 18, 2015, first patient in, to Oct 20 2017 data cut-off (DCO), 3014 patients were enrolled across 16 countries and received ≥ 1 dose of osimertinib (full analysis set [FAS]; median follow-up 7.9 months [range ≤1–24]), median age 62 yrs (27–92), 64% female, 69% Asian, 30% White, 11% WHO PS 2, 45% prior chemotherapy, 34% prior radiotherapy. All patients had T790M-positive status, identified from tissue in 1610 patients (53%), plasma ctDNA in 1241 patients (41%) and from other sources in 162 patients (5%). At DCO, 1276 patients (42%) had discontinued treatment (1738 [58%] ongoing); median duration of exposure 7.4 months (≤1–25); 1289 patients (43%) had a progression-free survival (PFS) event, 1276 (42%) had a time to treatment discontinuation (TTD) event, and 593 (20%) had died. In patients evaluable for response, the investigator-assessed clinical response rate was 56.6% (1625/2872; 95% confidence interval [CI] 54.7, 58.4). In the FAS, estimated median PFS was 11.0 months (95% CI 10.6, 11.1), median TTD was 12.6 months (95% CI 12.2, 13.1), and median OS was not reached (OS at 12 months was 75.8% [95% CI 73.7, 77.8]). Adverse events (AEs) leading to dose modification and treatment discontinuation were reported in 321 patients (11%) and 147 patients (5%), respectively. Serious AEs were reported in 505 patients (17%). ILD/pneumonitis-like events were reported in 41 patients (1%), and QTc prolongation in 48 patients (2%). Conclusion: ASTRI S, the largest reported study of osimertinib in T790M-positive NSCLC, demonstrates clinical activity similar to that observed in the osimertinib clinical trial program with no new safety signals.

MA02 IMPROVING OUTCOMES FOR PATIENTS WITH LUNG CANCER MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MA02.05 A DOUBLE-BLIND, RANDOMIZED, PLACEBO-CONTROLLED PHASE 3 NONINFERIORITY STUDY OF DARBEPOETIN ALFA FOR ANEMIA IN ADVANCED NSCLC

1Curie Manavata Cancer Centre, Maharashtra/IN, 2Hospital Clinic, Barcelona University, Barcelona/ES, 3Nemocnice Holovice, N. Hospital A.S., Holovice/CZ, 43rd Department of Medicine, Athens School of Medicine, Athens/GR, 5Medical Oncology, Hospital Do Câncer Mãe de Deus, Porto Alegre/BR, 6Centro Medico de Caracas, Colima/MX, 7Sun Yat-Sen University Cancer Center, East Guangzhou/CN, 8Amgen Inc., Thousand Oaks/US

Background: The effect of erythropoiesis-stimulating agents on overall survival (OS) in patients with chemotherapy-induced anemia has long been debated. This study (NCT00858364) evaluated noninferiority of darbepeo tin alfa (DAR) versus placebo for OS and progression-free survival (PFS) in anemic patients with NSCLC treated to a 12.0-μg/dl hemoglobin ceiling. Method: Adults with stage IV NSCLC expected to receive ≥2 cycles of myelosuppressive chemotherapy, life expectancy >6 months, ECOG 0–1, and hemoglobin ≤11.0 g/dl were randomized 2:1 to DAR (500 μg SC) or placebo Q3W. Patients were stratified by region, histology, and hemoglobin. Primary endpoint was OS; a Cox proportional hazards model, stratified by randomization factors, was used to evaluate noninferiority (margin based on upper confidence limit [CL] for hazard ratio [HR] <1.15). Secondary endpoints were PFS (noninferiority) and incidence of transfusions or hemoglobin ≥12 g/dl from week 5 to end of efficacy treatment period (EOETP). Result: 4161 patients were screened, 2549 enrolled, and 2516 included in the primary analysis set: 1680 randomized to DAR and 836 to placebo. The study was stopped early per independent DMC recommendation. Patients were well matched between arms for age (mean 61.8 years), sex (66.0% male), and race (47.5% White). DAR was noninferior to placebo for OS (HRadj 0.92; 95%CL 0.83–1.01) and PFS (HRadj 0.95; 95%CL 0.87–1.04). DAR was superior to placebo for transfusion of hemoglobin ≥8.0 g/dl from week 5 to EOETP (OR 0.70; 95%CL 0.57–0.86; P:0.001). Objective tumor response was similar between arms (DAR 36.2%; placebo 32.6%). Incidence of serious adverse events was the same in both arms (31.1%). No unexpected adverse events or cases of antibody-mediated PRCA were observed (Table).

A. No Palliative Care versus Outpatient Palliative Care

B. No Palliative Care versus Early Outpatient Palliative Care

Conclusion: We identified that OPC services are broadly underutilized in stage IV NSCLC patients across our multistate, community-based healthcare network. In addition, end-of-life documents were rarely completed in all clinical settings regardless of OPC. We confirmed prolonged survival associated with OPC in the community setting, but greater utilization is required to increase this benefit. These findings, as well as the additional benefits/value of OPC, require further study.

Keywords: palliative care, Stage IV NSCLC, outpatient palliative care
MA02.06 A RANDOMIZED, DOUBLE-BLIND, PLACEBO-CONTROLLED TRIAL OF CHEMOTHERAPY COMBINED WITH YANGZHENG XIAOJI IN ADVANCED NSCLC

Background: Yangzheng Xiaoji (YZXJ) is a Chinese medicine formulation made of 16 herbs and used in patients with solid cancers. The aim of this randomized, double-blind and placebo-controlled multi-center trial (YANG-1, ClinicalTrials.gov registration No. NCT02195453) is to evaluate the impact of Yangzheng Xiaoji capsule on the quality of life (QoL) and treatment-related side effects in patients with advanced non-small cell lung cancer (NSCLC) receiving chemotherapy. Method: Patients with advanced NSCLC and with Eastern Cooperative Oncology Group performance status 0 to 1, who receive first-line chemotherapy (gemcitabine or pemetrexed and cisplatin), were randomized (1:1) to Yangzheng Xiaoji (YZXJ) or placebo combined with chemotherapy. The primary endpoint was QoL (Functional Assessment of Cancer Therapy-Lung (FACT-L) and Lung Cancer Symptom Scale (LCSS)) after two or four cycles of chemotherapy. The second endpoints included overall response rate, progression free survival and toxicity. Result: Between 10/2014 and 4/2017, the trial enrolled and randomized 504 patients from 25 centers in China. 397 patients received at least two cycles of chemotherapy and were included for final analysis. Baseline characteristics, including FACT-L and LCSS scores, were well balanced between two groups. The mean FACT-L scores were significantly changed in both groups from the baseline to that after chemotherapy (97.58 increase to 100.89 in YZXJ/chemotherapy arm, P<0.001; 93.83 decrease to 97.93 in placebo arm, P=0.001). The mean score of LCSS from baseline was significantly changed in YZXJ/chemotherapy groups (25.84 decrease to 22.31, P<0.001), but there was no statistical difference in the placebo group (25.59 vs. 26.45, P=0.136). The YZXJ/chemotherapy arm had a better QoL than the placebo/chemotherapy arm (FACT-L, 3.30 vs. -4.09, P<0.001) as well as improved lung cancer symptoms compared with placebo (LCSS, -2.53 vs. -0.86, P<0.001). There was no statistical difference in chemotherapy completion rate, ORR and PFS between two groups. The most common adverse events were bone marrow toxicity (70.92% vs. 67.59%) and gastrointestinal reaction (34.66% vs. 63.24%) (YUX vs. Placebo, P=0.04 and P=0.01, respectively). The grade 3 and higher adverse events in the patients on the aprepitant arm. Conclusion: A randomised open-label study in patients with advanced lung cancer with cough for over 2 weeks despite therapy with a cough suppressant, with an ECOG performance status 0 to 2. Patients were randomized 1:1 to Arm A: aprepitant 125 mg orally on day 1, followed by 80 mg orally on days 2 to 7 along with physician’s choice of antitussive therapy. Patients were at baseline and then on days 3, 7, 9 and 12. Primary efficacy endpoint was subjective improvement in cough, measured with the Visual Analog Scale (VAS) and the Manchester Cough in Lung Cancer Scale (MCLCS). Secondary endpoints included toxicity and QoL, measured by the EORTC QLQ-C30 and iL13. The trial was approved by the institutional IEC and registered with (CTR/2017/05/008691). Result: Between June 2017 and June 2018, 128 patients were randomized: 64 to each arm. The median age was 53 yrs, 65% male, 64% never-smokers, 82% had adenocarcinoma. 88% had Stage IV disease; 80% had PS 1 and 20% PS 2. The median duration of cough was 90 days. VAS scores at baseline and day 9 was 67.93, 38.50 in Arm A and 63.15, 48.57 Arm B , with p<0.001 and the MCLCS scores at baseline and day 9 was 30.03, 22.32 in Arm A and 27.53, 25.80 Arm B , with p<0.001. Overall, there was no significant difference in the QoL scores in patients in the two arms, however there was a significant improvement in the cough-specific QoL domain in the patients on the aprepitant arm, p=0.017. There was no increase in the grade 3 and higher adverse events in the patients on the apreptiant arm. Conclusion: Aprepitant led to a significant improvement in cough in patients with advanced lung cancer, with no increase in severe side-effects. Aprepitant should be considered as one of the treatment options for cough in lung cancer patients.

MA02.07 APPRETIANT FOR COUGH SUPPRESSION IN ADVANCED LUNG CANCER: A RANDOMIZED TRIAL

Department of Medical Oncology, Tata Memorial Hospital, Mumbai/IN

Background: Cough is a distressing symptom in patients with lung cancer. Effective management of cough leads to improvement in quality of life (QoL) and overall quality of care. Aprepitant, a centrally acting neurokinin-1 inhibitor, has been shown in a pilot study to significantly decrease the cough frequency. Method: A randomized open-label study in patients with advanced lung cancer with cough for over 2 weeks despite therapy with a cough suppressant, with an ECOG performance status 0 to 2. Patients were randomized 1:1 to Arm A: aprepitant 125 mg orally on day 1, followed by 80 mg orally on days 2 to 7 along with physician’s choice of antitussive therapy. Patients were at baseline and then on days 3, 7, 9 and 12. Primary efficacy endpoint was subjective improvement in cough, measured with the Visual Analog Scale (VAS) and the Manchester Cough in Lung Cancer Scale (MCLCS). Secondary endpoints included toxicity and QoL, measured by the EORTC QLQ-C30 and iL13. The trial was approved by the institutional IEC and registered with (CTR/2017/05/008691). Result: Between June 2017 and June 2018, 128 patients were randomized: 64 to each arm. The median age was 53 yrs, 65% male, 64% never-smokers, 82% had adenocarcinoma. 88% had Stage IV disease; 80% had PS 1 and 20% PS 2. The median duration of cough was 90 days. VAS scores at baseline and day 9 was 67.93, 38.50 in Arm A and 63.15, 48.57 Arm B , with p<0.001 and the MCLCS scores at baseline and day 9 was 30.03, 22.32 in Arm A and 27.53, 25.80 Arm B , with p<0.001. Overall, there was no significant difference in the QoL scores in patients in the two arms, however there was a significant improvement in the cough-specific QoL domain in the patients on the aprepitant arm, p=0.017. There was no increase in the grade 3 and higher adverse events in the patients on the apreptiant arm. Conclusion: Aprepitant led to a significant improvement in cough in patients with advanced lung cancer, with no increase in severe side-effects. Aprepitant should be considered as one of the treatment options for cough in lung cancer patients.
Nabilone vs. placebo on the appetite, nutritional status, and quality of life in patients diagnosed with advanced Non-small cell lung cancer (NSCLC) (NCT02802540). **Result:** A total of 65 patients were enrolled and 47 were randomized to receive Nabilone (0.5 mg/2 weeks followed by 1.0 mg/6 weeks) or placebo. After 8 weeks of treatment, patients who received Nabilone increased their energy intake (342-kcal) and had a significantly improvements in Quality of life parameters.

**Conclusion:** Nabilone is an adequate and safe therapeutic option to aid in the treatment of patients diagnosed with anorexia. Larger trials are necessary in order to draw robust conclusions in regard to its efficacy in lung cancer patients.

**Keywords:** anorexia, orexigenic agent, lung cancer

**MA02 IMPROVING OUTCOMES FOR PATIENTS WITH LUNG CANCER**

**MA02.10 THE FIRST YEAR OF IMPLEMENTING A LUNG CANCER SCREENING PROGRAM IN AN URBAN SAFETY-NET HEALTH SYSTEM**

H. Hamann1, S. Lee1, T. Browning1, C. Chavez2, J. Sanders2, S. Abbara3, D. Ball9, R. Chi1, B. Moran2, N. Santini1, D. Gerber2

1University of Arizona, Tucson/AZ/US, 2University of Texas Southwestern Medical Center, Dallas/TX/US, 3Parkland Health and Hospital System, Dallas/US

**Background:** Little is known about implementing low-dose computed tomography (LDCT) -based screening for lung cancer in settings that care for minority and underinsured populations. These patients may benefit most from guideline-based screening but may also be least likely to complete this multi-step process. **Method:** Parkland Health & Hospital system provides care through a combination of federal, state, and county-supported funding for more than one million, racial/ethnically diverse residents of Dallas County, Texas. A systematic protocol for LDCT screening was implemented in February 2017. We report initial screens and follow-up procedures for the first year through June 2018. **Result:** 844 LDCTs were ordered; 528 (63%) were completed, 68 (8%) had been scheduled. We detail demographics of completers and non-completers (Table 1) and proportion of LungRADS scores (Figure 1). For every year older, patients are 3% more likely to complete their scan. Of 249 completers requiring some form of follow-up (47%), only 3 required CT biopsy.
Conclusion: While a systematic screening program in an urban safety-net setting generates high volume, a significant percentage of patients do not complete their initial screen. Of those who complete, many require follow-up procedures. More long-term data are needed to understand non-completion trends and subsequent annual screening.

Background: Cell-free DNA (cfDNA) next-generation sequencing (NGS) has emerged as an effective molecular profiling technique that is potentially faster and cost-saving in comparison to standard-of-care (SOC) tumour biopsy and tissue-based profiling. In a public payer system, the added value of cfDNA blood-based profiling compared to SOC remains unknown. This study will determine the incremental clinical utility and cost of cfDNA NGS versus SOC genotyping in patients with cancer associated genes. Two patient cohorts will be recruited: (1) treatment naïve patients with ≤10 pack year smoking history; and (2) patients with known abnormalities of EGFR, ALK, ROS-1 or BRAF after disease progression on all standard targeted therapies. SOC tissue profiling will be performed for all patients per institutional standards. The study will begin recruiting in May 2018, with estimated completion in 12 months. The primary endpoints are comparison of response rate (RR), progression-free survival (PFS) and time-to-treatment failure (TTF) using cfDNA versus tissue genomic testing. Secondary endpoints include number of actionable genomic aberrations identified, result turnaround time, potentially avoidable repeat tissue biopsies, costs, patient-reported quality of life (EQ-5D) and willingness-to-pay. Exploratory analyses of treatment outcomes in selected molecular subgroups will also be undertaken, including response to immunotherapy in those with KRAS/STK11 co-mutations. A decision-analytic model will be developed to perform cost-consequence analyses using a cfDNA versus tissue-based approach. Result: A total of 210 patients will be recruited across Canada. (Cohort 1 N=150, Cohort 2 N=60). Based on testing with either blood-based GUARDANT360TM or tissue-based profiling, the costs and benefits of blood-based profiling either at initial or repeat tumour biopsy and tissue-based profiling. Data from patients accrued until 08/2018 will be presented at the meeting. Conclusion: This study will determine the added value of cfDNA blood-based genotyping compared to SOC from the perspective of a public payer system (Canada).

Keywords: cell-free DNA, value

MAO2 LUNG CANCER SCREENING – NEXT STEP

MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MAO3.01 MANCHESTER LUNG CANCER SCREENING: RESULTS OF THE FIRST INCIDENCE SCREENING ROUND

H. Balata, P. Crosbie, M. Evison, R. Booton
North West Lung Centre, Manchester University NHS Foundation Trust, Manchester/GB

Background: The European position on lung cancer (LC) screening has recommended planning for implementation to commence throughout Europe (1). The Manchester lung cancer screening pilot is one of the first real world implementation projects to take place in Europe and to publish baseline results (2). In this abstract we share, for the first time, the results from the incidence screening round of the Manchester pilot. Method: The methodology and results of the baseline round of the Manchester screening pilot have been published previously (2). In brief, ever smokers, aged 55–74, from deprived areas of Manchester were invited to a free ‘Lung Health Check’ (LHC) in mobile units located at their local shopping centres. The PLCOm2012 LC risk stratification model was incorporated into the LHC and those at high risk of LC (PLCOm2012 ≥ 1.51%) were offered immediate LDCT in a co-located mobile scanner. At baseline, 75% of attendees were ranked in the lowest deprivation quintile; 56% were at high risk and 1384 screened with LDCT. 3% had LC diagnosed of which 80% were early stage (I-II) and 90% offered curative treatment. In this round of screening, all high risk individuals screened at baseline with no subsequent diagnosis of LC (screening or non-screening) were invited back for an annual LDCT scan at the same community locations. Exclusion criteria included death, other malignancies under follow-up and CT thorax within 3-months of due screening date. National and GP specific registries were checked for interval LC diagnosis. Result: A total of 1,194 LDCT scans were performed as part of the first incidence round of screening. Overall 28 (2.3%) individuals received a positive scan result and were referred to the MDT. Of these, 18 (1.5%) individuals were diagnosed with LC of which 78% (n=14/18) were lower stage (I-II) and 89% (n=16/18) offered curative treatment. The false positive rate was 0.8% of the screened population as a whole and 36% of those with a positive scan result. There were no interval LCs diagnosed at one year. The cumulative LC detection rate over the first 12 months of the programme was 4.3% (n=60/1384) of which 80% (n=51/64) were stage I-II. Conclusion: Annual LDCT screening of high risk individuals in this real world lung cancer screening implementation project continues to identify a significant number of early stage lung cancers amenable to curative treatment. No
interval lung cancers were diagnosed at one year suggesting the baseline selection criteria for screening was appropriate.

**Keywords:** Screening, early diagnosis, implementation

**MA03 LUNG CANCER SCREENING - NEXT STEP**

**MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00**

**MA03.02 PROSPECTIVE EVALUATION OF THE CLINICAL UTILITY OF THE INTERNATION LUNG SCREENING LUNG NODULE MANAGEMENT PROTOCOL**

S. Lam1, R. Myers1, S. Atkar-Khattra1, R. Yuan2, J. Yee2, J. English3, K. Grant1, A. Lee4, A. Mcguire5, A. McWilliams5, F. Brimens6, E. Stone6, V. Chini8, L. Chantrell8, M. Connellan8, M. Plitt8, H. Marshall9, I. Yang9, R. Bowman10, K. Fong10, J. Mayo11

1Integrative Oncology, British Columbia Cancer Agency, Vancouver/CA, 2Thoracic Surgery, Vancouver Coastal Health, Vancouver/BC/CA, 3Pathology, University of British Columbia, Vancouver/CA, 4Medicine, University of British Columbia, Vancouver/BC/CA, 5Fiona Stanley Hospital, Perth/AU, 6Respiratory Department, Sir Charles Gardner Hospital, Perth/AU, 7Thoracic Medicine, St Vincent’s Hospital, Sydney/AU, 8St. Vincent’s Hospital, Sydney/AU, 9The Prince Charles Hospital, Brisbane/AU, 10Department of Thoracic Medicine, University of Queensland Thoracic Research Centre at the Prince Charles Hospital, Brisbane/AU, 11Radiology, University of British Columbia, Vancouver/CA

**Background:** Several protocols are available to guide management of lung nodules identified by low-dose screening CT. It is important to objectively assess their clinical utility in order to weigh the potential harm versus potential beneficial impacts of the following: early recall imaging studies/biopsy and health care resource utilization. We aimed to prospectively evaluate clinical utility of the PanCan lung nodule management protocol in the International Lung Screen Trial (ILST).

**Method:** Ever smokers age 55 to 80 years were enrolled into ILST if they have a ≥30 pack-years smoking history and smoked within 15 years or if their PLCO 2012 6 year lung cancer risk was ≥1.51%. Figure 1 shows the ILST lung nodule management protocol based on the PanCan nodule malignancy risk calculator (NEJM 2013;369:908 & BMJ 2014;348:g2253).

**Result:** Since July 2016, 757 ever smokers (mean age 65 years, 44% female, 15% non-Caucasian) had been enrolled. The distribution of malignancy risk categories (CAT) were: CAT 1 70%, CAT 2 15%, CAT 3 11%, CAT 4 3.5%, CAT 5 0.4%. CT biopsy or bronchoscopic biopsy for diagnosis/staging was done in 16/25 CAT 4 (62%) and 7/84 CAT 3 (8%) participants. Lung cancer was confirmed in 15/757 (2%). Thus far, surgery was performed in 9 CAT 4 and 2 CAT 3 participants, with one benign resection (9%) for a growing FDG avid nodule. Of the 3 CAT 5 participants, one was found to have granulomatous changes in an enlarged paratracheal lymph node and two had segmental atelectasis due to mucoid impaction.

**Conclusion:** The ILST protocol triaged 70% of the screening cohort with low malignancy risk to biennial screening instead of annual repeat screening. Participants with high malignancy risk (CAT 4+5) were triaged to a diagnostic pathway (4%). Our preliminary results suggest the ILST protocol may decrease resource utilization and potentially minimize risk of screening for participants.

---

**MA03.03 PROLONGED LOW-DOSE COMPUTED TOMOGRAPHY (LDCT) SCREENING BEYOND 5 YEARS REDUCES OVERALL AND LUNG CANCER SPECIFIC MORTALITY**

U. Pastorino1, F. Sabha2, S. Sestini3, M. Silva1, M. Boeri1, A. Cantarutti1, N. Sverzellati1, G. Sozzi1, G. Corrao1, A. Marchianò6

1Thoracic Surgery, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 2Tumor Genomics Unit, Department of Experimental Oncology and Molecular Medicine, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 3Department of Statistics and Quantitative Methods, University of Milano-Bicocca, Milan/IT, 4Department of Medicine and Surgery (Dimec), University of Parma, Parma/IT, 5Tumor Genomics, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 6Department of Radiology, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT

**Background:** The National Lung Screening Trial (NLST) showed that lung cancer screening (LCS) by low-dose computed tomography (LDCT) improves the overall survival. The NLST and most of the LCS trials were limited to a 5-year period, therefore there is no prospective evidence about the optimal duration of LCS. The aim of this study was to assess the potential benefit of long term LC screening beyond 5 years, notably its effect in 10-year overall and LC specific mortality.

**Method:** The Multicenter Italian Lung Detection (MILD) trial prospectively enrolled 4,099 participants, randomized to either LDCT arm (n=2,376) or control arm (n=1,723); 38,561 person-years of follow-up were accumulated between 2006 and March 2017. The primary outcomes were 10-year overall and LC specific mortality. Moreover, a Landmark Analysis was used to test the long-term effect of LCS, beyond 5 years (notably by selective exclusion of events that occurred < 5 years). Cumulative mortality were evaluated using Kaplan-Meier estimator and differences among groups were tested using Log-rank test, adjusted for sex, age and pack-years. The prognostic value of assigned arm in predicting mortality was investigated by Cox’s proportional-hazard’s regression adjusted for the above variables.

**Result:** In the whole 10-year LCS, LDCT arm showed a protective non-statistically significant trend for reduction of overall mortality (HR: 0.82, 95% CI 0.63 to 1.07) and a significant 41% reduced risk of LC mortality (HR 0.59, 95% CI 0.38 to 0.92), compared to the control arm. Beyond the 5th year of screening, LDCT arm showed a significant 29% reduction of overall mortality (HR: 0.71, 95% CI 0.50 to 0.99), and a significant 62% reduced risk of LC mortality (HR 0.38, 95% CI 0.20 to 0.74) (Figure 1).

**Conclusion:** Prolonged LDCT screening beyond 5 years reduces overall mortality, and it is most beneficial in further reduction of LC specific mortality.

1Center for Medical Imaging North-East Netherlands, Department of Radiology, University of Groningen, University Medical Center Groningen, Groningen/NL; 2Department of Public Health, Erasmus MC, Rotterdam/NL; 3Department of Pathology, VU University Medical Center, Amsterdam/NL; 4Department of Pulmonary Diseases, University of Groningen, University Medical Center Groningen, Groningen/NL; 5Department of Pulmonary Medicine, Ku Leuven - University Hospitals Leuven, Leuven/BE; 6Department of Radiology, University Medical Center Groningen, Groningen/NL; 7Public Health, Erasmus MC, Rotterdam/NL

Keywords: subsolid nodules do not require a more aggressive follow-up approach

A new subsolid nodule after baseline. Contrary to new solid nodules, new subsolid nodules were detected after the screening rounds took place 1 year, 3 years, and 5.5 years after baseline screening. Participants with new subsolid nodules detected after the baseline screening round were included. A nodule was classified as (pre-)malignancy when it was diagnosed as lung cancer during diagnostic follow-up to explain the finding seen on the CTLS.

Result: 65% (33/49) of subsolid nodules were adenocarcinoma (in situ) and diagnostic work-up showed favorable staging (stage I). Overall, 6% (3/51) of participants with a new subsolid nodule (0.7% [51/7295] of participants with at least one incidence screening).

Conclusion: Almost 70% of the 286 significant incidental findings identified conditions requiring medical treatment, surgical intervention, or surveillance. There was one non-lung cancer diagnosis for every 7.5 lung cancers diagnosed in our screening program.

Keywords: Incidental finding, CT lung screening, lung cancer

MA03.07 DEVELOPMENT AND VALIDATION OF DEEP LEARNING MODEL FOR RECOGNITION OF HISTOLOGIC SUBTYPE OF LUNG ADENOCARCINOMA FROM CT IMAGES

Y. She, J. Deng, D. Xie, C. Chen
1Department of Thoracic Surgery, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN, 2Shanghai Pulmonary Hospital, Shanghai/CN

Background: The clinical decision to either follow-up or resection from radiologic features for lung adenocarcinoma (atypical adenomatous hyperplasia [AAH], adenocarcinoma in situ [AIS], minimally invasive adenocarcinoma [MIA] and invasive adenocarcinoma [IA]) appearing as Sub-solid nodules (SSNs) is still challenge, and currently more relies on measures of diameter, solid component ratio. With the successful application of deep learning neuro-network (DLNN) for the classification of skin or common treatable blinding retinal diseases, we hypothesized that DLNN might help the histologic subtype classification of SSNs from CT images.

The purpose of this study is to develop and validate a deep neural network model to classify AAH, AIS, MIA and IA or define a feasible classification for follow-up or treatment decision.

Method: A total of 869 patients with 1344 pathologic confirmed nodules (AAH: 75, AIS: 340, MIA:321, IA: 608) were enrolled into this study. Two 3D mixed-scale dense-connected convolutional neuro network models (3D MS-DenseNet) were developed for 2 classification tasks: 4-class (AAH, AIS, MIA, IA), 3-class (AAH, AIS/MIA, IA). Eighty percent of whole datasets were randomly selected for training set, while other 20% were used for testing set. The nodules were firstly selected using a bounding box of 256×256×128, and then resized into 128×128×matrix size as the input to MS-DenseNet, and the output layer from the network was a 4-node or 3-node softmax classifier. Confusion matrix were used for the performance evaluation of both models and the classification accuracy for each class was reported. The classification accuracy of AAH, AIS, MIA, IA in testing set was 0.75, 0.45, 0.52, 0.85 respectively by 4-class, suggesting that the differentiation between AIS and MIA from CT images by neuro-network is challenge. While in the 3-class classification task with purpose of decision supporting for treatment, the classification accuracy of AAH, AIS/MIA, IA were 0.70, 0.73, 0.88 in the same testing set.

Conclusion: The DLNN showed potential capability in differentiating AAH, IA from other adenocarcinoma subtypes, while failed to differentiate AIS and MIA. When combining AIS and MIA for reclassify adenocarcinoma subtypes from the perspective of treatment, the DLNN achieved reasonable performance, suggesting that DLNN might be useful in supporting clinical treatment decision whether to follow-up or take different resection for SSNs.

Keywords: lung adenocarcinoma, Deep learning, Sub-solid nodule
MA03.09 TRANSCRIPTOME-WIDE ASSOCIATION STUDY REVEALS CANDIDATE CAUSAL GENES FOR LUNG CANCER

A. Clementeau1, M. Lamontagne1, R. Carreras Torres1, M. Obeidat2, W. Timens3, P. Joubert1, C. Amos2, J. Mckay2, Y. Bossé4
1Institut Universitaire de Cardiologie Et de Pneumologie de Québec, Québec/QC/CA, 2International Agency for Research on Cancer, World Health Organization, Lyon/FR, 3The University of British Columbia Centre for Heart Lung Innovation, St Paul’s Hospital, Vancouver/BC/CA, 4Department of Pathology and Medical Biology, Gronick Research Institute, University of Groningen, University Medical Center Groningen, Groningen/NL, 5The Geisel School of Medicine at Dartmouth, Houston/US, 6Department of Molecular Medicine, Laval University, Québec/QC/CA

Background: Genome-wide association studies have identified robust susceptibility loci associated with lung cancer. As part of the OncoArray-TRICL consortium, we have recently completed the largest GWAS on lung cancer including 29,266 cases and 56,450 controls of European descent. The goal of this study is to integrate the complete GWAS results with a large-scale expression quantitative trait loci (eQTL) mapping study in human lung tissues (n=1,038) to identify candidate causal genes for lung cancer. Method: Transcriptome-wide association study (TWAS) was used to integrate GWAS and lung eQTLs and identify genes whose levels of expression in lung tissue are causally related to lung cancer. TWAS was performed on six histological and smoking subgroups, namely overall adenocarcinoma, squamous cell carcinoma, small cell carcinoma, never-smokers, and ever-smokers. Result: As expected, the main TWAS signal for all histological subtypes and ever-smokers was on chromosome 15q25. The genes most strongly associated with lung cancer at the top loci were IREB2 (P TWAS = 4.97E-104), and to a lower extent, CHRNA5 (P TWAS = 5.26E20) and HYK (P TWAS = 2.04E-17). TWAS-identified causal genes were different from those reported in GWAS including JAMLin1 on 23q33.3 in overall lung cancer (P TWAS = 1.39E-6) and adenocarcinoma (P TWAS = 2.09E-8), NOTCH4 on 6p21.32 in squamous cell carcinoma (P TWAS = 1.24E-12), ZNF218 on 6p22.1 in overall lung cancer (P TWAS = 3.41E-14) and ever-smokers (P TWAS = 2.99E-13), HIST1H2BD on 6p22.2 for small cell carcinoma (P TWAS = 3.54E-6), and NEXN on 1p31.1 in never-smokers (P TWAS = 2.64E-5). In addition, a new small cell carcinoma susceptibility locus was identified on 4q32.2 and associated with the expression levels of TMA16 (P TWAS = 4.2E-4). Conclusion: In conclusion, lung tissue TWAS on lung cancer, histological subtypes and smoking subgroups revealed novel causal genes in GWAS-nominated loci. A new locus for small cell carcinoma (4q32.2-TMA16) was also identified and will require further validation.

MONDAY, SEPTEMBER 24, 2018 - 10:30-12:00

MA03.10 POPULATION-BASED RELATIVE RISKS FOR LUNG CANCER BASED ON COMPLETE FAMILY HISTORY OF LUNG CANCER

L. Cannon-Albright1, W. Akerley2, S. Carr1
1Intramural, University of Utah, Salt Lake City/UT/US, 2Huntsman Cancer Institute, Salt Lake City/UT/US, 3Thoracic Surgery, University of Maryland School of Medicine, Baltimore/MD/US

Background: Published risk estimates for diagnosis of lung cancer based on family history are typically focused on close relatives, rather than a more diverse or complete family history. This study provides relative risks (RR) for lung cancer based on comprehensive family history data obtained from a statewide Cancer Registry linked to a high quality genealogy data resource. Risk estimates presented avoid common recall, recruitment, ascertainment, and cohort biases, and are based on an individual's (proband's) lung cancer family history constellation (pattern of lung cancer affected relatives). Method: A population-based genealogy resource linked to a statewide electronic SEER cancer registry estimated relative risks (RR) for lung cancer for an individual based upon the family history of cancer. Family history data available for a proband included degree of relationship (first to third-degree), paternal or maternal family lung cancer history, number of lung cancer affected relatives and age at diagnosis of affected relatives. Over 1.3M probands probands with specific family history constellation were identified. To estimate relative risks, the observed number of lung cancer cases among probands with a specific family history constellation was compared to the expected number using internal cohort-specific rates. Result: 50,048 lung cancer cases were identified. Significantly elevated RR was observed for each lung cancer first-degree relative (FDR) ranging from RR=2.57 (2.39, 2.76) for >= 1 FDR to RR=4.24 (1.56, 9.23) for >= 3 FDRs affected. In an absence of FDR family history, increased risk for lung cancer was significant for increasing numbers of affected second-degree relatives (RR ranging from 1.41 (1.30, 1.52) for > or = 1 SDR to 4.24 (1.56, 9.23) for >= 3 SDRs. This was also seen in the absence of FDRs and SDRs for affected third-degree relatives (TDR) ranging from 1.18 (1.11, 1.24) for 1 affected TDR to 1.55 (1.03, 2.24) for 4 or > 4 affected TDRs. RR were significantly increased with earlier age at diagnosis of a first-degree relative, and equivalent risks for paternal compared to maternal history were observed. Conclusion: This study provides unbiased, population-based estimates of lung cancer risk based on a proband's complete family history that can be 2-5 times increased. Estimates of RR for lung cancer based on family history are arguably very relevant clinically. The constellation RR estimates presented could serve in individual decision making to direct resource utilization, and could be pivotal in decision making for screening, treatment, and post treatment surveillance.

Background: Cemiplimab (REGN2810), a human monoclonal anti-PD-1, has exhibited substantial antitumor activity in patients with advanced malignancies in a first-in-human study. We report interim results of the Phase 1 expansion cohorts (ECs 1 and 2) of cemiplimab, alone or plus radiotherapy, in advanced NSCLC (NCT02383212). Method: Patients with advanced NSCLC who had relapsed after, or were refractory to, at least, first-line therapy received cemiplimab 200 mg Q2W in EC 1, or cemiplimab 3 mg/kg Q2W plus radiotherapy (9 Gy × 3 times/week 1 week after first dose of cemiplimab) to a single lesion in EC 2. For EC 2, or patients were required to have NSCLC for which palliative radiation therapy was indicated. Planned treatment duration was up to 48 weeks in both ECs. The co-primary objectives were to evaluate the safety, tolerability, and efficacy of cemiplimab, alone or plus radiotherapy. Tumor measurements (of non-irradiated lesions) were performed by RECIST 1.1 QBW. Result: As of Sept 1, 2017, 20 patients (13 M/ 7 F; median age 64.0 years [range,
Background: Prospective data on immunotherapy for NSCLC with oncogenic driver mutations are limited. We recently reported first results from the global IMMUNOTARGET registry (Mazières, ASCO 2018). Here, we present new data for PD-L1 and mutation subgroups. Method: In 2017, we started an international retrospective registry study ("IMMUNOTARGET") for patients with advanced NSCLC, known driver mutations (KRAS, EGFR, ALK, ROS1, BRAF, HER2, MET and RET) and PD-L1 immune checkpoint inhibitor therapy. Data collection is approved by University of Toulouse and Swiisfedics, and supported by University of Toulouse and Cantonal Hospital of Lucerne. Anonymized real-world data submitted to the coordinating center include: patient and disease characteristics, clinical data, therapeutic strategies, immune-related adverse events, best response, survival, and PD-L1 expression (optional). Statistical calculations including best response, median PFS and OS are done at University of Toulouse. Result: In April 2018, the registry included 551 pts from Europe, USA, Israel and Australia. Patients were 50% male/female, 28% current smokers, median age 60 years (range 28-83), 85% had PS0/1. Most (73%) tumors were stage IV at diagnosis, almost all (96%) were NSCLC. Materials and methods: In 2017, we started an international retrospective registry study ("IMMUNOTARGET") for patients with advanced NSCLC, known driver mutations (KRAS, EGFR, ALK, ROS1, BRAF, HER2, MET and RET) and PD-L1 immune checkpoint inhibitor therapy. Data collection is approved by University of Toulouse and Swisfedics, and supported by University of Toulouse and Cantonal Hospital of Lucerne. Background: Among patients with NSCLC and a PD-L1 tumor proportion score (TPS) ≥50%, the response rate to the PD-1 inhibitor pembrolizumab is ~45%. Whether certain subsets of patients with a PD-L1 TPS ≥50% are more likely to benefit from treatment with a PD-1 inhibitor is currently unknown. We compared outcomes among NSCLC patients treated with first-line pembrolizumab and different PD-L1 TPS groupings: 50-74% vs 75-100% or 50-89% vs 90-100%

Method: We retrospectively analyzed patients who received commercial pembrolizumab as first-line treatment for NSCLC with a PD-L1 TPS of ≥50% from the Dana-Farber Cancer Institute, Memorial Sloan Kettering Cancer Center, and Massachusetts General Hospital. Clinopathologic characteristics and clinical outcomes were compared among patients with a PD-L1 TPS of 50-74% vs 75-100% or 50-89% vs 90-100%. Event-time distributions were estimated using Kaplan-Meier and compared with the log-rank test. Result: 172 patients were included for analysis, with no inclusion in this study. In the entire cohort, the overall response rate (ORR) to pembrolizumab was 39.9%, median progression-free survival (mPFS) was 4.8 months, and median overall survival (mOS) was 20.6 months. Compared to patients with TPS 50-74% (N=108, 39.5%), patients with TPS 75-100% (N=104, 60.5%) had a significantly higher ORR (45.2% vs 20.6%, P<0.001), a significantly longer mPFS (5.3 vs 2.5 mo, HR=0.61 [95% CI: 0.41-0.91], P=0.008), and a trend towards improved mOS (33.6 vs 20.6 mo, HR=0.60 [95% CI: 0.34-1.04], P=0.056). Compared to patients with TPS 50-89% (N=99, 57.6%), patients with TPS 90-100% (N=73, 42.4%) had a significantly higher ORR (50.7% vs 24.2%, P<0.001), a significantly longer mPFS (6.4 vs 2.8 mo, HR=0.52 [95% CI: 0.36-0.76], P<0.001), and a significantly longer mOS (33.6 vs 18.0 mo, HR=0.46 [95% CI: 0.27-0.79], P<0.008). There were no significant differences in smoking history, histology, sex, and age between patients in each TPS cutoff group. Conclusion: Among NSCLCs with a PD-L1 TPS ≥50% treated with first-line pembrolizumab, higher PD-L1 TPS levels above 75% and 90% are associated with improved clinical outcomes compared to NSCLCs with lower PD-L1 TPS levels.

Background: In a subset of patients, named hyperprogressors (HPs), immunotherapy seems to paradoxically boost tumor growth. However, neither pathological and clinical features nor the underlying biological mechanism have been identified. We dissected the role of tumor-malignant cells interaction as possible players. Method: HPs were defined on the basis of clinical and radiological features. Baseline histological markers. We tested the effect on tumor growth of murine and human CD32b. No difference was observed between mice and human HPs. T cell compartment were observed. Murine and human PD1 blocking mAbs induced a boost of tumor growth in H460 xenografts in immunocompromised mice. Similar effect was observed in ESRF but not in KRAS+ and wt PD1x treated with human anti-PD1. Notably, no hyperprogression was observed after treatment with murine and human anti PD-1 (Fab2). Hyperprogressive tumors were enriched in arginase+ myeloid-macrophage cells and fibrotic features. ICI bind in vitro to human HPs macrophages and monocyttes interacting likely involving CD32b (FcgRIIb) and triggering functional polarization. Conclusion: Our results provide evidence that FcR triggering on macrophages by ICI delivers a signaling cascade promoting a functional reprogramming of these cells toward a more aggressive pro-tumorigenic behavior eventually inducing hyperprogression in a subset of patients with distinctive immune and genetic profile. A validation prospective study in ongoing.

MA04.07 MICRORNA-BASED LIQUID BIOPIST COMBINES WITH PD-L1 TUMOR EXPRESSION TO PREDICT RESPONSE TO IMMUNOTHERAPY IN ADVANCE NSCLC PATIENTS
1Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 2Medical Oncology 1, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 3Medical Oncology 2, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 4Thoracic Surgery, Fondazione IRCCS Istituto Nazionale Tumori, Milan/IT, 5Tumor Genomics, Fondazione IRCCS Istituto Nazionale Dei Tumori, Milan/IT

Background: The advent of the new immune checkpoint inhibitors (ICIs) targeting the PD-L1 axis drastically improves survival of advance non-small-cell lung cancer (NSCLC) patients. However, only a limited subset of patients actually benefits of ICIs treatment and PD-L1 as predictive biomarker has a limited reproducibility. We have previously identified a plasma microRNA-signature classifier (MSC) reflecting a circulating tumor-host interaction with diagnostic and prognostic value in low-dose computed tomography (LDCT) lung cancer screening trials. Method: The tumor immune contexture of 40 LDCT-screening detected lung tumors was characterized by the “cell-type identification by estimating relative subsets of RNA transcripts” (CIBERSORT) software. In a consecutive series of 84 advanced lung cancer patients treated with ICIs, both plasma and tissue samples were collected and prospectively analyzed. Both 2-years progression free (PFS) and overall survival (OS) in strata of plasma MSC risk level alone or combined with tumor PD-L1 expression were evaluated in univariate and multivariate analysis by log-rank test and Cox proportional hazards models. Result: A pro-tumorigenic immune contexture was identified in tumors of MSC high risk patients. Lower levels of cytotoxic CD8+ and CD4+ T cells and increased levels of γδ T cells, M2 macrophages characterized these tumors. In addition, genes differentially expressed according to MSC risk level (high vs. intermediate and low) were associated with 5-years OS in the screening series (p-values=0.02), as well as in additional 1000 cases from The Cancer Genome Atlas database (p-values<0.01). In the 84 advanced NSCLC patients treated with ICIs, the PFS hazard ratio ranged from 0.44 (95%CI: 0.25-0.75) of PD-L1 (adjusted p-value=0.005) and 0.38 (95%CI:0.2-0.73) of MSC (adjusted p-value=0.004) alone, to 0.25 (95%CI: 0.14-0.45) if combined (adjusted p-value=0.002). In the subgroup of 45 patients with both plasma and tumor tissue available, the combination of MSC and PD-L1 stratified patients in three groups with 2-years PFS ranging from 25% to 10% and 0% (p-value=0.01) according to the presence of 2, 1 or 0 favorable markers, respectively. Similar results were obtained when considering OS, where the median survival time for patients with no favorable markers was 5.6 months (p-value=0.0001). Conclusion: Overall, these findings suggest that a circulating microRNA-based risk level, reflecting an altered tumor immune contexture, could improve PD-L1 tumor tissue expression as predictive biomarkers of response to immunotherapy.

Background: Cisplatin-based chemotherapy, before or after surgery, provides only a 5% benefit in 5yr OS in resectable NSCLC. A 20 patient study (NEJM April 2018) showed that preoperative immune checkpoint inhibitor therapy yielded a clinically meaningful major pathologic response rate (MPR ≥10% residual viable tumor cells) and did not delay or complicate surgery. This large multicenter trial measures MPR and overall survival (OS) benefit using neoadjuvant atezolizumab (atze)-/chemo (atze/chemo) in stages IB-IIIA resectable NSCLC. [NCT02973701]. Method: We planned 2 cycles of atezo (1200mg, days 1, 22) in patients with stages IB-IIIa -selected IIIB resectable NSCLC prior to surgical resection (day 40 +/- 10). Chest CT. PET were planned pre-atezo and post-resection. Patients were divided into PD-L1 (+/+ -) and PD-L1 (-/- ) and blood samples were obtained before atezo and presurgery for biomarker studies. The primary endpoint was MPR. Secondary endpoints included safety, response by PD-L1, OS, and DFS. Result: For this updated efficacy and safety analysis (Feb'18 datacut), we report first 54 of 180 planned pts: 29 males, median age 65 yr, all ECOG 0-1, 17 current. 33 former smokers; 35 non-squamous NSCLC; clinical stages IIB/IIIA/IIIB/IVa = 11/13/20/5. Two pts received one dose of atezo due to treatment related AE (Gr 1 pyrexia, Gr 2 dyspepsia) but underwent uncomplicated recovery within two weeks of assessment. There was 1 unrelated Gr 2 AE (sudden cardiac death post surgical resection), 16 Gr 3-4 AEs (3 treatment related). Surgery was delayed in 1 pt due to Gr3 pneumonitis. By RECIST, 3 pts had PR, and 49 had SD. 50 pts underwent surgery and 47 pts had MPR assessment: 2 pts discontinued study prep due to radiographic PD and 2 discontinued due to other reasons; 3 pts had unresectable disease. MPR rate was 10/50 (20%, 95% CI 10-34%) including 3 pts who had pCR (no viable tumor cells) in the primary tumor. Excluding 5 pts with known driver mutations (EGFR 1, ALK 1), MPR rate was 10/45 (22%, 95% CI 11-37%), 11 pts had TPS ≥80% PD-L1+ status (TPS ≥50%). 5 of these 11 pts had high CD8+ T cell infiltrates (CD8+/Gr1% ≥60%) and 4 of these had high stromal cells (CD10+ ≥30%). Conclusion: In a multicenter study, neoadjuvant atezolizumab was well tolerated. Reactivity in confirming the role of checkpoint inhibitors in facilitating tumor clearance has been demonstrated in advanced NSCLC and has recently shown impressive efficacy in the neoadjuvant setting. The role of tumor mutational burden, and specifically T cells targeting neoantigens derived from these mutations, in promoting major pathologic response (MPR) and delaying relapse in resected post-treatment tissues. A bioinformatic platform was developed which identifies T cell receptor clonotypes corresponding to antigen specific T cells targeting neoantigens derived from these mutations, in facilitating tumor clearance. It has a high accuracy in predicting clinical and pathological responses are often discordant. Correlate analysis in blood samples are included in a separate abstract.

MA04.10 COMPREHENSIVE PERIPHERAL BLOOD IMMUNOPHENOTYPING AND T-CELL CLONAL ANALYSIS DURING NEOADJUVANT IMMUNOTHERAPY WITH ATEZOLIZUMAB IN NSCLC

1Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Dana-Farber Cancer Institute, Boston/MA/US, 3The University of Texas MD Anderson Cancer Center, Houston/TX/US, 4David Geffen School of Medicine at University of California, Los Angeles, Los Angeles/CA/US, 5Oncology, Johns Hopkins School of Medicine, Baltimore/MD/US

Background: Whole exome sequencing and neoantigen prediction was performed on pre-treatment tumor biopsies and matched normal tissue from 11 patients with resectable NSCLC treated with neoadjuvant nivolumab as part of a clinical trial (NCT02259621). T cell recognition of peptides representing candidate neoantigens was evaluated using the MANAFEAST assay, which identifies T cell receptor clonotypes corresponding to antigen specificities. T cell receptor sequencing was additionally performed on serial peripheral blood T cells, pre-treatment tumor biopsies, and resected post-treatment. A bioinformatics platform was developed to evaluate the dynamics of intratumoral T cell clonotypes, and more specifically neoantigen-specific clonotypes detected before, during, and after treatment and during long-term follow-up. Result: High-magnitude, polyclonal neoantigen-specific T cell responses were detected in the peripheral blood and persisted for many months after surgical resection and cessation of treatment. Binding to and stability with cognate HLA I molecules was validated for reactive neoantigens. Significant treatment-related evolution associated with clinical benefit would guide future immunotherapy development and support clinical decision-making. Here, we present an analysis of peripheral blood (PB) immunophenotyping and T-cell receptor (TCR) clonality before and after immunotherapy from an ongoing 180-patient phase II study of atezolizumab as neoadjuvant therapy with stage IB-IIIB resectable NSCLC (NCT02259621). Method: As of February 5th datacut, the first 54 enrolled and dosed patients are presented. The biomarker evaluable population (BEP) further subset to patients with paired PB samples analyzed within 72 hours after collection and a major pathological response (MPR) assessment. Comprehensive immunophenotyping (10-color flow cytometry, IMMUNOME) and TCR-VB analysis by flow cytometry were performed. Immunoprofile analyses were correlated with atezolizumab treatment, pathological response and PD-L1 expression. Result: In this ongoing analysis, BEP included 31 patients. 3 patients (10%, MPR ≥ 95% CI (5%, 34%)) all of which stained positive for PD-L1 by IHC using 22C3 (TPS≥1%) and SP142 (PD-L1 expression on ≥1% tumor cells (TC) and/or tumor infiltrating immune cells (IC)) at baseline. We observed significant increases in natural killer (NK) cells (p=0.005) and CD8+ T-cells (p=0.031) and a Th-1 related dendritic cell (DC) subpopulation (p=0.031) and significant decreases in B-cells (p=0.015) after treatment. Patients who achieved MPR show lower baseline levels of CD8+ T-cells (p=0.015), late-activated NK-cells (p=0.043), memory CD4+ T-cells (p=0.048) and memory CD8+ T-cells (p=0.032); changes in PB NK-cells (p=0.041), a decrease in M-MDSCs and a Th-2 and Th-17 response related DC subpopulation (p=0.043) in response to treatment were noted in patients with MPR versus non-MPR. Among the 16 patients with TC/IC 1/2/3 (> 1% PD-L1 expression) the fold changes in PD-L1 differences were observed compared to TC/ICO (7 patients): higher levels of late-activated CD4+ T-cells (p=0.025) and mid-activated CD8+ T-cells (p=0.044) at baseline, decrease of senescent T-cells (p=0.014), monocytecytoid suppressor cell subpopulations (M-MDSCs) and an increased CD4+ Th1-response related DC subpopulation (p=0.038) in responders. TCR clonality analysis showed expansions in Vβ-subtypes after atezolizumab treatment. Conclusion: Immunophenotyping and TCR-VB repertoire analysis in peripheral blood samples from NSCLC patients treated with neoadjuvant atezolizumab show differences in immune cell subsets in baseline samples and changes after treatment.

Keywords: neoadjuvant immunotherapy, immunophenotyping, NSCLC
induced systemic perturbations in the tumor-specific T cell repertoire and an influx of peripheral T cell clonotypes into tumor tissue and lymph nodes was observed in patients regardless of pathologic response, whereas peripheral clonotypic reshaping of the anti-tumor repertoire and intratumoral T cell clonality were associated with MPR status. Conclusion: We show significant and systemic alterations in the peripheral anti-tumor T cell repertoire in NSCLC patients treated with neoadjuvant anti-PD-1 regardless of MPR status. Notwithstanding, the impaired restructuring of the anti-tumor T cell repertoire in patients without MPR highlights a potential immunological deficiency to overcome in future therapeutic approaches aiming to increase the MPR rate in NSCLC patients treated with neoadjuvant PD-1 blockade.

MA05.01 E6508: PHASE II STUDY OF IMMUNOTHERAPY WITH TECEMOTIDE AND BEVACIZUMAB AFTER CHEMORADIATION IN UNRESECTABLE STAGE III NS-NSCLC

Background: Chemoradiation (CRT) is standard of care for unresectable stage III NSCLC. Tecemotide is a MUC1 antigen-specific cancer immunotherapy. Bevacizumab is considered to have a significant role in immunomodulation. Immune therapy in combination with VEGF blockade was tested in this phase II trial combining tecemotide and bevacizumab in patients with stage III NS-NSCLC. Method: Subjects with stage III NS-NSCLC suitable for definitive CRT received carboplatin(C) AUC 2 + paclitaxel(P) 45 mg/m2 weekly + 66 Gy/33fx/6.5wk and consolidation C AUC 6 + P 225 mg/m2 q21 days x 2. Patients with CR(PR/SD) were then registered onto Step 2 (S2). S2 was 6 weekly tecemotide injections followed by q6 weekly injections and bevacizumab 15 mg/kg q3 weeks for up to 34 doses. The primary endpoint was safety of tecemotide and bevacizumab after CRT and consolidation. The proportion of circulating dendritic cells and their expression of CD40, HLA-DR and CD123 (IL-3R) were analyzed by flow cytometry at various time points. Result: 70 patients were enrolled from Dec 2010 to Oct 2014; 68 started therapy, and 39 completed CRT and consolidation therapy. Reasons for discontinuation included progression (11) and toxicity (10). 33 patients were registered to S2. The median number of S2 cycles was 12 (range 2–34). S2 toxicity: gr 3 N=9 (6 hypertension), gr 4 N=1, gr 5 N=1. Among the treated and eligible patients (n=31), from study entry, the median PFS was 14.3 (95% CI 11.0–22.2) OS was 40.1 (95% CI 21.7–NA) months. A trend of increased expression of CD40 and HLA-DR on CD11c+ cells was observed at cycle 7.

Keywords: Immunotherapy, Stage III NSCLC, chemoradiation

Figure 1. Trend of lymphoid and dendritic cell populations during the course of therapy. Data shown are from the flow analysis of CD3, CD11c, CD40, HLA-DR and CD123 (IL-3R). A trend of increased expression of CD40 and HLA-DR on CD11c+ cells was observed at Cycle 7.

Conclusion: This cooperative group trial met its endpoint, demonstrating tolerability of tecemotide and bevacizumab after CRT and consolidation in NS-NSCLC pts. In this select group of patients, therapy with tecemotide and bevacizumab was associated with encouraging PFS and OS.

MA05.02 PACIFIC SUBGROUP ANALYSIS: PNEUMONITIS IN STAGE III, UNRESECTABLE NSCLC PATIENTS TREATED WITH DURVALUMAB VS. PLACEBO AFTER CRT
1University Hospitals Ku Leuven, Leuven/BE, 2Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins University, Baltimore/MD/US, 3Institute of Cancer Sciences, University of Manchester and the Christie NHS Foundation Trust, Manchester/GB, 4Istanbul University Cerrahpaşa School of Medicine, Istanbul/TR, 5Cancer Specialists of North Florida, Jacksonville/FL/US, 6Tennessee Oncology and Sarah Cannon Research Institute, Nashville/TN/US, 7Kanagawa Cancer Center, Yokohama/JP, 8Westmead Hospital and the University of Sydney, Sydney/AU, 9Chugoku National University Hospital, Chugoku National University College of Medicine, Cheongju/KR, 10Yonsei Cancer Center, Yonsei University College of Medicine, Seoul/KR, 11Nippon Medical School Hospital, Tokyo/JP, 12AstraZeneca, Cambridge/GB, 13AstraZeneca, Alderley Park/GB, 14AstraZeneca, Gaithersburg/MD/US, 15H. Lee Moffitt Cancer Center & Research Institute, Tampa/FL/US

Background: In the Phase 3 PACIFIC study of durvalumab versus placebo in patients with stage III, unresectable non-small cell lung cancer (NSCLC) after concurrent chemoradiotherapy (cCRT), on-treatment pneumonitis or radiation pneumonitis (‘pneumonitis’) occurred in both arms with similar rates of grade 3/4 pneumonitis (durvalumab, 3.4%; placebo, 2.6%). We performed exploratory analyses to further characterize time to onset and duration of pneumonitis and examine its relationship with underlying risk factors, including patient characteristics and prior CRT. Method: PACIFIC (NCT02125461) was a randomized, double-blind study of patients with WHO PS 0/1 without progression after ≥2 cycles of platinum-based cCRT. Patients were stratified by age, sex, and smoking history and randomized (2:1) 1–42 days after completing cCRT to durvalumab 10 mg/kg IV Q2W or placebo. Median time to onset of pneumonitis from treatment start was the same for both durvalumab and placebo, 55.0 days (73.0 and 76.5 days from RT completion). Pneumonitis was stratified by grade, sex, and smoking history and randomized (2:1) 1–42 days after completing cCRT to durvalumab 10 mg/kg IV Q2W or placebo up to 12 months. Potential associations between the presence of the AE pneumonitis (investigator assessed with review/adjudication by study sponsor) and baseline characteristics or patient disposition were investigated. Result: As of Feb 13, 2017, 709 patients had received treatment: 33.6% on durvalumab and 24.9% on placebo had any-grade pneumonitis. Treatment exposure was similar in patients with or without pneumonitis across both arms. Median time to onset of pneumonitis from treatment start was the same for both durvalumab and placebo, 55.0 days (73.0 and 76.5 days from RT completion). Pneumonitis was self-limited, with median durations of 64.0 and 57.0 days, respectively. Patients with pneumonitis were more likely to be Asian (47.9% vs 17.6%).

Keywords: Immunotherapy, Stage III NSCLC, chemoradiation
or have EGFR mutations (11.0% vs 3.8%); however, the proportions of patients with pneumonitis and these risk factors were numerically lower with durvalumab than with placebo (Asian: 44.4% [71/160] vs 57.6% [34/59]; EGFRm: 10.6% [17/160] vs 11.9% [7/59]), suggesting no apparent interaction with treatment. There were no apparent associations of pneumonitis with baseline respiratory disorders, prior RT dose, or prior cisplatin or carboplatin use. Previous induction CT was more commonly associated with the absence of pneumonitis in both treatment arms (durvalumab: 30.1% vs 17.5%; placebo: 31.5% vs 20.3%). The presence of pneumonitis was associated with greater discontinuation due to AEs (durvalumab: 25.6% vs 10.2%; placebo: 18.6% vs 6.8%) regardless of treatment. Conclusion: Rates of pneumonitis were higher in Asian patients and those with EGFRm, as previously reported. Durvalumab did not increase pneumonitis in patients with these risk factors. There were no differences in treatment exposure in patients based on the presence/absence of pneumonitis. Multivariate analyses may further assist in the discernment of etiologic risks.

MA05.03 IMMUNE MICROENVIRONMENT AND ITS ASSOCIATION WITH ADJUVANT CHEMOTHERAPY BENEFIT IN LOCOREGIONALLY ADVANCED LUNG ADENOCARCINOMA

R. Vaghjiani1, T. Eguchi1, N. Chintala1, X. Li1, R. Aly2, K. Emoto1, K.S. Tan1, D. Joffes3, P. Adusumilli3
1Thoracic Service, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Thoracic Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York/NY/US, 3Epidemiology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US

Background: The impact of the tumor immune microenvironment on the effectiveness of platinum-based adjuvant chemotherapy (ACT) in locoregionally advanced (stage II-III) lung adenocarcinoma (ADC) is unknown. We performed an analysis of the cellular components of the tumor and tumor-associated stromal immune environment in stage II-III lung ADC and examined their association with ACT benefit. Method: Tissue microarrays (6 tumor and 3 stromal cores from each tumor) were constructed using resected tissue from patients with pT2-T4N1 lung ADC (n=500, 2000-2012) who did (n=225) and did not (n=275) receive ACT. Multiplex immunofluorescence was used to determine the quantity, localization, and colocalization of 21 types of immune cells and markers (including PD-1, PD-L1, CD3, CD8, CD20, CD68, CD163, MPO, and PanCK). The association between immune cell infiltration and recurrence free probability (RFP) was compared using Kaplan-Meier methods, and benefit from ACT by unsupervised hierarchical cluster modeling. Result: Overall, increased tumoral infiltration of CD20+ B-cells and CD3+ and CD4+ T-cells was associated with an improvement in 5-yr RFP (CD20+ low vs high: 37% vs 49%, p=0.03; CD3+: 39% vs 48%, p=0.003; and CD4+: 39% vs 47%, p=0.02, respectively) whereas increased stromal MPO+ neutrophil infiltration was associated with a worse 5-yr RFP (CD20+ low vs high: 50% vs 38%, p=0.05; CD3+: 39% vs 48%, p=0.003; and CD4+: 39% vs 47%, p=0.02, respectively). Among patients who received ACT, cluster modeling revealed 5 risk groups (Groups A-E; Figure) with immune signatures including tumoral CD20+ B-cells and CD3+ and CD4+ T-cells and CD163+PD-L1+ macrophages as well as stromal CD57+ NK-cells and CD163+PD-L1+ macrophages that provided a progressive stratification of RFP following adjuvant treatment.

Conclusion: Immune infiltration analysis can predict benefit from ACT and thereby provide a rationale to select patients for either chemotherapy, immunotherapy, or combination therapy following surgical resection.

MA05.05 PHOTON-BASED CARDIAC SPARING VIA VOLUMETRIC MODULATED ARC THERAPY IN THORACIC RADIATION THERAPY FOR LOCALLY ADVANCED NON-SMALL CELL LUNG CANCER

M. Ferris1, K. Sykes1, O. Kayode1, J. Wolff1, R. Press1, J. Switchenko2, W. Curran, Jr.1, K. Higgins1
1Radiation Oncology, Winship Cancer Institute at Emory University, Atlanta/GA/US, 2Biostatistics & Bioinformatics, Winship Cancer Institute at Emory University, Atlanta/US

Background: Increasing radiation dose to the heart is associated with worse survival in stage III non-small cell lung cancer. Techniques to reduce the dose to the heart, including proton beam therapy (PBT), are being evaluated in ongoing clinical trials. However, advanced technologies such as PBT are not readily accessible for most patients. We therefore sought to evaluate the efficacy of volumetric modulated arc therapy (VMAT), a readily available technology in the United States, to spare cardiac substructures and determine how a cardiac optimization treatment planning algorithm influences dose distribution to other thoracic organs at risk (OARs). Method: We selected stage III non-small cell lung cancer patients who were treated at our institution with VMAT to 60 Gy in 2 Gy fractions. Cardiac substructures were retrospectively contoured, and included: valves, atroventricular node (AVN), coronary arteries (CA), chambers, and great vessels. New radiation treatment plans were created to spare these structures while preserving planning target volume (PTV) coverage and maintaining standard dose constraints to OARs. Dosimetry variables—maximum dose (Dmax), mean dose (Dmean), and common clinically relevant dose-volume relationships—for the new cardiac-sparing radiation treatment plans were compared via paired t-test to the original radiation treatment plans. Result: Twenty-six patients, treated from July 2013 to September 2017, were included. Statistically significant improvements were demonstrated for all cardiac structures for the new cardiac-sparing plans compared to the original plans, while maintaining appropriate lung, esophagus, and spinal cord constraints, and PTV coverage goals, as demonstrated in Table 1 (significant P-values in bold). Conclusion: Dose to the heart and cardiac substructures can be substantially lowered using a cardiac-sparing optimization algorithm with VMAT, which results in increased lung dose on breath hold (DIBH) without compromising PTV coverage. Though time-consuming, delineation of the full complement of cardiac substructures provides an effective means of improving the quality of radiation treatment plans with readily available technologies.

MA05.06 LOCALLY ADVANCED LUNG CANCER RADIOTHERAPY IN DEEP INSPIRATION BREATH HOLD: DOSIMETRIC BENEFITS FROM A PROSPECTIVE TRIAL
M. Josipovic1, M. Aznar2, J. Rydhög3, J. Thomsen1, S. Damkjaer1, L. Nygård1, M. Pohl1, S. Langer1, L. Specht1, G. Persson1
1Department of Oncology, Rigshospitalet Copenhagen University Hospital, Copenhagen/DK, 2Division of Cancer Sciences, Manchester Cancer Research Centre, Manchester/GB, 3Radiation Physics, Skåne University Hospital, Lund/SE

Background: Radiotherapy for locally advanced non-small cell lung (NSCLC) cancer is often complicated by treatment-related toxicity. Here, we report dosimetric benefits of DIBH for NSCLC at a single academic institution.

Method: Patients referred for definitive radiotherapy of locally advanced NSCLC (66Gy/33 fractions) were included from May 2015–Dec 2017. All patients underwent respiratory coaching for voluntary visually guided DIBH and were imaged with PET/CT, 4D-CT and DIBH-CT. Target volumes were defined according to national guidelines. PTV margins were patient- and modality-specific. For all patients, FB and DIBH plans were made with volumetric modulated arc therapy, with equal PTZ coverage. The plan with the lowest lung and/or heart dose was chosen for treatment. Normal tissue complication probability for pneumonitis was calculated retrospectively based on a logistic dose response model. Result: The treatment intent was maintained in 69 of included 88 patients (2 patients were downstaged, 12 upstaged, 2 withdrew consent, other causes in 3). 62/69 were DIBH compliant and in 61 patients a FB and a DIBH plan were made (in one patient, 4DCT image quality was not sufficient). In 54/61 patients, the DIBH plan was chosen for treatment. 3/54 patients lost DIBH compliance within the first few fractions. All data is presented as median (range), with p<0.001 (Wilcoxon signed rank). Lung volume increased in DIBH by 5% (20–168%). Compared to FB, DIBH reduced mean lung dose from 14.4Gy (1.2–25.3Gy) to 11.8Gy (1.0–20.4Gy), and lung V20 from 23.7% (1.5–47.8%) to 20.8% (1.2–39.7%). Reduced lung dose translated to decreased pneumonitis risk: from 8.6% (2.3–23.3%) to 6.5% (2.1–14.4%). Lung dose constraints were violated in 5/62 patients in FB and 1/62 patients in DIBH. Mean heart dose was reduced from 3.6Gy (0.1–25.8Gy) in FB to 2.4Gy (0.1–25.3Gy) in DIBH. DIBH reduced mean heart dose in 44/61 patients. The differences between FB and DIBH varied between –7% and 0%, while there was a 9Gy difference in the heart dose on the second cycle, with either 2 Gy daily, 5 days a week, to a total dose of 68 Gy (standard arm A) or escalated therapy (B) based on constraints to the spinal cord, esophagus and lungs up to 84 Gy by adding an extra fraction of 2 Gy per week while keeping the total treatment time constant at seven weeks with the same dose to involved nodes and primary tumor. Result: A pre-planned safety analysis revealed excessive toxicity and decreased survival in the escalated arm, and the study was stopped. Thirty-six patients were included during 2011-2013 (56% male, 78% with adenocarcinoma, 64% with PS 0 or 1, 53% with stage IIIB). The median progression-free survival (PFS) and overall survival (OS) were 11 and 17 months in the dose escalated group compared to 28 and 45 months in the standard group. The 1-, 3- and 5-year survival rates were 56%, 33% and 17% in the escalated arm and 72%, 61% and 34% in the standard arm. There were four toxicity-related deaths due to esophageal perforations (one in arm A and three in arm B) and three deaths due to pneumonitis (one in arm A and two in arm B). Conclusion: Dose escalated concurrent chemoradiotherapy to 84 Gy for locally advanced NSCLC and nodal disease is hazardous, with a high risk of excessive toxicity, whereas modern standard dose chemoradiotherapy with proper staging given in the control arm shows a promising outcome with a median survival of 45 months and a 5-year survival of 34%. A possible step forward will be to improve future approaches with escalated radiotherapy may include boost techniques to remaining PET positive areas or different escalation schedules to the primary tumor and mediastinal nodes.

MA05.09 PFS AND CARDIAC-TOXICITY-ADJUSTED-PFS AS PREDICTORS OF OS IN LOCALLY ADVANCED NSCLC TREATED WITH CONCURRENT CHEMORADIATION
C. Hu1, M. Machtya2, J. Dignam3, R. Paulus4, J. Bradley5
1NRG Oncology Statistics and Data Management Center, Philadelphia/PA/US, 2Department of Radiation Oncology, Uh Cleveland Medical Center, Case Western Reserve University, Cleveland/DH/US, 3Radiation Oncology, Washington University School of Medicine, St. Louis/MO/US

Background: Overall survival (OS) is the gold standard for LA-NSCLC with concurrent chemoradiotherapy. While the correlation between PFS (PD) and OS are also of increasing scientific and clinical interest. Method: NRG Oncology RTOG 0617 (NCT00533949) was a randomized phase 3 (1:1) comparing standard (SD) and escalated (ED) treatment arms. Results are similar when using CTA-PFS with 6mo or 12mo time points. CTA-PFS event was the first occurrence of grade 2+ treatment-related toxicity event or a PFS event. Landmark analyses at 6mo were used to minimize the immortal time bias. Cox model related cardiac toxicity event or a PFS event. Landmark analyses at 6mo were used to minimize the immortal time bias. Cox model related cardiac toxicity event or a PFS event. Results were 13.4mo (95%CI: 10.0-19.0mo) and 30.7mo (95%CI: 28.0-37.0mo) for SD and ED, respectively. Results were 13.4mo (95%CI: 10.0-19.0mo) and 30.7mo (95%CI: 28.0-37.0mo) for SD and ED, respectively. The 1-, 3- and 5-year OS were 56%, 33% and 17% in the escalated arm and 72%, 61% and 34% in the standard arm. The median progression-free survival (PFS) and overall survival (OS) were 11 and 17 months in the dose escalated group compared to 28 and 45 months in the standard group. The 1-, 3- and 5-year survival rates were 56%, 33% and 17% in the escalated arm and 72%, 61% and 34% in the standard arm. There were four toxicity-related deaths due to esophageal perforations (one in arm A and three in arm B) and three deaths due to pneumonitis (one in arm A and two in arm B). Conclusion: Dose escalated concurrent chemoradiotherapy to 84 Gy for locally advanced NSCLC and nodal disease is hazardous, with a high risk of excessive toxicity, whereas modern standard dose chemoradiotherapy with proper staging given in the control arm shows a promising outcome with a median survival of 45 months and a 5-year survival of 34%. A possible step forward will be to improve future approaches with escalated radiotherapy may include boost techniques to remaining PET positive areas or different escalation schedules to the primary tumor and mediastinal nodes.

Background: Neoadjuvant concomitant chemoradiation (NACCRT) was historically limited to 45 Gy. We recently published data on the safety of a higher radiation dose in this setting. Here we evaluate the pathologic response of locally advanced non small cell lung cancer (LANSCLC) treated with 60 Gy NACCRT combined with modern IGRT. Method: Our cohort comprised patients that underwent NACCRT followed by surgery during August 2012–December 2017 at our institution. We retrospectively collected the demographic, stage, histology, and treatment details. Radiation was planned using eclipse system to deliver 2 Gy per fraction to a total of 60 Gy Treatment effect was determined from the pathologic specimen in accordance with College of American Pathologists recommendations, based on the modified tumor regression grading. Favorable pathologic responses included major tumor regression (MTR); we also evaluated the average percent of the residual tumor cells seen in the specimen. Statistical analysis was performed to analyze treatment effect on the pathologic response using spearman correlation and Cruskal-Wallis test with SPSS software v.24. Result: Our cohort included 70 patients. Mean age was 63 years (range 45–79.7), men n=49 (70%), smoking status: never smokers n=11 (16.2%), past smokers n=10 (14.7%), current smokers n=47 (69.1%). Histology consisted adenocarcinoma n=42 (60%), squamous n=21 (30%) and other n=7 (10%). Stage T2 were n=65 (78.3%) and stage T3 n=15 (21.4%). Chemotherapy consisted of platinum-doublet administered to 69 patients (98.5%). A mean radiation dose of 59 Gy (range 46–72 Gy) was delivered with IGRT prior to each fraction. Five patients received lower radiation doses due to toxicity or dose constraints. Surgery comprised of lobectomy n=50 (71.4%), chest wall resection n=9 (12.9%) or pneumonectomy n=11 (15.7%). Negative surgical margins were achieved in n=63 (90%) and positive margins in n=7 (10%). Stage N2 were n=65 (78.3%) and stage N3 n=15 (21.4%). Chemotherapy consisted of platinum-doublet administered to 69 patients (98.5%). A mean radiation dose of 59 Gy (range 46–72 Gy) was delivered with IGRT prior to each fraction. Five patients received lower radiation doses due to toxicity or dose constraints. Surgery comprised of lobectomy n=50 (71.4%), chest wall resection n=9 (12.9%) or pneumonectomy n=11 (15.7%). Negative surgical margins were achieved in n=63 (90%) and positive margins in n=7 (10%). Stage T2 were n=65 (78.3%) and stage T3 n=15 (21.4%). Chemotherapy consisted of platinum-doublet administered to 69 patients (98.5%). A mean radiation dose of 59 Gy (range 46–72 Gy) was delivered with IGRT prior to each fraction. Five patients received lower radiation doses due to toxicity or dose constraints. Surgery comprised of lobectomy n=50 (71.4%), chest wall resection n=9 (12.9%) or pneumonectomy n=11 (15.7%). Negative surgical margins were achieved in n=63 (90%) and positive margins in n=7 (10%). Stage N2 were n=65 (78.3%) and stage N3 n=15 (21.4%). Chemotherapy consisted of platinum-doublet administered to 69 patients (98.5%). A mean radiation dose of 59 Gy (range 46–72 Gy) was delivered with IGRT prior to each fraction. Five patients received lower radiation doses due to toxicity or dose constraints. Surgery comprised of lobectomy n=50 (71.4%), chest wall resection n=9 (12.9%) or pneumonectomy n=11 (15.7%). Negative surgical margins were achieved in n=63 (90%) and positive margins in n=7 (10%). Stage N2 were n=65 (78.3%) and stage N3 n=15 (21.4%).

Conclusion: Pathologic response of NACCRT treated with higher radiation doses is promising. The median 6.5%. Percent of residual tumor cells did not correlate to pathological complete response in 25 (35.7%) and < 10% residual tumor cells n=7 (10%). 30-day mortality was n=2 (2.8%) both cases after Right-sided pneumonectomy. Surgical margins were achieved in n=63 (90%) and positive margins in n=7 (10%).

MA05.11 RADIOMICS ANALYSIS USING SVM PREDICTS MEDIASTINAL LYMPH NODES STATUS OF SQUAMOUS CELL LUNG CANCER BY PRE-TREATMENT CHEST CT SCAN

X. Wang1, W. Nan1, S. Yan1, Q. Li2, N. Guo3, Z. Guo2
1Department of Thoracic Surgery II, Peking University Cancer Hospital & Institute, Key Laboratory of Carcinogenesis and Translational Research (Ministry of Education), Beijing/CH, 2Radiology, Massachusetts General Hospital, Harvard Medical School, Boston/US

Background: Assessment of mediastinal lymph nodes (N2 station) is essential in staging patients with Non-small-cell lung cancer (NSCLC), for patients with pathologic confirmed N2 status should follow neoadjuvant therapy before surgery, and occult N2 status should be avoided. There are several invasive and non-invasive exams available for preoperative N staging, like EBUS-TBNA and PET-CT scan. Chest CT scan was the basic examination of every patient, while only the length of minor axis could be used to predict lymph node involvement, and the potential value of CT might be underestimated. In this study we aimed to explore the value of radiomics analysis with machine learning in differentiating N2 from N0/N1 subjects using pre-treatment chest CT. Method: Ninety-three patients with squamous cell lung cancer, who underwent pre-treatment CT scans were included in this study. By use of Laplacian of Gaussian (LoG) filter and matrix based radiomics models (e.g. gray-level co-occurrence matrix), comprehensive radiomics features were extracted from the regions of interest which were manually delineated on primary tumors. We performed radiomics analysis using support vector machine (SVM) to test texture and heterogeneity features derived from pre-treatment CT images as indicators for the staging of lymph node metastasis, especially N2. The gold standard of N staging is confirmed pathologically after systematic mediastinal lymphadenectomy (N2 subjects =31). Result: For the performance evaluation of single image feature, there are 16 features able to differentiate N2 subjects from others (N0 and N1) with p value <0.05. Furthermore, SVM training and classification were performed using 5-feature combinations as inputs. With feature selection, the best performance of N2 prediction is 83% accuracy with 87% sensitivity and 81% specificity.

Background: Lung cancer is the most frequent cause of cancer death. Programmed death 1 (PD-1) in T cells and its ligand PD-L1 in tumor cells play a key role in immune checkpoint therapy and had applied to advanced stage lung cancer. Migration and invasion of tumor cells is a prerequisite for tumor cell metastasis. Since intrinsic PD-1 receptor functions promote tumor growth was reported, we will investigate the interaction between PD-1 and PD-L1 in lung adenocarcinoma cell lines, the impact on chemosensitivity, and clinical outcome. Method: In vitro experiments, lung adenocarcinoma CL1-5 cells, derived from CL1-0 cells. We prepared PD-L1-overexpression human lung adenocarcinoma cell line.
derived from CL1-0 cells (CL1-0-PD1). Migration and invasion ability were assessed by transwell assay. EMT marker and regulator were evaluated by Western blot. We also observed the reciprocal interaction between PD1 and PD-L1, we added anti-PD-1 antibody into CL1-0, CL1-5, and CL1-0-PD1 cells, and then test migration, invasion, and cellular morphology. We also suppressed PD-1 by siRNA to test whether PD-1/PD1-L1 interaction contributed to the EMT change. Further, we evaluated cellular proliferation and chemosensitivity by MTT assay and colony formation assay. We will correlate PD-1 expression in lung cancer cells with clinical outcome by IHC stain clinically. Result: In CL1-0 derived from CL1-0 cells, with high PD-1 expression possessed higher cellular migration ability than the parental CL1-0 cells with less PD-L1 expression. CL1-0 cells with PD-L1 overexpression had more expression of EMT (epithelial mesenchymal transition) regulator and mesenchymal maker. We also observed that CL1-5 and CL1-0-PDL1, which had more PD-L1 expression, showed like spindles; while CL1-0 cells are more rounded. Therefore, PD-L1 up-regulated cell migration and invasiveness in human lung adenocarcinoma cells and promotes EMT. After adding anti-PD-1 antibody in CL1-5, CL1-0, and CL1-0-PD1 cells, migration and invasion ability decreased. This result indicated PD-1 antibody block the link between PD-1 and PD-L1 in cancer cells. The phenomenon was confirmed by PD-1 siRNA. Therefore, PD-1/PD-L1 axis regulated cancer cells migration and invasiveness. PD-L1 expression also decreased cellular proliferation and had little influence on chemosensitivity. Finally, we found that higher PD-L1 expression was correlated with lymph node metastasis in clinical specimen. Conclusion: Lung adenocarcinoma cells with higher PD-L1 expression promote cell proliferation, invasion and EMT, and increase chemoresistance. PD-L1 expression lowers proliferation rate. PD-1 and PD-L1 interaction on lung adenocarcinoma cells contribute cellular migration and invasiveness.

**MA06.02 PROSPECTIVE IMMUNOGENOMIC PROFILING OF NON- SMALL CELL LUNG CANCER: GENOMIC AND IMMUNE PROFILING UPDATES FROM PROJECT ICON**

1Department of Oncology, Clinica Universidad de Navarra, Pamplona/ES, 2Program in Solid Tumors, Center for Applied Medical Research (CIMA), Pamplona/ES, 3Department of Oncology, Clinica Universidad de Navarra, Madrid/ES, 4Program in Immunotherapy, Center for Applied Medical Research (CIMA), University of Navarra, Pamplona/ES, 5Program in Solid Tumors, Center for Applied Medical Research (CIMA), University of Navarra, Pamplona/ES

**Background:** From 2016-2018, 127 patients were accrued and 50 surgical resection were performed. The majority of patients had upfront surgery (76/50, 90%). With median follow-up of 19 months, 15 patients have relapsed. Median tumor mutational burden is 7.8mut/m and predicted neoantigen burden was 10/sample (range: 0-250). Predicted neoantigen burden is significantly correlated with PD-L1 expression (r=0.4, p=0.002). The most commonly mutated genes are TP53, KRAS, CDK2NA, PK3CA, EGFR, BRAF, GRIN2A and ATM. C-A transversions and C-T transitions were the most common mutational subtypes. PD-1 expression and regulation of T-cell (CD4+FOXP3+) infiltration are significantly increased in tumor tissue compared to normal tissue (p=0.003 and p=0.02 respectively), while CD3, CD8, granzyme B and CD45RO are decreased in tumor tissue compared to normal lung. Conclusion: NSCLC tumors have an immunosuppressive microenvironment compared to tumor adjacent normal lung tissues. Clinical data will be adequate to conduct genomic and immune profiling comparisons across different clinical subgroups. Mutational and neoantigen profiling are consistent with previously reported studies and correlations between molecular and immune landscapes and its impact on patient survival are ongoing.

**MA06.03 PD-1 AND ID1 COMBINED BLOCKADE IMPACTS TUMOR GROWTH AND SURVIVAL THROUGH PD-1 EXPRESSION AND TUMOR INFILTRATION BY IMMUNE-RELATED CELLS**

I. Gil-Bazo1, I. Barabari1, M. Roman Moreno1, I. Lopez2, J. Corral3, J. Llasarte4, A. Calvo5, S. Vicent2, D. Ajona3

1Department of Oncology, Clinica Universidad de Navarra, Pamplona/ES, 2Program in Solid Tumors, Center for Applied Medical Research (CIMA), Pamplona/ES, 3Department of Oncology, Clinica Universidad de Navarra, Madrid/ES, 4Program in Immunotherapy, Center for Applied Medical Research (CIMA), University of Navarra, Pamplona/ES

**Background:** PD-1/PD-L1 inhibitors are approved in advanced non-small cell lung cancer (NSCLC). Long-term survival rates associated to PD-1/PD-L1 blockade have changed treatment paradigm. However, many patients do not benefit from PD-1/PD-L1 blockade. New therapeutic combinations are under investigation. Id1 is involved in proliferation, angiogenesis and immunosuppression. We described Id1 as an independent prognostic factor in NSCLC (Ponz-Sarvise, Clinic Cancer Res 2011) and more recently showed Id1’s role in lung cancer metastasis (Castanon, Cancer Letters 2017). Here we test a combined therapeutic strategy targeting PD-1 and Id1 in a murine lung cancer model. Method: Three in vivo studies evaluated the impact of Id1 inhibition in tumor cells, tumor microenvironment and in both, on tumor volumes and mice survival. A syngeneic tumor model using C57BL/6 and Id1-/- , Id1+/+ mice was created by subcutaneous injection of Lewis Lung Carcinoma (3LL) cells with Id1 silenced 3LL (Id1Shi) cells. After injection, mice were treated with an anti-PD-1 (RMP-1-14) monoclonal antibody or PBS. Tumor volumes according to mice strain, Id1 status in tumor cells and multiplexed immunohistochemistry results will be presented at the meeting. Result: Id1 inhibition in the tumor environment and the injected tumor cells, combined with anti-PD-1 treatment, induced a significant tumor growth impairment (p < 0.0001) and increased survival (p = 0.0051). CD3+ and CD8+ TILs and tumor CD68+ cells were quantified by specific immunostainings. Result: Id1 inhibition in the tumor environment and the injected tumor cells, combined with anti-PD-1 treatment, induced a significant tumor growth impairment (p < 0.0001) and increased survival (p = 0.0051). CD3+ and CD8+ TILs and tumor CD68+ cells were quantified by specific immunostainings. Result: Id1 inhibition in the tumor environment and the injected tumor cells, combined with anti-PD-1 treatment, induced a significant tumor growth impairment (p < 0.0001) and increased survival (p = 0.0051). CD3+ and CD8+ TILs and tumor CD68+ cells were quantified by specific immunostainings.

MA06.05 THE MICRO-ENVIRONMENTAL CROSS TALK BETWEEN MAST CELLS AND LUNG CANCER CELLS THROUGH CELL-TO-CELL CONTACT

B. Shemesh1, Y. Gorzalczany2, S. Geva1, L. Roisman1, R. Sagi-Eisenberg3, N. Peled4
1Dept. of Cell and Developmental Biology, Sackler Faculty of Medicine, Tel Aviv University, Tel Aviv/IL, 2Institute of Oncology, Soroka Medical Center, Ben-Gurion University, Beer-Sheva/IL

Background: Mast cells (MCs) are key effectors in allergic reactions, but are also involved in tissue remodeling, wound healing and protection against pathogens. MCs infiltrate tumors and their number within the tumor microenvironment in certain cancer types, such as lung cancer, have been correlated with poor prognosis. The nature of crosstalk between lung cancer and MCs remain poorly resolved. In this study, we investigated the activation patterns within the MCs following cell-to-cell contact with lung cancer cells showing CD73 involvement and implying metabolic changes. Method: Human MCs (HMC-1 and LAD-2) were exposed to Human lung cancer cells (H1299), derived membranes to recapitate cell contact mediated activation. Lyases of MCs were tested for protein expression and post-translational modifications (i.e. phosphorylation) by targeted western blotting. We unraveled the intracellular signaling molecules that are necessary for this signaling pathway by a pharmacological approach using several inhibitors. Each condition was repeated at least twice. Result: H1299 membrane exposure activated the ERK 1/2 MAP kinases in HMC-1 and in LAD-2 cells. AKT signaling was also activated in LAD-2 cells as a result of this contact. CD73 dephosphorylates AMP to adenosine within the MCs. Interestingly enough, this ERK 1/2 activation was inhibited by CD73 inhibitor and A3 receptor antagonists in HMC-1 cells. ERK 1/2 activation was inhibited by A3 receptor antagonists and PI3K in LAD-2 cells. Furthermore, we discovered that protein kinase C (PKC) inhibitor augments the activation of ERK 1/2 in LAD-2 cells. In contrast, PKC inhibitor inhibits the activation of ERK 1/2 in HMC-1 cells. In addition, we discovered that the AKT activation was inhibited by A3 receptor and PI3K inhibitors but not by CD 73 inhibitors. Conclusion: Our results suggest that H1299 membranes activate ERK 1/2 in HMC-1 cells by a mechanism that involves autocrine formation of adenosine, which is mediated by CD 73 and A3 receptor. In contrast, we discovered that there is an important difference between the ERK 1/2 MAP kinase signal transduction in HMC-1 and LAD-2 cells. PKC is an inhibitor of the H1299 activation of ERK 1/2 in LAD-2 cells. In contrast, the H1299 membrane activation of ERK 1/2 kinase in HMC-1 cells is mediated by PKC. Furthermore, we can conclude that H1299 membranes activate AKT in an A3 receptor dependent mechanism that is mediated by PI3K.

Background: Anti-tumor efficacy of human immunotherapeutic agents, such as antibodies, chimeric antigen receptor (CAR) and T-cell receptor transduced T cells, are currently being investigated in immunodeficient mice prior to clinical translation. We developed and optimized an ex-vivo culture system utilizing malignant pleural effusions (MPEs) to compliment these investigations in a human, immunocompetent, tumor-like environment. We hypothesized that CAR T cells’ cytotoxicity will vary by the different immune compositions in each MPE, which are conditions unavailable in current effiacy assays. Method: Mesothelin-targeted CAR T cells from multiple donors were exposed to MPEs derived from non-small cell lung cancer patients (n=15) and RPMI culture medium. Influence of the MPEs on CAR T-cell efficacy was evaluated by viability and phenotype (flow cytometry), cytotoxicity (chromium release assay), and gene expression (NanoString). Group-based trajectory modeling was used to stratify the inhibitory effect of MPEs. MPE composition (ELISA and Luminox assays) was evaluated to interpret its influence on CAR T cells. Result: With the incorporation of our optimized protocols, T cells retain their viability, phenotype (CD4/CD8), and percentage of CAR expression when cultured in MPEs. MPE soluble factor levels remained stable over multiple freeze/thaw cycles. CAR T cells co-cultured in MPE exhibited variable antigen-specific cytotoxicity (Fig. A). MPE-induced T-cell inhibition of was stratified into groups of strong, mild, or no inhibition. (Fig. B). Compared to MPEs with either mild or no inhibition, MPEs with strong inhibition had significantly higher levels of TGFβ-2 (average TGFβ-2 level in strong vs. mild inhibition: 402 vs. 50 pg/mL, p<0.05) (Fig. C), IL-6, RANTES, and IL-5.

Conclusion: Our results suggest that H1299 membranes activate ERK 1/2 in HMC-1 cells by a mechanism that involves autocrine formation of adenosine, which is mediated by CD 73 and A3 receptor. In contrast, we discovered that there is an important difference between the ERK 1/2 MAP kinase signal transduction in HMC-1 and LAD-2 cells. PKC is an inhibitor of the H1299 activation of ERK 1/2 in LAD-2 cells. In contrast, the H1299 membrane activation of ERK 1/2 kinase in HMC-1 cells is mediated by PKC. Furthermore, we can conclude that H1299 membranes activate AKT in an A3 receptor dependent mechanism that is mediated by PI3K.

Keywords: cancer, mast cells, Cell Communication

Conclusion: We present the first human immunocompetent culture system that can be used to evaluate immunotherapeutic agents’ efficacy prior to their clinical translation. Furthermore, analyses of the culture system’s soluble factors sheds light on their relative influence on T-cell efficacy.

MA06.07 GENETIC AND EPIGENETIC ALTERATIONS ARE ASSOCIATED WITH TUMOR MUTATION BURDEN IN NON-SMALL CELL LUNG CANCER

L. Cai, H. Bai, Z. Wang, S. Wang, J. Duan, S. Gao, J. He, J. Wang
National Cancer Center/cancer Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing/CN

Background: Although several studies have indicated that tumor mutation burden (TMB) is associated with non-small cell lung cancer (NSCLC) development and clinical efficacy of immune checkpoint inhibitors (ICIs), identification of factors associated with TMB is still a major biological issue. It is well-known that DNA transcription can be regulated through methylation and demethylation, gene silencing caused by DNA hypermethylation is associated with cancer development. However, the relationship between DNA methylation and TMB in NSCLCs remains unclear. Method: The landscape of DNA sequence in Chinese NSCLCs population were surveyed by using whole-exome sequencing (WES) by profiling 178 lung tissues (89 without any systemic anti-cancer therapy tumors and matched normal lung tissues). According to the 104 median-level of TMB in our cohort, high TMB (n=16, 252-465 range mutations per tumor) and low TMB (n=13, 57-79 range mutations per tumor) groups were divided. The NSCLC methylome between high and low TMB was characterized on a genome-wide scale using Illumina Infinium MethylationEPIC arrays combined with the WES data. Result: The results show frequently aberrant DNA methylation, abundant chromosomal amplifications and deletions, and mutational signatures in high TMB lung cancer. Combining with clinical data, cigarette smoking adjusted with high TMB were observed in our cohort. Cancer-specific epigenetic alterations were observed in 294,141 CpG sites, comprising both tumor hyper- (769,38) and hypo- (217,203) methylation in high TMB lung cancer while none in low. These different methylations sites cover 12,32 genes including 25 HOX genes. Conclusion: Global DNA hypomethylation and TPS3 mutation, associated with increased chromosomal instability, were associated with TMB in NSCLCs. The high TMB NSCLCs are characterized by numerous copy number alterations and aberrantly methylated sites and display distinct mutational signatures. 25 hypermethylated HOX genes can be potentially useful as DNA methylation markers for prediction of TMB level. The results provide insights into the epigenetic impact of TMB, which may contribute to improve precision management of NSCLCs.

4Medical Oncology, St. James’s Hospital, Dublin/IE.
5Histopathology, St. James’s Hospital & Trinity College Dublin, Dublin/IE.

Background: Alterations in the DNA repair capacity of damaged cells is now recognised as an important factor in mediating resistance to chemotherapeutic agents.

Method: DNA Repair Pathway RT2 Profile Arrays were used to elucidate key DNA repair genes implicated in chemoresistant NSCLC cells using cisplatin resistant (CisR) and corresponding parental (PT) H460 cells. DNA repair genes significantly altered in CisR cells were validated at the mRNA and protein level. The translational relevance of differentially expressed genes was examined in a cohort of chemo-naïve matched normal and tumour lung tissues from NSCLC patients. Loss of function studies were carried out using siRNA technology.

The effect of XRCC6BP1 gene knockdown on apoptosis was assessed by FAC5. Cellular expression and localisation of XRCC6BP1 protein and γH2AX foci in response to cisplatin were examined by immunofluorescence (Cyte1). To investigate a role for XRCC6BP1 in lung cancer stem cells, Side Population (SP) studies were used to characterise stem-like subpopulations within chemoresistant cells. XRCC6BP1 mRNA analysis was also examined in ALDH1+ and ALDH1 subpopulations. Immunohistochemistry analysis was carried out in resected lung tumour tissues and XRCC6BP1 expression was correlated with survival in addition to the number of clinicopathological variables such as tumour stage and grade, gender, smoking status and chemotherapy.

Result: We identified a number of critical DNA repair genes that are differentially regulated between PT and CisR NSCLC cells. XRCC6BP1 mRNA and protein expression was significantly increased in H460 CisR cells relative to their PT counterparts. Relative to matched normal lung tissues, XRCC6BP1 mRNA was significantly increased in lung adenocarcinoma patients. Gene silencing of XRCC6BP1 induced significant apoptosis of chemoresistant cells and reduced their DNA repair capacity. Immunofluorescence studies showed an increase in XRCC6BP1 protein expression and γH2AX foci in CisR cells. SP analysis revealed a significantly higher stem cell population in resistant cells, while XRCC6BP1 mRNA expression was considerably increased in SKMES-1, H460 and H1299 CisR cells positive for ALDH1 activity (ALDH1+). Compared to ALDH1+ cells, IHC scoring of XRCC6BP1 demonstrated poor survival outcomes for NSCLC patients with high expression of this DNA repair gene. Conclusion: Our data highlight the potential of targeting components of the DNA repair pathway, in particular XRCC6BP1, in chemoresistant lung cancer. Furthermore, XRCC6BP1 may play an important role in subsets of lung cancer stem cells which, at least in part, may be responsible for driving and maintaining the cisplatin resistant phenotype in NSCLC.

MA06.11 DISTINCT ORIGINS OF LYMPHATIC AND BRAIN METASTASIS IN LUNG CANCER

T. Jiang1, Y. Yan2, C. Zhou3
1Department of Medical Oncology, Shanghai Pulmonary Hospital. Tongji University School of Medicine, Shanghai/CH.
2The First Affiliated Hospital of Zhengzhou University. Zhengzhou/CH.
3/7

Background: Generally, distant metastases are seeded by lymph node metastases in most solid tumors. This concept provides a mechanistic basis for the TNM staging system and is the rationale for surgical resection of tumor-draining lymph nodes. However, a recent study found that lymphatic and distant metastases could arise from independent subclones in the primary colorectal cancer. The current study aimed to investigate the origins of lymphatic and brain metastasis in lung cancer.

Method: 39 samples from twelve patients with primary lung cancer and brain metastases were identified. Three of them had the matched lymph node metastases. All tissues and matched peripheral blood samples were collected before any systemic treatment. Whole-exome sequencing were conducted on these samples.

Result: Compared to the primary lesions, both brain and lymph node metastases showed the similar mutation pattern in terms of transition and transversion, and all of samples displayed a higher percentage of C>T transition. Brain metastases had numerically higher TMB than primary lesions but it did not reach the statistical significance. Notably, we observed the totally distinct origins of lymphatic and brain metastasis in all three matched cases.

Conclusion: The current evidence suggested that brain metastases and matched lymph node metastases had different mutational landscape in patients with lung cancer. Brain metastases had higher TMB than their primary lesions. Lymphatic and brain metastasis had distinct origins in lung cancer. These results had profound clinical implications for application of immunotherapy and improvement of prognosis in patients with lung cancer and brain metastases.

MA07.02 LINE OF THERAPY AND PATIENT PREFERENCES TREATING LUNG CANCER: A DISCRETE-CHOICE EXPERIMENT
J. Bridges1, U. Basu Roy2, E. Janssen4, A. Ferris4
1Department of Biomedical Informatics, the Ohio State University College of Medicine, Columbus/OH/US, 2Research and Policy, Lungevity, Bethesda/MD/US, 3Icon, Gaithersburg/MD/US, 4Lungevity Foundation, Bethesda/US

Background: Patient preferences now play an important role in cancer research, regulatory science, and value assessment. While there is a growing literature exploring the preference of patients with lung cancer, few studies have explored how preferences vary with patients’ treatment experience. We sought to quantify patient preferences for the benefits and risks of therapy and explore how they vary across line of treatment.

Method: Preferences were estimated using a discrete choice experiment (DCE) developed in partnership with a patient and stakeholder advisory boards. A D-optimal experimental design was used to generate 3 blocks of 9 choice tasks spanning five attributes: progression-free survival (PFS), short-term side effects, long-term side effects, risk of developing late-onset side effects, and mode of administration – each defined across 3 relevant levels. A diverse sample was recruited via email sent to the LUNGevity lung cancer patient database and via social media. A choice model was estimated using a conditional logistic regression where the dependent variable was the respondents preferred treatment in each profile. The relative attribute importance (conditioned on the chosen attribute levels) was then compared across the respondents’ self-reported line of treatment.

Result: In total we had 350 eligible respondents, of which 279 (80%) completed at least on DCE task of which 3% did not receive a first line therapy, and 58% had two or more lines of therapy. With previous studies, PFS was the most important attribute for patients and was similarly valued (P=0.406) among first- and later (second lines and more) lines of treatment (33.4% v 33.8%). Patients on first-line treatment placed great emphasis (P=0.001) on long-term side (18.9% v 14.1%) and late onset side effects (15.3% v 10.3%), but less emphasis (P=0.001) on short-term side effects (27.8% v 28.8%) and mode of administration (4.6% v 12.0%) than those on later lines.

Conclusion: Population estimate of patient preference remain important, but more effort is needed to understand how patient preference vary across patient with different backgrounds and treatment experiences. We show that line of treatment does not effect how patients value time, but their experience may have an impact on treatment heterogeneity.

MA07.03 ATTITUDES TO LUNG CANCER IN EUROPE: FINDINGS FROM A GLOBAL CONSUMER SURVEY
A. McNamara1, M. Rigney2, J. Fox3, G. Manuel4, S. Winstone5

Background: If lung cancer is diagnosed early, patients’ chances of successful treatment are increased. Stigma around lung cancer, as a tobacco-related cancer, can discourage patients from talking to their doctor about potential symptoms. In 2017, the GLCC commissioned Populus to undertake an international consumer survey in each of the 25 countries of the GLCC members. Method: 1,000 adults, in 16 European countries, participated via an online survey in July 2017. To assess attitudes to lung cancer, they were told that lung cancer is mainly caused by smoking and other tobacco products. They were then asked the extent to which they agreed or disagreed with the statement: “I have less sympathy for people with lung cancer than for people with other cancers.”

Result: One in five (20%) people in Europe agreed that they have less sympathy for people with lung cancer than other forms of cancer (Chart 1). There was variation between countries with 30% of people in Portugal agreeing they have less sympathy in comparison to only 17% agreeing in Denmark, the Netherlands, Norway, Russia, Slovenia and Spain. Men in Europe are generally less sympathetic than women, and those aged over 55 are most sympathetic. In addition, there was a statistically significant correlation between those countries with lower cigarette consumption and people agreeing that they have less sympathy for people with lung cancer. Chart 1: European attitudes to lung cancer

Conclusion: Everyone - no matter what the cause of their cancer - deserves to have high quality treatment and care. The persistent and varied levels of stigma associated with lung cancer across Europe needs to be addressed, so that people experiencing symptoms are not discouraged from seeking early intervention.

MA07.05 PSYCHOSOCIAL NEEDS AND PROGRAMS OF CANCER PATIENTS/SURVIVORS AND THEIR RELATIVES: UNMET NEEDS FROM AN INTERNATIONAL STUDY
S. Serpentini1, C. Dejì2, S. Goswami3
1Veneto Institute of Oncology, Iov-IIRCIS, Padova, Italy, Padova/IT, 2Romania, Romania/RO, 3Savita Goswami, Savita Goswami/IN

Background: In consideration of the dynamic nature of cancer patients’ needs, systematic understanding of their unmet needs from a socio-ecological perspective may be essential as the patients’ needs and available services are likely to vary by different healthcare systems in different countries. To investigate the role of geographical influence in cancer patients’ unmet needs, this study seeks to compare the unmet needs of and available programs for cancer patients/survivors and their family members by different types of healthcare systems across different countries. Method: The IPOS Survivorship Online Survey is distributed to international and regional Psycho-Oncology organization members, which covers countries in six continents. Survey participants’ countries where they practice/research will be categorized into four groups by the types of healthcare system: Beveridge Model, Bismarck Model, National Health Insurance Model, and Out-of-Pocket Model. Result: With estimated survey to be completed by August 30th, 2018, repeated measures ANOVA will be employed to test differences in patients’ unmet needs by the four healthcare system groups, separately for patients’ unmet needs and their family caregivers’. Differences by individual countries will also be explored. Conclusion: Findings will provide a global overview and a specific knowledge of the geographical differences in the psychosocial unmet needs and psycho-oncological programs for cancer patients/survivors and their family members/caregivers. Findings will also guide how to prioritize areas of cancer care that require improvement in psycho-oncology interventions and practices; and to highlight critical aspects for delivering quality care that vary by healthcare systems.

MA07.06 TELEPHONIC COMMUNICATION IN PALLIATIVE CARE FOR BETTER MANAGEMENT OF TERMINAL CANCER PATIENTS IN RURAL INDIA - AN NGO BASED APPROACH
N. Mandal
Palliative Care, Narikeldaha Prayas, Purba Medinipur/IN

Background: Due to financial incapability and absence of manpower poor families often fail to carry their advanced cancer patients to the nodal centres. This pilot study will explore whether communication by mobile phone can lessen this burden. Method: Initially a plan was generated regarding management of an advanced cancer patient in a nodal centre at District Head Quarter. Subsequently every two week a trained social worker attached to nodal centre will follow up and give necessary advice and emotional support to the patients and their families through their registered mobile phone number. Patient’s family were also encouraged to communicate with the team by phone in case of fresh complain and urgency in between. Result: Since initiation in January 2017, 210 cancer patients were contacted by mobile phone every two weeks to enquire about their difficulties. In 76% of the situation trained social workers could give necessary advice by phone regarding management of their physical symptoms. Moreover patient’s family were really overwhelmed by the emotional support offered by the team over phone. Only 24% of cancer patients has to attend the nodal centre for expert advice from Palliative Care specialists. Conclusion: This novel approach helped
- In providing regular physical and emotional support to the patients and their families. * In significantly reducing the financial and manpower problems of carrying patients to the nodal units.
- * In improve the quality of life of patients by continuous guidance.

More and more team members can take help of this new strategy for better communication and uninterrupted care.

MA07.07 IDENTIFYING THE SEVERITY OF PSYCHOSOCIAL SYMPTOMS AMONG PATIENTS DIAGNOSED WITH LUNG CANCER. DO WE REALLY NEED EMOTIONAL SUPPORT GROUPS?
A. Fatima1, S.S.A. Zaidi2
1Shaikut Khanum Cancer Hospital and Research Centre, Lahore/PK, 2Wecare Medical Centre, Lahore/PK

Background: Lung cancer is the second most common cancer among men and women. Most of the lung cancers are diagnosed at later stages among those patients who are undernourished. The diagnosis and treatment of lung cancer is a continuous emotional distress for both patient and their family. We aim to identify the severity of depression, emotional distress, stress and mental fatigue among those patients who are diagnosed with lung cancer. Method: A cross sectional study was conducted in Shaikut Khanum Hospital, Lahore from March 2014 to April 2015. Exclusion and Inclusion criteria were made. 150 were enrolled in the study. Socio demographic characteristics were evaluated using Beck Depression Inventory and socio demographic form. Severity of depression was estimated by using Hamilton D (HAM-D). Various variables were analysed including parent’s age, level of education, socioeconomic status, gender and number of children. Result: 68% of the participants exhibited severe range of depression. 27% showed moderate depression where as 5% participants were showing the mild range of depression. An inverse co relation was found between educational status, occupational status (paid or unpaid), their marital status, socioeconomic family status and depression. Women 71% were found be more depressed than males. Conclusion: We concluded that majority of patients from psychosocial symptoms particularly depression and it is mainly associated with some factors. There is need to incorporate patients into the diagnosis and treatment process so that we can over come the effects of depression on the health outcomes of patients diagnosed with lung cancer. This can only be possible through appropriate education and emotional support programmes.

MA07.09 WILLINGNESS TO PERFORM MULTIPLE BIOPSIES TO IMPROVE QUALITY OF LUNG CANCER CARE: UNDERSTANDING THE ONCOLOGISTS’ PERSPECTIVE
U. Basu Roy1, M. Jacobson2, A. Ferris3
1Research and Policy, Lungevity, Bethesda/MD/US, 2Lungevity Foundation, Chicago/IIL/US, 3Lungevity Foundation, Bethesda/MD/US

Background: Biomarker testing of advanced-stage non-small cell lung cancer (NSCLC) at the time of diagnosis is required to determine if a patient will benefit from a targeted therapy or immunotherapy. A patient may, however, need additional biopsies (rebiopsy) if the cancer recurs to determine the next line of therapy or to determine eligibility for a new drug or participation in a clinical trial. A LUNGevity study, conducted with 340 patients, revealed that patients were willing to undergo rebiopsies if that meant access to additional treatment options at the time of recurrence. However, only 36% of patients reported that their doctors recommended repeated biopsies at progression. Method: To understand this patient-physician communications gap, we conducted an IRB-approved semi-structured survey-based study of 130 oncologists from academic research centers, community cancer centers, and private practice. Result: Of the 130 oncologists surveyed, - Ninety percent of oncologists reported recommending a rebiopsy to their patients. However, when stratified by advanced-stage patient volume, oncologists with higher advanced-stage patient volumes reported higher rebiopsy and testing rates than those with low volumes (95% vs. 78%, p<0.05). Only 29% of the oncologists prescribed a rebiopsy in the past one year. - Major barriers to rebiopsy reported by oncologists included cost/ reimbursement of a rebiopsy and treatment delay for 2nd- or subsequent lines of therapy. - Among the types of biomarker testing performed at the time of progression, oncologists were more likely to prescribe testing for biomarkers with approved treatments (driver mutations – 94%, PD-L1 – 85%) unlike biomarkers for treatments in clinical development (43%) (p<0.05). - A forward linear regression analysis revealed that positive predictors of rebiopsy included treatment at a NCI Designated Cancer Center, while treatment at a community cancer center or private practice, presence of driver mutations at the time of diagnosis, and performance status of patient were negative predictors of rebiopsy. - When presented with specific treatment scenarios for biomarkers (EGFR and ALK) that have 2nd-line treatment options, oncologists differed in their approach, suggesting a need for oncologist education about rebiopsying and subsequent biomarker testing Conclusion: Our study demonstrates that rebiopsy practices vary by practice settings and volume of advanced-stage lung cancer patients. Even when rebiopsies are prescribed, a comprehensive biomarker profile of the tumor may not be obtained, due to variations in tests requested. A major implication is the need for appropriate oncologists’ education to ensure practice change for delivery of optimal care to lung cancer patients.

MA07.10 UTILIZING A PERSONALIZED NAVIGATION PROGRAM TO IDENTIFY BARRIERS AND INCREASE CLINICAL TRIAL PARTICIPATION AMONG LUNG CANCER PATIENTS
A. Ciupek, T. Perloff, A. Jaitly, J. King

Background: Only about 5% of cancer patients participate in clinical trials. We previously conducted a survey of U.S. lung cancer patients and found that only 22% reported discussing clinical trials with their oncologist at the time of making treatment decisions. We hypothesized that a personalized navigation program could both increase rates of trial discussion and identify barriers to participation among lung cancer patients. Method: We asked callers to Lung Cancer Alliance’s 1-800 support line if they had considered clinical trial participation and referred willing callers to a navigator for further discussion. Navigators provided basic clinical trial education and a personalized list of trial matches. Patients were encouraged to discuss these trials with their treating oncologist. Navigators then regularly followed up with participants, via email or phone, at two to four-week intervals, to offer further support and collection outcomes information. Result: We referred sixty callers to a navigator. Only 43% of callers reported a prior clinical trials conversation with their provider. Patients who had not started treatment or were on first-line treatment reported lower discussion rates (30%) than those on later treatment lines (65%). Among patients with follow up, 13 of 20 patients who had not discussed trials with their provider reported doing so after navigation. Ten of eleven patients that had a previous

MA07.11 DRUG PRICE COMPARISON IN ADVANCED LUNG CANCER - HIGH COST PRICES IS ACCOMPANIED BY PATIENT BENEFITS?
L. Bonan
Scimed/Anvisa, Brasilia/BR

Background: In our recent decade we are seen new drugs coming up with high price and with high potential to attend personalized conditions in lung cancer treatment. After the first TKI for EGFR mutation, many other target drugs such as TKI for ALK/ROS1 alteration, third-generation EGFR TKI, anti-PD-1/PD-L1 immunotherapies bring together an improvement in survival with better quality of life than chemotherapy. But this new specialty drugs are also testing the affordability of the market with new launched ceiling prices. Frequently, their prices have been settled down in a context of an unmet condition appeal rather than the truly health benefits. In pricing it is a common practice to use the external reference price between countries to align the prices based on international market. But if the first price is launched (frequently in USA) in countries that don’t use metrics based on evidence or clinical benefits, the price plateau could be replicated even without necessarily deserving this price. The objective of this presentation is to show the price comparison of drugs included in TKI class and immunotherapy class between high and middle-income countries. Then to compare the cost-treatment of therapies commonly used in advanced lung cancer and their magnitude of clinical benefit Method: All local currencies were converted to US dollars using PPP factor. The magnitude of effect was evaluated based on the ESMO Magnitude of Clinical Benefit Score. Result: USA has the highest drug price followed by Brazil, especially in recent launched drugs. Costs of advanced lung cancer treatment significantly increase 5 times more when compared first-generation TKI and new generation TKI. Immunotherapy for second line costs 6 times more than first line with EGFR TKI and could cost more than 7 to 130 times the chemotherapy with docetaxel. Clinical benefits do not reach the same scale. Conclusion: The market of anticancer drug increasing 10% annually, but clinical benefits don’t advance in the same compass. Specialized drugs come into the market with pricing warrant of unmeet conditions, but if we think in precision medicine all new drug-target biomarker could be priced higher because it will cover a rare or unmet condition. In the context of precision medicine, is it fear a patient pays more because he has a different biomarker for the same clinical condition? If countries do not start to evaluate and pricing drugs based on value, market strategists will continue to test the ceiling prices that health systems can (not) afford.

MA08 CLINICAL TRIALS IN BRAIN METASTASES
MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

MA08.02 PROPHYLACTIC CRANIAL IRRADIATION REDUCES THE RISK OF BRAIN METASTASES IN HIGH-RISK LUNG CANCER PATIENTS: EGFR AND ALK MUTATIONS
O. Arrieta1, F. Maldonado1, L. Ramirez-Tirado1, F. Barron1, Y. Campos-Salgado2, M. Blake1, A. Cardona2, J. De La Garza2
1Unidad Funcional de Oncología Torácica Y Laboratorio de Medicina Personalizada, National Cancer Institute, Mexico City/MX, 2Clinical and Translational Oncology Group, Foundation for Clinical and Applied Cancer Research - Ficmac, Bogotá/CO

Background: Prophylactic Cranial Irradiation (PCI) is considered standard-of-care for small-cell lung cancer (SCLC). Whole Brain Radiotherapy (WBRT) is a standard-of-care treatment for NSCLC patients with multiple brain metastases. Elevated EGFR expression and activity are important causes of tumor resistance to radiotherapy. This phase 2 trial sought to determine if concurrent erlotinib and WBRT will benefit patients with NSCLC and BM compared with WBRT alone. Method: In this open label, randomised, multicenter phase 3 study in China (NCT01887795), we enrolled NSCLC patients with at least two metastatic brain lesions who were naïve to brain radiation and free from any EGFR-TKI for at least 4 weeks. Participants were randomly assigned (1:1) to receive either WBRT (2.0 Gy per day, 5 days per week, to 40 Gy) or WBRT plus concurrent oral erlotinib 150 mg daily (Erlotinib was given for 6 days then concurrently with WBRT). Subsequent treatments were maintenance therapy of erlotinib for EGFR-positive patients or standard chemotherapy for EGFR-negative patients until unacceptable adverse events or disease progression. The primary endpoint was intracranial progression-free survival (iPFS), defined as time from randomisation to either intracranial disease progression or death for any cause. Result: Between August 7, 2013 and November 25, 2016, in total 222 patients from 11 centers across China were randomized to treatments: 115 with WBRT alone and 107 with WBRT and concurrent erlotinib. Median follow-up was 11.2 months (IQR 4.6-18.2). Median iPFS was 11.2 months (95% CI; 7.2-13.7) with WBRT and concurrent erlotinib versus 9.2 months (95% CI; 6.7-10.9) with WBRT alone (HR 0.926; 95% CI: 0.695-1.234; P=0.601). In the subgroup of 109 patients who were positive for the EGFR mutation, iPFS was not significantly longer among those who received WBRT with concurrent erlotinib than WBRT with sequential erlotinib (14.6 [95% CI 11.8-17.7] vs 12.8 [7.9-14.9] months; HR 0.743; 95% CI: 0.489-1.129; P=0.164). Median PFS of concurrent erlotinib arm was 5.3 months versus 4.0 of WBRT alone (HR 0.969; 95% CI: 0.735-1.277; P=0.825) and median overall survival (OS) was 9.2 vs 10.0 months (95% CI: 6.7-10.9) with WBRT alone (HR 0.926; 95% CI: 0.680-1.226; P=0.545). Conclusion: This multi-institutional study demonstrated WBRT with concurrent erlotinib improved neither iPFS significantly than WBRT alone in the intention-to-treat population and the EGFR-positive PFS group, nor improved OS in the intention-to-treat population, indicating that erlotinib played limited role when concurrently used with WBRT and for EGFR-positive NSCLC patients, WBRT with concurrent erlotinib was not significantly superior to WBRT with sequential erlotinib.

1 Cancer Center, Research Institute of Surgery, Daping Hospital, Third Military Medical University, Chongqing/CN, 2Department of Thoracic Oncology, West China Hospital, Sichuan University, Chengdu/CN, 3Department of Radiation Oncology, The First Affiliated Hospital of Kunming Medical University, Kunming/CN, 4Department of Radiation Oncology of the Chest and Abdomen, Affiliated Tumor Hospital, Anhui Medical University, Urumqi/CN, 5Institute for Cancer Prevention and Treatment, Chongqing Sansiao Central Hospital, Chongqing/CN, 6Department of Medical Oncology, Xinqiao Hospital, Third Military Medical University, Chongqing/CN, 7The 963 Project, West China Hospital of Sichuan University, Chengdu/CN, 8Department of Radiation Oncology, Cancer Hospital, Guangxi Medical University, Nanning/CN, 9Department of Radiotherapy, General Hospital of Ningxia Medical University, Yinchuan/CN, 10Department of Health Statistics, West China School of Public Health, Sichuan University, Chengdu/CN
Conclusion: PCI significantly increases IPFS and decreases risk of death in patients with advanced NSCLC, without neurocognitive impairment or decreased QoL. This intervention appears to be particularly useful for patients with good performance status and driver mutations. PCI increased IPFS without neurocognitive impairment or decreased QoL.

Keywords: brain metastases, ALK, prophylactic cranial irradiation

MA08.03 EGFR-TKI PLUS BRAIN RADIOTHERAPY VERSUS EGFR-TKI ALONE IN THE MANAGEMENT OF EGFR MUTATED NSCLC PATIENTS WITH BRAIN METASTASES: A META-ANALYSIS

X. Xia, M. Guo, J. He, W. Liang
Thoracic Surgery and Oncology, The First Affiliated Hospital of Guangzhou Medical University, China State Key Laboratory of Respiratory Disease & National Clinical Research Center for Respiratory Disease, Guangzhou/CN

Background: It has been confirmed that epidermal growth factor receptor-tyrosine kinase inhibitors (EGFR-TKIs) presented better efficacy than brain radiotherapy (brain RT) in the treatment of brain metastasis (BM) in EGFR mutated NSCLC patients. However, whether the combination of EGFR-TKI and brain RT is better than EGFR-TKI alone remains unclear. We aim to compare the benefit of adding brain RT to EGFR-TKI by a meta-analysis of currently available data.

Method: A systematic search for relevant articles was conducted in six databases (PubMed, EMBASE, Cochrane database, Medline, Web of Science, Google Scholar). The primary outcome was overall survival (OS) between groups, and the secondary outcome was intra-cranial progression-free survival (icPFS), both being measured as hazard ratios (HRs). The data was synthesized by random-effects model using STATA 13.0. Cumulative incidence of BM at 1-yr was higher among patients without PCI (22% vs. 3%, p=0.001). Relative risk for IPFS in patients with DM was 0.29 (0.10-0.82, p=0.01). HR for OS was 0.48 (0.20-1.16, p=0.098). Median OS was higher in the PCI group compared to control [42.8 (95% CI: 28.1–57.6) vs. 25.9 (95% CI: 17.7–34.2) months. Last, PCI was associated with lower hazards of death, 0.47 (0.24–0.95), p=0.035.

Conclusion: PCI significantly increases IPFS and decreases risk of death in patients with advanced NSCLC, without neurocognitive impairment or decreased QoL. This intervention appears to be particularly useful for patients with good performance status and driver mutations. PCI increased IPFS without neurocognitive impairment or decreased QoL.

MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

MA08.05 BRAIN PENETRATION OF LORLATINIB AND CUMULATIVE INCIDENCE RATES FOR CNS AND NON CNS PROGRESSION FROM A PHASE 1/2 STUDY

T. Bauer1, A. Shaw2, M. Johnson1, A. Navarro3, J. Gainer2, H. Thurman4, Y. Pithavala5, A. Abbattista6, E. Felip7
1Sarah Cannon Cancer Research Institute/Tennessee Oncology, Pllc, Nashville/TN/US, 2Massachusetts General Hospital, Boston/MA/US, 3Vall D’Hebron Institute of Oncology (VHIO), Vall D’Hebron University Hospital, Barcelona/ES, 4Pfizer Oncology, La Jolla/CA/US, 5Pfizer Oncology, Milan/IT

Background: The potent, selective, third-generation ALK/ROS1 tyrosine kinase inhibitor (TKI) lorlatinib was designed to penetrate the blood-brain barrier (BBB). In a phase 1/2 study, lorlatinib showed robust clinical activity in patients with ALK-positive non-small cell lung cancer (NSCLC), most of whom had CNS metastases and failed ≥1 ALK TKI. In preclinical studies, lorlatinib demonstrated high BBB permeability with rapid brain uptake in vivo and significant activity against ALK-positive intracranial tumor models.1,2 To assess brain penetration of lorlatinib in a clinical setting, we report exploratory analyses from a phase 1/2 study (NCT01970865), evaluating CSF-to-plasma concentration ratios from a small sample of patients and cumulative incidence rates (CIRs) of CNS progression, non-CNS progression and deaths for pretreated patients with ALK-positive NSCLC ± baseline CNS metastases. Method: Across the ongoing phase 1/2 study, 5 patients at lorlatinib 100 mg QD starting dose underwent CSF sampling. Patients with ALK-positive NSCLC with ≥1 prior ALK TKI were analysed for progressive disease, categorized as either CNS or non-CNS progression, based on independent central review. CIRs for patients in expansion cohorts EXP2–5 from the phase 2 portion of the phase 1/2 study (N=198) were calculated using competing risks methodology. Result: In patients (n=5), mean CSF-to-plasma concentration ratio was 0.73 (SD 0.14). The table shows CIRs at 6 and 12 months.

1Patients in expansion cohorts EXP2–5 from the phase 2 study NE, not evaluable

Conclusion: Lorlatinib showed high BBB permeability as evidenced by a high mean CSF-to-plasma concentration ratio, in line with preclinical rat studies showing CNS penetration. This translated into high activity against CNS metastases as suggested by the numerically higher probability of the first progression event being extracranial rather than intracranial, including in patients with a history of CNS metastases.

Keywords: lorlatinib, CNS, NSCLC

MA08 CLINICAL TRIALS IN BRAIN METASTASES
MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

MINI ORAL ABSTRACT SESSIONS
MONDAY, SEPTEMBER 24, 2018

ABSTRACTS IASLC 19th World Conference on Lung Cancer | 171

WWW.IASLC.ORG
Brain metastases are frequent in NSCLC. In ASTRIS Korean subset, patients with or without CNS metastasis had comparable efficacy outcome. This data continues to support osimertinib’s clinical benefit on EGFR T790M NSCLC patients with CNS metastasis.

**Keywords:** osimertinib, T790M, ASTRIS

**MA08.07 REAL WORLD DATA OF OSIMERTINIB IN PATIENTS WITH CENTRAL NERVOUS SYSTEM (CNS) METASTASIS IN ASTRIS KOREAN SUBSET.**

1Medical Oncology, Department of Medical Oncology, Seoul St. Mary’s Hospital, College of Medicine, the Catholic University of Korea, Seoul/KR, 2Medical Oncology, Yonsei Cancer Center, Seoul/KR, 3Department of Internal Medicine, Seoul National University Hospital, Seoul/KR, 4Sumsung Medical Center, Sunghyonkwan University School of Medicine, Seoul/KR, 5Seoul National University Bundang Hospital, Seongnam/KR, 6Internal Medicine, Department of Internal Medicine, School of Medicine, Kyungpook National University, Daegu/KR, 7Korea University College of Medicine, Seoul (Korea University Guro Hospital)/KR, 8Department of Internal Medicine, Korea Cancer Center Hospital, Seoul/KR, 9Pulmonary, Allergy and Critical Care Medicine, Hallym University Sacred Heart Hospital, Anyang/KR, 10Lung and Esophageal Cancer Clinic, Gunnam National University Hwasun Hospital, Jeonnam/KR, 11Department of Internal Medicine, The Catholic University of Korea, Yeouido St. Mary’s Hospital, Seoul/KR, 12Department of Oncology, Asan Medical Center, University of Ulsan College of Medicine, Seoul/KR

**Background:** More than 40% of non-small cell lung cancer (NSCLC) patients develop CNS metastasis in their lifetime. Osimertinib is a third-generation EGFR-TKI which selectively inhibits both EGFR-sensitizing and EGFR T790M-mutant EGFR, so this study aimed to evaluate osimertinib in CNS metastasis in a real-world setting. The primary endpoint was overall survival (OS); other endpoints included investigator-assessed response rate (RR), progression-free survival (PFS), time to treatment discontinuation (TTD) and safety. These endpoints were also analyzed according to presence of CNS metastasis. Result: A total of 446 patients received osimertinib 80mg from 31 Korean sites. CNS metastasis was evaluated in 310 patients and was present in 211 (68.1%) patients (CNS-met); 181 brain only, 1 leptomeningeal only, 29 both. 99 (31.9%) patients did not have CNS metastasis (CNS-no), and 155 patients were not evaluated (CNS-ne). At DCO, 236 patients (50.6%) were ongoing and median duration of exposure was 11.2 (0–19) months. In patients evaluable for response, defined as at least one dose of osimertinib and one response assessment, RR was 71% (320/451; 95% CI, 66.5–75.1); PFS for CNS-met (N=211), without evidence of BM and NBM, was 10.8 months (95% CI, 9.2–14.5) in CNS-no, and 15.1 months (95% CI, 13.6–18.2) in CNS-ne. Median TTD was 16.5 months (95% CI, 14.9–18.1); 11.2 months (95% CI, 9.4–14.8) in CNS-met, 14.7 months (95% CI, 12.2–16.6) in CNS-no, and NC (95% CI, 15.5–NC) in CNS-ne. OS was not reached (data maturity: 19.7%). Serious adverse event (AE) regardless of causality were reported in 116 patients (24.9%) and AEs leading to death in 13 patients (2.8%). ILD pneumonitis-like events were reported in 8 patients (1.7%), and QTc prolongation in 7 patients (1.5%). Conclusion: Osimertinib is well tolerated in both CNS-met and CNS-no patients in daily clinical practice. Osimertinib demonstrated significant clinical benefit in patients with CNS metastasis. This real-world data supports the role of osimertinib as a standard of care in patients with CNS metastasis.

Department of Pulmonary Diseases, Hospital Avicenne, Bobigny/FR, 9Radiation Oncology, Gustave Roussy, Villejuif/FR, 10Radiotherapy, Gustave Roussy, Villejuif/FR, 11Pathology, Gustave Roussy, Villejuif/FR, 12Radiation Oncology (Maastro Clinic), Maastro University Medical Center, Maastricht/NL, 13Pulmonary Diseases, Maastro University Medical Center, Maastricht/NL, 14Department of Cancer Medicine, Gustave Roussy, Villejuif/FR

**Background:** Brain metastases (BM) are frequent in NSCLC. Unfortunately, patients with untreated BM are often excluded from ICI trials so that their outcome on ICI is largely unknown. **Method:** Retrospective data collection of all consecutive advanced ICI treated NSCLC patients in 6 centers (5 French, 1 Dutch) (Nov 2012 – March 2018). BM was defined as non-irradiated new and/or growing lesions on brain imaging ≤ 6 weeks before ICI start. Progression free survival (PFS), overall survival (OS) and site of progression on ICI was collected. **Result:** 945 patients included: 63% male, 83% WHO PS 0-1, median age 64 years, 73% non-squamous, 4% targetable driver mutations, 33% known PD-L1 (≥ 1% expression). ICI treatment was median 2nd line (range 1-12), 94% had monotherapy PD-(L)1 inhibition. 241 patients (26%) had BM, 68% had previous cranial irradiation, 40% had active BM. BM patients were significantly younger than others (60 vs 68 years), had more adenocarcinoma (78 vs 62%), more organs involved (median 2 vs 3), a poorer PS (0-1: 76 vs 85%) and more steroids at baseline (median 3 vs 2), a poorer PS (0-1: 76 vs 85%) and more steroids at baseline (median 3 vs 2), a poorer PS (0-1: 76 vs 85%). Median PFS and OS were 10.0 months (95% CI, 7.4-12.2) and 13 (9-16) months, respectively. In multivariate analysis, > 2 metastatic sites, PS 0-1, smoking and healthcare resource utilization were also higher in the BM cohort. These findings highlight an unmet treatment need for patients with BM treated with ICI.
MA08.10 REAL-LIFE INTRACEREBRAL EFICACY OF NIVOLUMAB IN NON-SMALL CELL LUNG CANCER PATIENTS WITH BRAIN METASTASES

M. Geier1, R. Descour1, R. Corre1, G. Léveiller2, R. Lamy4, E. Goarant5, J. Routy5, M. Tehfe1, N. Blais1, M. Florescu1

1Department of Oncology, Chru Morvan, University Hospital of Brest, Brest/FR, 2CHU de Rennes, Rennes/FR, 3Department of Pulmonary Diseases, Ch Yves Le Foll, Hospital of Saint-Brieuc, St Brieuc/FR, 4Centre Hospitalier Bretagne Sud-Lorient, Lorient/FR

Background: Data regarding intracerebral efficacy of nivolumab in advanced non-small cell lung cancer (NSCLC) are lacking because of routinely exclusion of patients with active brain metastases (BMs) from clinical trials. We aimed at assessing intracerebral activity of nivolumab in routinely exclusion of patients with active brain metastases from NSCLC and RCC (NCT02978404), 8 patients were enrolled (1 RCC and 7 NSCLC) in the first trial cohort. Herein, only the NSCLC cases are reviewed. Patients were eligible if their KPS ≥70, were centrally assessed, and had ≤10cc of untreated brain metastases. Prophylactic corticosteroids were not given. Nivolumab (240mg IV q2w) was started 2 weeks prior to SRS, and administered until RECIST progression. SRS (15–20Gy in 1 fraction) was given to each brain metastasis. The aim of the first patient cohort is to estimate the tolerability of the combination treatment strategy.

Result: The median follow-up of the three male and four female patients was 2 months. Median age was 63 years (55–84 years). Five NSCLC patients completed ≥1 cycle of nivolumab and patients, and were evaluable for intracerebral response, there was one partial response and three stable diseases. All three patients had stable extracranial disease. The median number of nivolumab cycles administered is 4.5 (1–15). Intracranial adverse effects were limited to apraxia and paresthesias in the patient who had the largest volume of peri-tumoral brain edema at baseline (46.97cc).

Nivolumab was held and dexamethasone was given for 74 days at doses >1mg/day until neurological symptoms resolved. Systemic adverse events included one patient with grade 2 arthritis necessitating a 6-week treatment delay and 51 days of prednisone ≤10mg. At last follow-up, three patients had died of extracranial disease progression, including the two patients who did not receive protocol SRS. Among the three patients evaluable for intracranial response, there was one partial response and two stable diseases. All three patients had stable extracranial disease.

Conclusion: Combining SRS and immunotherapy is safe in regards to acute toxicity with a manageable side effect profile. Close monitoring is required for patients with significant baseline brain edema. Evaluation for efficacy awaits further follow-up and completion of recruitment in the phase 2 component of the trial.

MA08.11 EARLY SAFETY DATA OF A PHASE I/II COMBINING NIVOLUMAB AND STEREOTACTIC BRAIN RADIOSURGERY FOR TREATMENT OF BRAIN METASTASES IN PATIENTS WITH NSCLC
R. Alameddine1, P. Wong1, L. Masucci2, D. Roberge3, C. Menard4, B. Routy5, M. Tehfe1, N. Blais1, M. Florescu1

1Hematology and Medical Oncology, Centre Hospitalier de L’Université de Montréal, Montreal/CA, 2Radio-Oncology, Centre Hospitalier de L’Université de Montréal, Montreal/CA

Background: Radiotherapy can stimulate the immune system through various means. Highly cytotoxic stereotactic radiosurgery (SRS) doses (>100gy per fraction) may synergize with anti-PD1 to reduce intracranial disease progression or recurrence. Method: Within a phase I/II trial evaluating the combination of nivolumab with SRS in the treatment of brain metastases from NSCLC and RCC (NCT02978404), 8 patients were enrolled (1 RCC and 7 NSCLC) in the first trial cohort. Herein, only the NSCLC cases are reviewed. Patients were eligible if their KPS ≥70, had ≤10cc of untreated brain metastases. Prophylactic corticosteroids were not given. Nivolumab (240mg IV q2w) was started 2 weeks prior to SRS, and administered until RECIST progression. SRS (15–20Gy in 1 fraction) was given to each brain metastasis. The aim of the first patient cohort is to estimate the tolerability of the combination treatment strategy.

Result: The median follow-up of the three male and four female patients was 2 months. Median age was 63 years (55–84 years). Five NSCLC patients completed ≥1 cycle of nivolumab and patients, and were evaluable for intracerebral response, there was one partial response and three stable diseases. All three patients had stable extracranial disease. The median number of nivolumab cycles administered is 4.5 (1–15). Intracranial adverse effects were limited to apraxia and paresthesias in the patient who had the largest volume of peri-tumoral brain edema at baseline (46.97cc). Nivolumab was held and dexamethasone was given for 74 days at doses >1mg/day until neurological symptoms resolved. Systemic adverse events included one patient with grade 2 arthritis necessitating a 6-week treatment delay and 51 days of prednisone ≤10mg. At last follow-up, three patients had died of extracranial disease progression, including the two patients who did not receive protocol SRS. Among the three patients evaluable for intracranial response, there was one partial response and two stable diseases. All three patients had stable extracranial disease.

Conclusion: Combining SRS and immunotherapy is safe in regards to acute toxicity with a manageable side effect profile. Close monitoring is required for patients with significant baseline brain edema. Evaluation for efficacy awaits further follow-up and completion of recruitment in the phase 2 component of the trial.

MA09 LUNG CANCER SURGICAL AND MOLECULAR PATHOLOGY
MONDAY, SEPTEMBER 24, 2018 - 15:15-16:45

MA09.01 CORRELATION OF PRE-OPERATIVE CANCER IMAGING TECHNIQUES WITH POST-OPERATIVE MACRO AND MICROSCOPIC LUNG PATHOLOGY IMAGES

1Clinical Oncology, Beatson West of Scotland Cancer Centre, Glasgow/GB, 2Engineering, University of Strathclyde, Glasgaw/GB, 3Clinical Pathology, NHS Greater Glasgow and Clyde, Glasgow/GB, 4Medical Devices Unit, NHS Greater Glasgow and Clyde, Glasgow/GB

Background: This research project aims to investigate the performance of several PET radiotracers in lung cancer by aligning PET-CT and pathology imagery acquired from the same patients at different points in time. The discrimination of tumour substructures is of great importance in therapy planning, as a given treatment may be better adapted depending on the local characteristics of the carcinoma. Method: Due to the high deformability of lung tissue, several intermediate steps must be used for merging pathology and pre-operative PET-CT in a coherent manner.
Conclusion: Adenocarcinoma in situ or minimally invasive adenocarcinoma ≥ 1 cm by frozen section were more likely to be invasive adenocarcinoma because of sampling error.

Keywords: frozen section, Tumor size, lung adenocarcinoma
MA09.03 MULTIPLE PATHOLOGICAL VARIABLES PREDICT EFFICACY OF ADJUVANT CHEMOTHERAPY IN PRIMARY LUNG ADENOCARCINOMA

M. Sereno1, C. Smith1, M. Dasi1, R. Hastings1, G. Rake1, D. Moore1, J. Le Quesne1
1Leicester Cancer Research Centre, University of Leicester, Leicester/GB, 2Hodgkin Building, Mrc Toxicology Unit, Leicester/GB, 3University of Leicester, Leicester/GB

Background: Adjuvant chemotherapy has become established as a vital complement to surgery over the last decade, and improves survival by targeting micrometastatic disease which is clinically inapparent at the time of surgery. However, in comparison to other common malignancies, the guidelines for the administration of adjuvant chemotherapy in lung cancer are rudimentary, being based solely upon clinical stage II and above at the time of surgery. We set out to discover pathological factors with the potential to better identify patients who are likely to benefit from this vital therapy. Method: 682 cases of primary lung adenocarcinoma treated with surgery with curative intent were identified from 2005-2014: 109 received adjuvant chemotherapy. Comprehensive survival/recurrence data, pathological data, and treatment history data were collected. Detailed histopathological data (growth pattern, vascular invasion, pleural stage) were collected by review of scanned histopathological images. Multivariate Cox regression survival models were used to identify interactions between clinicopathological variables and adjuvant chemotherapy. A propensity score matching approach was used to reduce selection biases in the data. Result: The existing stage criteria for the recommendation of adjuvant chemotherapy are stage pN1/2 and size>40mm; only nodal invasion interacts with chemotherapy in an OS model (interaction term HR=0.67 P=0.017). However, significant interactions are seen with predominant growth pattern (HR=0.47, P=0.001), pleural stage (HR=0.62 P=0.002), and vascular invasion (HR=0.56 P=0.033). We reduced selection bias by balancing treated and untreated groups by propensity matching for all prognostic variables. In the matched dataset, patients with predominantly in situ tumours experience no benefit of chemotherapy (HR=1.81 P=0.18), while higher-grade cases show substantial benefit (HR=0.53 P<0.01). Similar benefits were seen for patients with increasing pleural stage and vascular invasion. On multivariate analysis, we identified which variable(s) had the most ability to predict treatment efficacy, only tumour growth pattern showed a significant interaction with chemotherapy treatment (HR=0.51 P=0.01). Conclusion: We find that the existing stage-based criteria for adjuvant chemotherapy can be much improved. Low-grade cases experienced only negative effects of chemotherapy, while higher-grade cases showed a benefit. Pleural stage and vascular invasion were also significantly predictive. We suggest that the current criteria may be leading to substantial over- and under-treatment. A nuanced algorithm for the identification of patients likely to benefit from chemotherapy, which includes these additional pathological measures, may significantly improve patient outcomes. This would be especially impactful to the majority of surgical patients for whom no personalised therapy is as yet available.

Keywords: adjuvant chemotherapy, Adenocarcinoma, histopathology

MA09.05 CAN WE PREDICT RADIOSENSITIVITY IN NON-SMALL CELL LUNG CANCER?

J. Baena1, C. Talbot2, J. Le Quesne3
1Genetics, University of Leicester, Leicester/GB, 2University of Leicester, Leicester/GB, 3Leicester Cancer Research Centre, University of Leicester, Leicester/GB

Background: Patients with lung cancer receive different treatments depending on their detailed clinical-pathological context. However, over 70% of patients are treated with radiotherapy, which is of varying efficacy. Rather surprisingly, no biomarkers are currently used to predict tumour response and to aid with radiotherapy dosing or regimen. The aim of this study is to identify histopathological features which may predict tumour radiosensitivity in patients with NSCLC. Method: We have identified a set of 67 NSCLC cases with a history of radiotherapy for which pre-treatment archival tissue and CT imaging follow-up is available from the period 2009 to 2014. Digital images of archival diagnostic tissue sections were examined to derive morphological measures with the potential to predict radiosensitivity. Quantitative radiological measures of response up to 6 months after radiotherapy were derived. Since radiographic measurements were taken at variable timepoints, we standardised by inferring the fractional maximum diameter of the tumour 100 days after radiotherapy (FRT100) Result: The density of multipolar mitoses seen microscopically is related to radiosensitivity (regression against FRT100: R² = 0.14, p=0.005*) and a trend toward a negative relationship with neuroendocrine differentiation (R² = -0.06, p=0.058). The presence of multipolar mitoses was further associated with poor overall survival (Univariate Cox p= 0.02*). Patients with radiological evidence of good response (ie low FRT100) showed a time-dependent survival benefit (p=0.02*), while after 2 years tendency of both groups was similar. Patients showing squamous differentiation had a poor prognosis, with no overall survival after 4 years, while 21.8% of the ACA were still alive after 4 years (p= 0.04*) Conclusion: Multipolar mitoses and neuroendocrine differentiation may be predictive histological markers of radiosensitivity in NSCLC. More samples are being gathered, and immunohistochemical and DNA sequence biomarkers of radiosensitivity are currently being assessed.

Keywords: Radiotherapy, predictive histological markers, NSCLC

MA09.06 THE NEWLY RECOGNIZED FILIGREE PATTERN OF MICROPAPILLARY (MIP) LUNG ADENOCARCINOMA (LADC) IS AS CLINICALLY IMPORTANT AS THE CLASSICAL PATTERN

K. Emoto1, T. Eguchi1, R. Vaghjiani1, Y. Takahashi1, N. Rekhtman2, P. Adusumilli2, W. Travis2
1Thoracic Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Dept of Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US

Background: Filigree pattern is a newly recognized addition to the morphological spectrum of the poor prognostic category of micropapillary (MIP) LADC. However, its morphologic features and clinical importance are not well understood. The aim of this study was to investigate the morphologic spectrum and clinical significance of filigree MIP pattern. Method: Filigree pattern was defined as tumor cells growing in delicate lace-like narrow stacks of cells (at least 3 piled-up nuclei) without fibrovascular cores, with frequently visible attachments to alveolar walls. This differs from the 2015 WHO description of classical MIP pattern as tumor cells growing in papillary tufts forming florets that lack fibrovascular cores. In order to assess for filigree vs classical MIP, we documented the frequency and extent of both patterns in 1325 Stage I LADC. These were correlated with recurrence free probability (RFP) and lung cancer-specific survival (LCSS) using Kaplan-Meier analysis. Result: In addition to 87 MIP predominant ADC previously diagnosed, we identified 57 more cases of MIP predominant LADC due to the new criteria of MIP filigree pattern. Of these 57 cases, 37, 16, and 4 cases respectively. Survival curves of previously diagnosed MIP and newly diagnosed MIP for RFP showed a similar worse prognosis compared to other LADC histologic subtypes (previously diagnosed MIP vs newly diagnosed MIP, 5-year RFP 66% vs 68% [Figures]) as well as LCSS (previously diagnosed MIP vs newly diagnosed MIP, 5-year LCSS 82% vs 85%). When the MIP cases were divided into filigree or classical predominant MIP, no significant prognostic differences were observed between the two groups.

(See next page)
Background: Invasive mucinous adenocarcinoma (IMA) is a variant of lung adenocarcinoma with a predominance of mucinous type neoplastic epithelial cells, often showing aerogenous spreading and multifocality. The correlation between histopathological features and prognosis has not been well studied due to its relatively rare incidence compared to non-mucinous adenocarcinoma. Our study aims to evaluate the significance of histopathological features in relation to clinical outcome. Method: We reviewed a series of 101 cases of IMAs resected between 2000 to 2012, comprised of stage I‒IV tumours. Five pathological features were scored for each tumour: predominant histological pattern (lepidic: 1, acinar/ papillary: 2, solid/micropapillary/cribriform: 3), mitotic activity per 2mm² (<4: 0, papillary: 2, solid/micropapillary/cribriform: 3), nuclear atypia (mild:1, moderate: 2, severe: 3), mitotic activity per 2mm² (<4: 0, ≥ 4: 1), necrosis (absent: 0, present: 1), lymphovascular invasion (absent: 0, present: 1), and pleural invasion (PL0: 0, PL1: 1, PL2: 2, PL3: 3). Each pathological feature was correlated with disease-free (DFS) and overall survival (OS).

Cases were then divided into three grades based on the total pathological score (grade I: 1-4, grade II: 5-7, grade III: 8-11) and correlated with OS. Histological pattern and necrosis showed no significant correlation in relation to OS (p = 0.09). Pleural invasion and lymphovascular invasion were significantly correlated with DFS (p < 0.05), while a trend was noted for nuclear atypia (p = 0.086). No correlation with DFS was seen for histological pattern (p = 0.499), necrosis (p = 0.464), and mitotic activity (p = 0.931). There was an inverse correlation between OS and grade, with grade III tumours showing a significantly worse prognosis (p = 0.001). There was no significant difference in DFS between the three groups (p = 0.201).

Conclusion: The lack of significant prognostic difference between filigree vs classical predominant MIP LADC supports our proposal that the filigree pattern is an important addition to the morphologic spectrum of the MIP subtype.

Keywords: filigree, lung adenocarcinoma, micropapillary

### MA09.07 DEVELOPING A PATHOLOGICAL GRADING SYSTEM IN PREDICTING PROGNOSIS FOR INVASIVE MUCINOUS ADENOCARCINOMAS

W. Chang¹, Y.Z. Zhang², E. Lim³, A. Nicholson²

¹Pathology, Mackay Memorial Hospital, Taipei/TW, ²Histopathology, Royal Brompton and Harefield NHS Foundation Trust, London/GB, ³Thoracic Surgery, Royal Brompton and Harefield NHS Foundation Trust, London/GB

**Background:** Invasive mucinous adenocarcinoma (IMA) is a variant of lung adenocarcinoma with a predominance of mucinous type neoplastic epithelial cells, often showing aerogenous spreading and multifocality. The correlation between histopathological features and prognosis has not been well studied due to its relatively rare incidence compared to non-mucinous adenocarcinoma. Our study aims to evaluate the significance of histopathological features in relation to clinical outcome.

**Method:** We reviewed a series of 101 cases of IMAs resected between 2000 to 2012, comprised of stage I‒IV tumours. Five pathological features were scored for each tumour: predominant histological pattern (lepidic: 1, acinar/papillary: 2, solid/micropapillary/cribriform: 3), nuclear atypia (mild:1, moderate: 2, severe: 3),mitotic activity per 2mm² (<4: 0, ≥ 4: 1), necrosis (absent: 0, present: 1), lymphovascular invasion (absent: 0, present: 1), and pleural invasion (PL0: 0, PL1: 1, PL2: 2, PL3: 3). Each pathological feature was correlated with disease-free (DFS) and overall survival (OS).

Cases were then divided into three grades based on the total pathological score (grade I: 1-4, grade II: 5-7, grade III: 8-11) and correlated with OS. Histological pattern and necrosis showed no significant correlation in relation to OS (p = 0.09). Pleural invasion and lymphovascular invasion were significantly correlated with DFS (p < 0.05), while a trend was noted for nuclear atypia (p = 0.086). No correlation with DFS was seen for histological pattern (p = 0.499), necrosis (p = 0.464), and mitotic activity (p = 0.931). There was an inverse correlation between OS and grade, with grade III tumours showing a significantly worse prognosis (p = 0.001). There was no significant difference in DFS between the three groups (p = 0.201).

**Conclusion:** The lack of significant prognostic difference between filigree vs classical predominant MIP LADC supports our proposal that the filigree pattern is an important addition to the morphologic spectrum of the MIP subtype.

### MA09.09 EBUS-TBNA IN ASSESSING PD-L1 EXPRESSION IN NSCLC

J. Agulnik¹, G. Kasymjanova¹, H. Wang¹, L. Sak¹, D. Small¹, V. Cohen¹, A. Spatz²

¹Division of Pulmonary, Jewish General Hospital & McGill University, Montreal/QC/CA, ²Division of Pathology, McGill University Health Center & McGill University, Montreal/QC/CA

**Background:** Pembrolizumab is the only immunotherapy approved as a first line agent for metastatic NSCLC in patients with high programmed death-ligand 1 (PD-L1) expression. The standard samples for PD-L1 testing are considered surgical or core biopsies. In this study, our primary objective is to identify the adequacy of endobronchial ultrasound-guided transbronchial needle aspiration (EBUS TBNA) tumor samples in detecting PD-L1 expression.

**Method:** Between July 2016 and April 2017 a total of 1352 consecutive cases of non-small cell lung cancer (NSCLC) were identified. 29 specimens were deemed inadequate (less than 100 viable tumor cells) and were excluded. 1323 specimens analyzed included surgical samples (N=238), small biopsy (N=744) and cytology cell blocks (N=341). Cytology cell blocks were from EBUS-TBNA (N=190), fine needle aspiration (FNA) (N=61) and pleural/pericardial fluid (N=90).

**Result:** PD-L1 expression was examined by staining with Dako PD-L1 IHC 22C3 pharmDx kit. A Tumor Proportion Score (TPS) was categorized as <1%, 1%-49% and ≥ 50%. Rate of PD-L1 positivity was no different in non-squamous (37%) compared to squamous (32%). Diagnostic yield of PD-L1 expression was examined by staining with Dako PD-L1 IHC 22C3 pharmDx kit. A Tumor Proportion Score (TPS) was categorized as <1%, 1%-49% and ≥ 50%. Rate of PD-L1 positivity was no different in non-squamous (37%) compared to squamous (32%). Diagnostic yield of PD-L1 for different sample types varied substantially (Table 1). The EBUS-TBNA samples had the highest yield for TPS ≥ 50% (p=0.025).

Conclusion: Our results show that cytology cell blocks could be considered as a valuable resource for PD-L1 testing in advanced NSCLC. Future studies are warranted to explore clinical correlation of PD-L1 on EBUS-TBNA samples and immunotherapy outcome.

MA09.10 MOLECULAR PROFILING AND PD-L1 STATUS IN 900 CASES OF SURGICALLY RESECTED NON-SMALL CELL LUNG CANCER WITH CLINICAL AND PATHOLOGICAL CORRELATION

Z. Xu1, M. Castonguay2, W. Greer1, A. Alwithenani1, D. Bethune1, A. Drucker1, G. Flowerdew1, M. Forstyhe1, D. French1, H. Henteleff1, M. Johnston1, M. Macneil1, W. Morzycyki, M. Plourde1, S. Snow1, A. Surette1
1Community Health and Epidemiology, Dalhousie University and QEII Health Sciences Centre, Halifax/CA, 2Pathology, Dalhousie University and QEII Health Sciences Centre, Halifax/CA

Background: Precision medicine provides efficient treatment options for lung cancer patients as it targets the individual tumor’s genetic makeup. Recent development of immune therapy based on immune checkpoint inhibitor also provides hope for patients. Currently lung cancer mutational data available in the literature are mainly from advanced stage non-small cell lung cancer. There is insufficient information from early stage lung cancer patients. PD-L1 status in relation to clinical and pathological characteristics is also unclear. This study tried to address these issues from 900 cases of surgically resected lung cancer.

Method: Multiplexed molecular profiling in 900 surgically resected lung cancer specimens. A panel of gene including EGFR, KRAS, BRAF, PIK3CA, HER2 and ALK was tested. PD-L1 was also evaluated by immunohistochemistry using pharmDX. Tumor Proportional Score (TPS) in a 10% increment was measured. Mutational status and PD-L1 TPS in each cancer subtype in relation to cancer pathological characteristics were investigated. Correlations between gene mutation, PD-L1 status and cancer staging were performed. Gene mutation and PD-L1 status with patients’ demographic information such as gender, age, smoking history, as well as survival data after surgery were also analysed.

Result: This cohort includes adenocarcinoma (65%), squamous cell carcinoma (24%), large cell carcinoma (6%), other subtypes (5%). Stage I accounts for 56%, stage II, 26%, stage III, 16%, stage IV, <2% with a mean age of 66 years. In adenocarcinoma, KRAS accounts for 36%, EGFR 10%, BRAF 1%, PIK3CA 1%, ALK 0.2%, no mutations 52%. Only 5% squamous cells carcinoma showed mutations. PD-L1 TPS >1% accounts for (37%), TPS 1-9% (18%), TPS 10-19% (7%), TPS 20-29% (5%), TPS 30-39% (5%), TPS 40-49% (1%), TPS 50-59% (5%), TPS 60-69% (4%), TPS 70-79% (4%), TPS 80-89% (5%), TPS 90-99% (7%) and unsuccessful (2%). PD-L1 expression were significantly associated with female (p<0.001) and never smokers (p<0.001), with well differentiated adenocarcinoma (p<0.001), and with absence of vascular invasion (p<0.01). KRAS mutations were more prevalent in younger age group (p=0.003). Poorly differentiated cancer histology was associated with absence of KRAS or EGFR mutations. There was no significant association between PD-L1 expression and age, sex, pathological stage and smoking status. PD-L1 expression was significantly associated with vascular invasion (p=0.035). EGFR mutations were significant associated with absence of PD-L1 expression (p=0.02), but no association between KRAS mutations and PD-L1 expression (p=0.10). Conclusion: This study provides comprehensive information enhancing our knowledge in depth about driver gene mutations and immune checkpoint PD-L1 status in non-small cell lung cancer patients.

MA10 CONSIDERATIONS IN IMMUNOTHERAPY / REAL WORLD
TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MA10.02 IMPACT OF ANTIBIOTICS ON OUTCOME OF METASTATIC NON SMALL CELL LUNG CANCER PATIENTS TREATED WITH IMMUNOTHERAPY
G. Galli1, M. Poggi2, G. Fuc3, M. Imbimbo2, C. Proto2, D. Signorelli2, M. Vitali2, N. Zilembo1, M. Ganzinelli1, F. De Braud1, M. Garassino2, G. Lo Russo3
1Medical Oncology, Istituto Nazionale Dei Tumori, Milan/IT, 2IRCCS Istituto Nazionale Dei Tumori, Milan/IT, 3Department of Respiratory Diseases and Thoracic Oncology, Aphp – Hôpital Ambroise Paré, Boulogne-Billancourt/FR

Background: Immunotherapy (IO) is effective against metastatic non small cell lung cancer (mNSCLC). Gut microbiota has a strong impact on immune functions and its imbalance due to antibiotics (atbs) may impair the efficacy of IO. Recent works on other malignancies supported this evidence, but data are still lacking. We studied this topic in a case series of mNSCLC patients (pts) treated with IO.

Method: Data about all consecutive pts with mNSCLC treated with IO at Istituto Nazionale dei Tumori, Milan, Italy, between 04/2013 and 01/2018 were retrospectively collected. Pts were stratified according to atb use before 1 month (mo) and 3 mos after the beginning of IO, and to atb exposure (AEx) defined as the ratio “days under atb/days under IO”. Survival was estimated with Kaplan-Meier method. Log-rank test was used to compare curves. Multivariate analysis was performed with Cox proportional model.

Result: One hundred fifty-seven pts were analyzed, for a median follow-up of 28.6 mos. IO consisted in an anti-PD1 agent in 62.4% of cases, in an anti-PDL1 agent in 32.5% of cases, in a combination anti-PDL1+anti-CTLA4 in 5.1% of cases. First-line IO was administered in 25 cases, second-line IO in 66 cases, third- or more advanced-line IO in 66 cases. Twenty-seven pts received atbs. The 3 most commonly used atbs were levofloxacin (55.6%), amoxicillin/clavulanate (25.9%), and ceftriaxone (14.8%). No differences in either response rate, progression free survival (PFS) and overall survival (OS) were observed between the subgroups defined by atb use (p = .14, .18 and .24, respectively). Median AEx of the treated pts was 5%. The pts with an AEx longer than the median one had significantly worse PFS (2.2 vs 7.7 mos, p < 0.0001) and OS (4.9 vs 16.3 mos, p = 0.0004) than the others. This result maintained significance after correction for IO line (p = 0.0003) and performance status (p = 0.0002), which were the only other variables influencing PFS and OS. Conclusion: Though no differences in outcome could be observed in our population according to simple atb use, a significant disadvantage in PFS and OS became evident for pts with a higher AEx. If confirmed, these data may suggest to carefully weigh the prescription of atbs to mNSCLC pts treated with IO.

Keywords: Antibiotics, Immunotherapy, metastatic non small cell lung cancer

MA10.05 EFFECT OF EARLY STEROIDS USE IN ADVANCED NSCLC PATIENTS TREATED WITH IMMUNOTHERAPY
Medical Oncology, Istituto Nazionale Dei Tumori, Milan/IT

Background: Immunotherapy (IO) radically improved patients (pts) outcomes in advanced non-small cell lung cancer (NSCLC). Because of their immunosuppressive activity, the use of steroids as supportive care medications or for mild adverse events, even if anti-inflammatory dosage, is debatable. In this study we assessed the effect of early steroids use on clinical outcomes of pts with advanced NSCLC treated with IO. We retrospectively collected demographics, clinical and pathological data of pts with advanced NSCLC treated with IO at our institution with at least one instrumented response assessment. Early use of steroids was defined as the use of a daily prednisone-equivalent dose ≥ 10 mg for at least 1 day within 28 days from the start of IO. Chi-square test or Fisher’s exact test were used to compare the proportion of early use of steroids with pts’ characteristics. The Kaplan-Meier method and the Cox proportional-hazards model were used for survival analyses while the reverse Kaplan-Meier method was used for follow-up quantification. Result: We included 151 pts, 38 (23%) of whom recur to an early use of steroids. Six pts (4%) received combinational PD-L1+CTLA-4 blockade while 145 (96%) received single agent anti PD-1/PD-L1. Early use of steroids was positively associated with ≥ 2 metastatic sites (OR 3.08, 95% CI 0.91-10.25; P = .01) and ECOG PS ≥ 2 (OR 4.57; 95% CI 1.10-20.37; P = .03) and negatively associated with disease control (OR 0.32; 95% CI 0.14-0.71, P = .006). With a median follow-up of 28.61 months, early use of steroids characterized a poorer median OS (4.86 vs 15.14 months; HR
MA10.06 IMPACT OF IMMUNE-RELATED ADVERSE EVENTS ON SURVIVAL IN PATIENTS WITH ADVANCED NON-SMALL CELL LUNG CANCER TREATED WITH NIVOLUMAB

B. Ricciuti1, C. Genova2, A. De Giglio1, M. Brambilla1, M. Bassanelli3, M.G. Di Bello1, S. Bagliovation, G. Metrov, F. Grossiov, R. Chiariv, R. Premiani1, A. Chiari1

1Medical Oncology, Santa Maria Della Misericordia Hospital, Azienda Ospedaliera Di Perugia, Perugia/IT, 2Lung Cancer Unit, IRCCS Aou San Martino - ist, Genova/IT, 3Oncology, San Camillo de Lellis Hospital, Rieti/IT, 4Medical Oncology, IRCCS Aou San Martino – ist, Genova/IT

Background: Anti PD1 and anti PD-L1 monoclonal antibodies represent the standard of care for platinum-pretreated advanced non-small cell lung cancer (NSCLC) patients. The exact role of immune-related adverse events (irAEs), which we hypothesize might reflect antitumor response, needs to be clarified. In this study we investigated whether the development of irAEs was associated with nivolumab efficacy in patients with advanced NSCLC.

Method: We conducted a multicenter retrospective study of patients with advanced NSCLC treated with nivolumab between October 2013 and September 2017. irAEs were defined as AEs having immunological components. The chosen taxane was paclitaxel in 60% of patients.

Results: Among 195 patients (median age 63, [30-40] years; 129 men [65.6%]; 67 squamous [34.4%]; irAEs were observed in patients 43.6%, including 15 patients (7.6%) with grade 3 or 4 events. Median PFS was 5.7 months in patients with irAEs compared to 2 months of those without irAEs (P < 0.0001). Median OS was 17.8 months compared to 4.0 months of no-irAEs group (P < 0.0001). The survival benefit of irAEs was consistent also in 12- and 6-weeks landmark analysis. Patients who developed ≥ 2 irAEs (n = 37) had a significantly longer median PFS and OS compared to those with one AE (n = 48) or none (n = 110) (PFS: 8.5 months vs 4.6 vs 2, P < 0.0001; OS: 26.8 months vs 11.9 vs 4, P < 0.0001). Multivariable analysis revealed that irAEs were positively associated with survival outcome, with hazard ratios of 0.48 (95%CI, 0.34-0.77; P < 0.0001) for PFS and 0.38 (95%CI, 0.26-0.56; P < 0.0001) for OS. Conclusion: This is the largest study conducted to date aimed to evaluate whether the development of irAEs is predictive of nivolumab efficacy in pre-treated NSCLC patients. In this study we confirmed that the development of irAEs was a strong predictor of survival outcomes in NSCLC patients who had received nivolumab in ≥ 2 line setting. This data was consistent in the 12- and 6-weeks landmark analysis, suggesting that an early onset of irAEs might be predictive of durable clinical benefit in NSCLC patients treated with nivolumab. Moreover, patients who experienced ≥ 2 irAEs had a more pronounced survival benefit compared to those with 1 irAE. Further studies are required to investigate the molecular mechanisms underlying this association.

Blokhin National Medical Research Center of Oncology, Moscow/RU, 8University Hospital Tuebingen, Tuebingen/DE, 9Tohya University Edmura/TR, 10Oncology, Queens University, Kingston/ON/CA, 11Department of Thoracic Oncology, Kanagawa Cancer Center, Yokohama/JP, 12Thoracic Oncology, Jilin Provincial Cancer Hospital, Changchun/CH.

Background: In the randomized, double-blind, phase 3 KEYNOTE-407 study (NCT02775435), pembrolizumab plus chemotherapy with carboplatin and paclitaxel or nab-paclitaxel significantly prolonged OS (HR 0.64, 95% CI 0.49-0.85, P=0.0008) and PFS (HR 0.56, 95% CI 0.45-0.70, P=0.0001) compared with placebo plus chemotherapy in patients with previously untreated, metastatic squamous NSCLC.

The benefit of pembrolizumab plus chemotherapy was observed irrespective of PD-L1 TPS. Pembrolizumab plus chemotherapy also had a manageable safety profile. We performed an exploratory analysis of outcomes by investigator’s choice of paclitaxel or nab-paclitaxel, which was a randomization stratification factor. Method: 559 eligible patients were randomized 1:1 to pembrolizumab 200 mg or placebo Q3W for up to 35 cycles plus 4 cycles of carboplatin AUC 6 mg/mL/min Q3W and investigator’s choice of paclitaxel 200 mg/m² Q3W or nab-paclitaxel 100 mg/m² QW. Primary end points were OS and PFS; ORR and safety were secondary. Result: Paclitaxel was the chosen taxane in 60% of patients. The addition of pembrolizumab to chemotherapy improved OS, PFS, and ORR regardless of choice of carboplatin or paclitaxel or carboplatin and nab-paclitaxel (Table). Incidence of grade 3-5 AEs in the pembrolizumab plus chemotherapy arm vs placebo plus chemotherapy arm was 63.9% vs 59.3% in paclitaxel recipients and 78.9% vs 81.4% in nab-paclitaxel recipients. AEs led to discontinuation of all treatment in 13.6% vs 8.4% of paclitaxel recipients and 12.8% vs 3.5% of nab-paclitaxel recipients and led to discontinuation of any treatment in 19.5% vs 13.2% and 29.4% vs 9.7%, respectively. Immune-mediated AEs occurred in 29.6% vs 9.6% of paclitaxel recipients and 27.5% vs 7.1% of nab-paclitaxel recipients.

Conclusion: Adding pembrolizumab to chemotherapy with carboplatin and a taxane improved efficacy and was generally tolerable compared with chemotherapy alone as first-line therapy in patients with metastatic squamous NSCLC regardless of whether paclitaxel or nab-paclitaxel was the chosen taxane.

MA10.09 NECPAL-2: A MULTICENTRE DESCRIPTIVE STUDY OF PRIMARY AND CONTINUOUS ATTENTION IN PALLIATIVE CARE IN ARGENTINA: LUNG CANCER COHORT

C. Gabay1, M. Bonet1, M. Castro2, R. Tranier3, S. Sandijian4, S. De Lellis5, A. Sauri6, V. Tripodoro7, G. De Simone3
1Thoracic Oncology and Translational Research Unit, Instituto de Oncologia Angel H. Roffo, University of Buenos Aires, Buenos Aires/AR, 2 Palliative Care Unit, Instituto Angel H Roffo, University of Buenos Aires, Caba/AR, 3 Pallium Institute, Latin America, Buenos Aires/AR, 4 Palliative Care Unit, Instituto Investigaciones Medicas Alfredo Lanari, University of Buenos Aires, Caba Argentina, Buenos Aires/AR

Background: In Argentina, lung cancer is the most deadly neoplasm (9230 annual deaths). Early identification of palliative care (PC) needs has proven benefits in terms of quality of life, survival, and decision making in lung cancer patients. The NECPAL CCOMS-ICO© tool is face and content-validated instrument to identify patients likely in need of PC.

Method: To implement and evaluate a demonstration multicenter program for early and continuous PC for lung cancer patients in Buenos Aires using the NECPAL-CCOMS-ICO© tool (multifactorial assessment) in every level of attention. We reported the results of one University Cancer center lung cancer cohort (2016-2018). We categorized patients as surprise question positive (SQ+). (Would you be surprised if this patient were to die in the next 12 month?). If the healthcare professional answered ‘NO’, the patient was considered SQ+ and they were also considered NECPAL+ when they presented at least one additional parameter from the NECPAL tool. All patients classified as NECPAL+ were considered to be in need of PC. Then using a Cox regression model analyzed predictors for overall survival (OS). Result: 82 patients out of 206 were SQ+ and NECPAL+. Median age 64 (35-82). 46% had stage IVB (8%), 18% IVA. 19.5% locally advanced, and 7 pts early stage. 6 pts presented SCLC. Male were 59%. 78 pts were analyzed for overall survival; n=4 were excluded due lost of follow up. 56% had died with a Median OS of 11 months (7.2-14.7). 5/82 pts did not receive any kind of oncology treatment due ECOG, comorbidities or patients’ choice. Median OS was 17 months (10.5-23.4) for men and 10 months (3.7-16.2) for females (p=0.08). In the univariate analyses, only metastasis in vital organs (nervous central system, liver, massive lung) was predicted of survival (17 vs 8 months; p=0.035). The other NECPAL indicators did not met the criteria for significance. The multivariate analysis, did not find a statistically significant combination of predictors for overall survival except metastasis in vital organs. It was noted an small number of low PPS score (11/78), as well as nutritional (14/78) or severe functional deterioration (5/78), in spite of the majority of the cohort had advanced disease.

Conclusion: This Program adds a prospective direct method of measuring prevalence of PC needs including a Palliative approach. The results provided support consideration of the NECPAL tool as a prognostic tool in our setting.

MA10 CONSIDERATIONS IN IMMUNOTHERAPY / REAL WORLD

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MA10.10 LUNG CANCER STIGMA: A TEN-YEAR-VIEW OF PATIENT, PROVIDER, AND PUBLIC ATTITUDES ABOUT LUNG CANCER

J. King1, M. Rigney2, L. Carter-Harris3

Background: The presence of lung cancer stigma is well documented (Chapple, 2004; Chambers, 2012; Marlow, 2015) and impacts the care and treatment of lung cancer survivors (Tod, 2008; Carter-Harris, 2014). In 2008, a large survey of patients, oncologists, and general public revealed that most participants felt lung cancer was principally caused by external factors, was preventable, and lung cancer patients were partly to blame for their illness (Weiss 2014; 2017). We replicated the survey to understand whether perceptions have changed over the last decade.

Method: 1001 members of the general public, 208 lung cancer patients, and 205 oncologists who treat lung cancer were surveyed with the identical instrument as 2008 plus 3-11 questions at the end including Cataldo Lung Cancer Stigma Scale (Cataldo, 2011) strongest-loaded items for the patient survey. The survey was administered by phone and online during summer 2018.

Result: General lung cancer awareness has significantly improved in a decade with 94% of the public reporting familiarity with lung cancer, every segment reporting increased media visibility (65%, 78%, 85% for public, patients, and oncologists, respectively), and patients reporting significantly increased use of advocacy organizations (39% vs 18%, p<.05). Additionally, significantly more oncologists reported having adequate treatment options to prolong patients’ lives (52% vs 31%, p<.05) and most patients reported satisfaction with medical care (87%) and treatment options (71%). Despite these advances, stigma remains a critical problem. In 2018, significantly more of the public believed lung cancer patients are viewed/treated differently than other cancer patients (37% vs 31%, p<.05) and a similar proportion (56%) felt patients are partly to blame for their illness. Oncologists continue to believe there is stigma associated with lung cancer (68%) although more felt stigma was lower for never-smokers. More oncologists indicated patients blame themselves (67% vs 57%). Patients reported significant increases (p<.05) in presence of stigma associated with lung cancer (70% vs 54%), lung cancer patients being treated differently by society (63% vs 45%), having personally been treated differently by society (43% vs 25%), and loved ones would be more supportive if they had a different type of cancer (25% vs 11%).

Conclusion: After a decade of lung cancer research progress, results indicate considerably elevated awareness. Unfortunately, disease stigma remains. Interestingly, stigma is reported more frequently by lung cancer patients and may be felt more acutely, perhaps due to increased awareness and empowerment. This work underscores the need to address stigma with proactive multilevel approaches (Hamann, 2018).

Keywords: stigma, survivorship, quality of life

MA11 BIOMARKERS OF IO RESPONSE

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MA11.01 COMPARATIVE EFFICACY OF T-CELL INTRINSIC VERSUS EXTRINSIC PD-1 BLOCKADE TO OVERCOME PD-L1+ TUMOR-MEDIATED EXHAUSTION

J. Dozier, N. Chen, J. Saini, N. Chintala, P. Adusumilli
Thoracic Service, Department of Surgery, Memorial Sloan Kettering Cancer Center, New York/US

Background: Anti-PD-1 agents are effective in overcoming PD-L1+ mediated T-cell exhaustion. Effective therapeutic regimens include multiple, long-term administration. We hypothesized that a single dose of T-cell intrinsic PD-1 blockade by expression of a dominant negative receptor (PD1-DNR) can be equally effective as multiple doses of anti-PD-1 agent administration in the treatment of PD-L1 overexpressing thoracic cancers. Method: Human T cells engineered to target the cancer-antigen mesothelin (MSLN) by expression of a chimeric antigen receptor (CAR) with or without co-transduction with a PD1-DNR underwent repeated antigen stress with cancer cells with constitutive overexpression of PD-L1. For comparative efficacy evaluation, anti-PD-1 antibody was co-administered with CAR T cells (CARs). In vitro efficacy was evaluated by cytotoxicity (chromium-51 release assay). In vivo, mice with established pleural tumor were treated with either a single dose of MSLN CARs (with and without anti-PD-1 agent) or MSLN PD1-DNR CARs. Tumor burden reduction by bioluminescence imaging and median survival were evaluated. Result: In vitro, constitutive PD-L1 overexpression (Fig A) inhibits MSLN CAR effector function as evidenced by a decrease in cytotoxicity following repeated stimulation with MSLN-PD-L1+ tumor cells (Fig B). MSLN PD1-DNR CARs had increased cytotoxicity when compared to MSLN CARs with or without high frequency anti-PD-1 antibody supplementation. In vivo, mice treated with MSLN CAR (with or without anti-PD-1 antibody) or MSLN PD1-DNR CARs demonstrated enhanced tumor regression (Fig C) and prolonged median survival (Fig D) compared to MSLN CARs alone. Furthermore, a single low dose of MSLN PD1-DNR CARs shows equal anti-tumor efficacy compared to MSLN CARs with multiple doses of anti-PD-1 antibody.

(See next page)
MA11.02 INCREASED CD3+ TIL INFLTRATION AND LOW FOXP3+/CD8+ TIL RATIO CAN PREDICT ANTI-PD-1 THERAPEUTIC RESPONSE IN NON-SMALL CELL LUNG CANCER PATIENTS

H. Kim1, H.J. Kwon2, Y.B. Han1, S.Y. Park1, E.S. Kim1, J. Chung2
1Seoul National University Bundang Hospital, Seongnam/KR, 2Seoul National University Bundang Hospital, Seoul National University College of Medicine, Seoul/ KR

Background: To determine whether distinct tumor microenvironments differentially affect the clinical response to anti-PD-1 therapy in non-small cell lung cancer (NSCLC), we investigated the expression level of PD-L1 and tumor infiltrating lymphocytes (TILs) and elucidate their predictive role.

Method: Forty pretreated specimens (including 21 resected and 19 biopsied tissues) from 36 advanced, treatment-refractory NSCLC patients who underwent PD-1 blockade therapy were analyzed. PD-L1 expression by tumor cells and the distribution of CD3, CD8, CD4, FOXP3 and PD-1 positive TILs were immunohistochemically assessed. The mean number of cells positive for each marker in covered total fields was expressed in density per mm² using digital image analyzer. In addition, CD8+/CD3+, CD8+/CD8+, CD8+/CD4+, FOXP3+/CD8+, and PD-1+/CD8+ ratios were calculated for each specimen using the mean number of total fields. Result: CD3+ and CD8+ TILs were distributed more in PD-L1 positive group compared to PD-L1 negative group. Inversely, EGFR mutant group showed fewer CD3+ TILs than EGFR-naive group. The patients in the clinical benefit group with PD-1 blockade showed a higher number of CD3+, CD8+ TILs and a higher CD8+/CD3+ TIL ratio (p=0.003, p=0.001, and p=0.042) and a lower FOXP3+/CD8+ TIL ratio compared to non-responders (p=0.001).

We analyzed the effects of TIL, PD-L1 and clinicopathologic factors in PD-1 blockade therapeutic response using logistic regression. In multivariate analysis, increased CD3+ TIL infiltration and low FOXP3+/CD8+ TIL ratio were found to be independent predictors of clinical benefit with PD-1 blockade. (p=0.014 and p=0.03, respectively).

Using receiver operating characteristic curves, levels of CD3+ TIL and FOXP3+/CD8+ TIL ratio that provide the best distinguishing point between responder versus non-responder to PD-1 blockade were 617.5/mm² and 25%, respectively (p=0.007 and p=0.003). Considering that 1 mm² is about 5 high power fields (HPF), a good response to the PD-1 blockade can be expected when CD3+ TIL is observed in 120 per 1 HPF and CD8+ TIL : FOXP3+ TIL are greater than 4 : 1. In addition, there were no difference between sample acquisition method (resection vs. biopsy) and duration (3, 6, and 12 months before PD-1 blockade treatment), and TIL expression.

Conclusion: Based on our results, TIL is an independent predictive factor of response to PD-1 blockade and we suggested a cutoff value of TIL to predict responder group. In addition, properly sampled small biopsy tissue and well preserved archival specimens are feasible to evaluate TIL status.

MA11.03 INTERACTION OF TUMOR INFILTRATING LYMPHOCYTES AND CANCER NUCLEI PREDICTS RESPONSE TO NIVOLUMAB IN NON-SMALL CELL LUNG CANCER (NSCLC)

X. Wang1, C. Barrera2, C. Lu1, V. Velcheti3, A. Madabhushi1
1Biomedical Engineering, Case Western Reserve University, Cleveland Heights/OH/US, 2Universidad Nacional de Colombia, Bogotá/CO, 3Cleveland Clinic, Pepper Pike/US

Background: Immune checkpoint inhibitors, particularly drugs targeting the Programmed death-1 (PD-1) pathway, are promising agents in NSCLC. These drugs however are effective in only a small subset of patients. Programmed death Ligand-1 (PD-L1) expression in the tumor predicts response to these agents but is not an optimal biomarker because of spatial and temporal heterogeneity associated with PD-L1. PD-L1 is upregulated in response to inflammation in the tumor and strongly correlates with Tumor-infiltrating lymphocytes (TILs). In this work, we evaluated whether quantitative measurements relating to the spatial interplay and arrangement of TILs and cancer nuclei from diagnostic biopsy tissue slide images (H&E) was predictive of response to Nivolumab.

Method: Tumor biopsies of total 82 NSCLC patients previously treated...
with Nivolumab from two different institutions were employed in this study. The RECIST criteria was used to define response. [v1] The 492 features characterizing the global interaction of TILs and cancer cells through graph interplay metrics are extracted from tumor regions delineated by two expert pathologists to interrogate the difference of phenotypes. Top 5 features were learnt on learning set by random forest classifier from one institution (n = 32) and independently validated on patients from a second site (n = 50). Result: The most predictive features comprised of difference of characteristic path length between lymphocyte graph and cancer nuclei graph and cosine similarity between lymphocyte node and cancer nuclei node based on their node centrality index. The random forest classifier yielded an area under the receiver operating characteristic curve (AUC) of 0.76 on the training cohort and 0.68 on the validation set (Figure 1).

**Conclusion:** Our results showed that quantitative measurements relating to the spatial interplay and arrangement of lymphocyte and cancer nuclei from H&E slide images were predictive of response to Nivolumab in NSCLC. Additional independent multi-site validation of these features is needed.

**Keywords:** Prediction response to Nivolumab, Quantitative image analysis, Interaction of TILs and cancer cells

**Background:** Indoleamine 2,3-dioxygenase-1 (IDO-1) is a cytosolic enzyme involved in the catabolism of tryptophan; IDO-1-related immune suppression is due to decreased tryptophan availability and to the generation of tryptophan metabolites, culminating in substantial suppression of T-lymphocytes. Here we investigate IDO-1 expression in a cohort of non-small-cell lung cancer (NSCLC) specimens, both in tumor cells and in immune infiltrate, with correlation of IDO-1 to PD-L1 expression, clinical patient demographics and outcomes. **Method:**

A cohort of 1,200 NSCLC samples were obtained from 437 patients who underwent surgical lung resections at Austin Health, Melbourne, Australia. IDO-1 expression was evaluated by immunohistochemistry. Correlations were assessed using Spearman and Kendall tests. A Cox proportional hazards (PH) model was used to assess if overall survival (OS) was associated with IDO-1 positivity in univariate and multivariable settings. Result: Samples from 437 patients were analyzed for IDO-1 expression, with 111 (25.4%) determined as positive (H-Score ≥ 1) and 326 patients (74.6%) as negative (H-Score: 0). IDO-1 expression was determined to be greater in tumor immune infiltrate, with 406 patients (93.8%) determined as positive, while just 27 (6.2%) were IDO-1 negative. There was a significant positive correlation between IDO-1 positive tumor cells and immune cells (0.2167, p < 0.001). Both continuous and binary versions of tumor H-Score showed a significant positive correlation with the amount of tumor immune infiltrate (0.1806 and 0.1698, p < 0.0001, respectively). None of the analyzed variables (age, sex, histology, stage, EGFR, KRAS and PD-L1 status) were found to display a significant correlation with IDO-1 positivity in tumor and immune cells. IDO-1 positivity in tumor cells was found to be significantly associated
with OS in the univariate setting and was borderline significant in the multivariable model \([P-value = 0.006 and 0.053, respectively; HR: 0.798 (95\% CI: 0.635-1.003)]\). Conclusion: To our knowledge, this is the most extensive analysis of IDO-1 expression in NSCLC patients reported in the literature. Our results suggest the possible prognostic role of IDO-1 expression in tumor and immune cells, highlighting the relevance of IDO-1 detection in tumor tissue. Since new compounds targeting IDO-1 are actually under investigation, the identification of potential prognostic and predictive biomarkers will be needed.

Background: Recent research has unveiled novel molecular mechanisms linking imbalanced complement activation and cancer progression. In this context, complement inhibition has emerged as a treatment option for maximizing the clinical efficacy of current immunotherapies that target the PD-1/PD-L1 immune checkpoint. Method: Lung cancer tissues were obtained from 140 patients treated by surgery at the Clínica Universitaria de Navarra. Inclusion criteria were: NSCLC histology, complete resection of the primary tumor, absence of cancer within the five years previous to the lung cancer surgery, and no treatment with chemo- or radiotherapy prior to surgery. Resected primary lung tumors were fixed in formalin and embedded in paraffin. After antigen retrieval samples were incubated with antibodies: C4d (Dako), C5aR1 (Dako), Kallikrein 1 (Dako) and anti-PD-1 followed by detection with the Envision system (Dako). Peroxidase activity was visualized with 3,3′-diaminobenzidine. Sections were slightly counterstained with hematoxylin. Two independent and blinded observers calculated the percentage of positive staining for all these proteins, indicating complement activation in primary NSCLC.

Background: Recent research has unveiled novel molecular mechanisms linking imbalanced complement activation and cancer progression. In this context, complement inhibition has emerged as a treatment option for maximizing the clinical efficacy of current immunotherapies that target the PD-1/PD-L1 immune checkpoint. Method: Lung cancer tissues were obtained from 140 patients treated by surgery at the Clínica Universitaria de Navarra. Inclusion criteria were: NSCLC histology, complete resection of the primary tumor, absence of cancer within the five years previous to the lung cancer surgery, and no treatment with chemo- or radiotherapy prior to surgery. Resected primary lung tumors were fixed in formalin and embedded in paraffin. After antigen retrieval samples were incubated with antibodies: C4d (Dako), C5aR1 (Dako), Kallikrein 1 (Dako) and anti-PD-1 followed by detection with the Envision system (Dako). Peroxidase activity was visualized with 3,3′-diaminobenzidine. Sections were slightly counterstained with hematoxylin. Two independent and blinded observers calculated the percentage of positive staining for all these proteins, indicating complement activation in primary NSCLC. Results: Immunohistochemical analysis showed positive staining for all these proteins, indicating complement activation in primary lung tumors. Importantly, high levels of C1q, C4d, and C5aR1 predict poor disease-free survival (P=0.004; P=0.044; and P=0.02; respectively) and poor overall survival (P=0.031; P=0.022; and P=0.048; respectively) in NSCLC patients. A significant association between PD-1 expression levels in immune cells and disease-free survival was found (P=0.016), but this association was not significant for overall survival. PD-L1 expression levels in both immune cells and tumor cells were not associated with prognosis in NSCLC patients. Interestingly, those patients with high levels of C4d presented a significant decrease of PD-L1 expression in tumor cells (P=0.001) suggesting a link between complement activation and the immune homeostasis of the tumor microenvironment. Conclusion: Complement activity in primary NSCLC tumors predicts poor prognosis. C4d, a marker of complement activation, is associated with low levels of PD-L1 expression in tumor cells. Harassing complement system by therapeutic tari may enhance PD-1/PD-L1 immune checkpoint-based immunotherapies.

MA11.07 EXPRESSION OF LAG-3 AND NY-ESO-1 IN TUMOR CELLS IS PROMISING BIOMARKER PREDICTING DURABLE CLINICAL BENEFIT OF PD-1 BLOCKADE IN ADVANCED NSCLC
H.R. Jang1, S.H. Kim1, K.J. Suh1, Y.J. Kim2, M.S. Kim1, B. Keam3, T.M. Kim1, J. Chung1, D. Kim1, D.S. Heo1, J. Lee2

Background: Anti-PD-1 antibodies are currently used in treating advanced non-small cell lung cancer (NSCLC). PD-L1 expression in tumor cells and available predictive biomarker is the only available predictive biomarker in the clinic. Lymphocyte activation gene-3 (LAG-3) is an inhibitory checkpoint in immune cells and NY-ESO-1 is an antigen expressed in tumor cells. We investigated LAG-3 and NY-ESO-1 protein expression and its relationship to response to anti-PD-1 therapy in NSCLC. Method: We retrospectively reviewed the medical records of 38 patients with advanced NSCLC who were enrolled in prospective clinical trials of nivolumab or pembrolizumab monotherapy (NCT01295827, NCT01905857, and NCT02175017) between October 2013 and April 2017 at Seoul National University Hospital and Seoul National University Bundang Hospital. Immunohistochemical staining (IHC) of NY-ESO-1 (E978, Invitrogen), and PD-L1 (22C3, Dako) in tumor cell and LAG-3 (EPR4394, Abcam) in immune cell was determined to perform protein expression. Results: LAG-3 and NY-ESO-1 protein expression were detected in 75% and 52% of samples, respectively. Sixteen patients with durable clinical benefit (DCB, anti-PD-1 therapy more than 6-month) were grouped as responder. NY-ESO-1 expression (DCB 11/19 vs 5/19, p = .05) and LAG-3 expression (DCB 16/29 vs 0/9, p = .003) were significantly correlated with the DCB to Anti-PD-1 therapy, while PD-L1 expression was identified in 5 patients with DCB (5/7 vs 11/29, p = .12). Patients with both NY-ESO-1 and LAG-3 expression had high rate of DCB (73.3%, 11/15 pts). With the results of the interaction with DCB, the calculation of positive predictive value and negative predictive value about durable clinical benefit is assessed and the significance of each measurement was presented by Fisher’s exact test. By analyzing LAG-3 expression in tumor cell was 100% and PPV of each protein expression was LAG-3 (55.17%), NY-ESO-1 (57.89%) and PD-L1 (71.43%) respectively. In survival analysis, LAG-3 expression was a significant predictor for DFS (HR 0.170; CI 0.086-0.437; p = .0001) and OS (HR 0.50; CI 0.140-0.598; p = .002). Conclusion: NY-ESO-1 expression on tumor tissue and LAG-3 expression on tumor microenvironment may be useful for identifying advanced NSCLC patients for the treatment of anti-PD-1 therapy. These protein markers seem quite promising and warrant further investigation in large sample size.

MA11 BIOMARKERS OF IO RESPONSE
TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MA11.09 SINGLE-CELL CHARACTERIZATION OF THE IMMUNOLOGIC MICROENVIRONMENT IN ADVANCED-STAGE, ONCOGENE-DRIVEN NSCLC
J. Rutow1, C. Mccooach1, A. Maynard2, D. Naeger1, Y. Gesthalter1, K.P. Kollip2, S. Darmanis3, T. Bivona1, C. Blakely1, J. Weissman1
1 Medicine, University of California, San Francisco, San Francisco/US; 2 Chan Zuckerberg Biohub, San Francisco/US; 3 Radiology, University of California, San Francisco/US

Background: The immunologic microenvironment in oncogene-driven non-small cell lung cancer (NSCLC) is poorly understood. Despite high initial response rates to tyrosine kinase inhibitors (TKIs) in patients with oncogene-driven NSCLC, responses are incomplete and transient. Furthermore, response rates to subsequent checkpoint inhibitor immunotherapies are very low. Understanding the immunologic microenvironment may facilitate understanding treatment resistance in this population. Method: From October 2016 to March 2018 we performed single-cell sequencing on 35 tissue samples from 28 patients with NSCLC. Fresh tissue samples were obtained at time of standard of care biopsies and as research sample collections. Single-cell level whole transcriptome RNA sequencing was performed using SmartSeq2. Cells were clustered into distinct cell states on a multi-dimensional gene expression space and visualized using t-distributed stochastic neighbor embedding (t-SNE) for further dimensionality reduction. Cellular identities for each cluster were established by examining the enrichment of known cell-type specific genes across all distinct clusters. Result: Tumor samples were obtained from a predominantly stage IV lung adenocarcinoma (90.6%) harboring an oncogenic driver (EGFR-mutant 50%, ALK-rearranged 21.9%, BRAF V600E 9.4%, ROS1-rearranged 9.4%, MET exon 14 skipping 6.3%, and KRAS-mutant 3.1%). Samples were collected prior to treatment (21.9%), during treatment (46.9%), and at disease progression on therapy (31.3%). All patients with a targeted oncogenic driver received a standard of care TKI and the KRAS-mutant patient received pembrolobuzim monotherapy. A total of 6048 cells were isolated, including 3457 immune cells, with an average of one million reads and 2500 genes per cell. The immunologic microenvironment (average 108 immune cells/sample) included macrophages/microcytes (33% of cells), T cells (31.9%), and B cells (11.6%), as well as a smaller fraction (<10%) of dendritic cells, Langerhans cells, mast cells,
neutrophils, and NK cells. Unbiased gene expression-based subclustering of T cells identified 7 distinct T cell populations, including naive (22.6%), cytotoxic and/or memory T cells (44.1%), and T regulatory cells (5.8%), as well as 6 tumor-associated macrophage populations with distinct gene expression patterns. **Conclusion:** Single-cell RNA sequencing to identify immune cell populations is feasible in advanced-stage NSCLC biopsy specimens across multiple time points during treatment. Here, we describe the heterogeneity of infiltrating immune cell phenotypes including T cell and macrophage subtypes. An improved understanding of the immunologic microenvironment in oncogene-driven NSCLC may facilitate patient stratification and individualized treatment and aid in the rational design of alternative or combination immunotherapy strategies for a patient population rarely responsive to current immunotherapeutic agents.

**Keywords:** Immunology, Single-cell, Targeted therapy

MA11 BIOMARKERS OF IO RESPONSE

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

**MA11.10 IDENTIFICATION OF MISMATCH REPAIR DEFICIENT LUNG ADENOCARCINOMAS USING TARGETED NEXT-GENERATION SEQUENCING**

N. Mahadevan1, P. Shrivastava1, J. Nowak1, M. Awad1, L. Sholl1

1Pennsylvania State University Health System, Hershey/US, 2Pennsylvania State University College of Medicine, Hershey/US

**Background:** Mismatch repair (MMR) deficiency/microsatellite instability (MSI) results from the inactivation of DNA mismatch repair proteins. Due to the defect in DNA repair, MMR-deficient (D) tumors display an elevated tumor mutation burden (TMB) and a characteristic increase in small insertions/deletions within homopolymer tracts (‘homopolymer indels’), a signature that can be detected using whole-exome sequencing methods. MMR-D/MSI predicts response to immune oncology (IO) therapy1,2. We have previously reported the identification of 8 MMR-deficient lung adenocarcinomas (mostly inoperable) using targeted next generation sequencing and characterized the clinicopathologic associations of MMR-D in this tumor type. **Method:** TMB and MSI status was derived from a 309-447 gene targeted next generation sequencing panel (OncoPanel) using an internally validated method (Nowak et al., 2017), that relies on an empirically defined homopolymer indel cutoff of >1.52/Mb to identify candidate MMR-D tumors. MMR/MSI status was confirmed using MSI PCR (5 marker panel) and/or immunohistochemistry (IHC) for MLH1, PMS2, MSH2, and MSH6. When indicated, MLH1 promoter methylation status was evaluated by methylation-specific PCR. **Result:** 2242 lung tumors, including 1835 non-squamous non-small cell lung carcinomas (NSCLC), were interrogated. A total of three lung tumors (all adenocarcinoma) with confirmed MSI/ MMR-D by orthogonal methods were identified, for a prevalence of 0.1% of all tumors and 0.2% of non-squamous NSCLC. The TMB of these tumors averaged 42.5 mutations/Mb with 7-10 homopolymer indels / Mb. All three tumors showed loss of MLH1 and PMS2 staining by IHC, two cases had somatic loss-of-function MLH1 variants and one showed MLH1 promoter methylation. All were from female patients whose mean age was 68 years (range: 53-83). All showed a poorly-differentiated phenotype. The other two patients had moderate/heavy smoking histories (12.5-80 pack-years) and showed no BRAF or KRAS mutations. One tumor evolved in the context of usual interstitial pneumonia. **Conclusion:** MMR-D is very rare in lung tumors, where it appears to arise as somatic event and is enriched in adenocarcinoma. MMR-D may coexist with other relatively uncommon driver alterations, including those not traditionally associated with IO response. Additional investigation is needed to determine if MMR-D confers sensitivity to IO in lung carcinomas.

**Keywords:** MMR deficiency, lung adenocarcinoma, next generation sequencing

MA11 BIOMARKERS OF IO RESPONSE

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

**MA11.11 DISCREPANCY OF TUMOR NEOANTIGEN BURDEN BETWEEN PRIMARY LESIONS AND MATCHED METASTASES IN LUNG CANCER**

T. Jiang, C. Zhou

Department of Medical Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN

**Background:** Personalized vaccine based on tumor neoantigen was shown to have a significant and potential role in curing cancer. However, whether tumor neoantigen identified from primary lesions were similar to their matched metastases remain unknown. Here, we aimed to compare the tumor neoantigen burden (TNB) between primary lesions and matched metastases in lung cancer. **Method:** Primary lung cancers, matched metastatic sites and peripheral blood (10 mL, EDTA) were collected before any systemic therapy as part of the standard clinical care. Genomic DNA was extracted from all included samples. The matched peripheral blood leukocytes were used as the source for germline DNA control. DNA libraries were subjected to whole-exome capture and then sequenced on an Illumina HiSeq X-TEN platform. The criteria for tumor neoantigen identification were tumor specific mutations (missense, frameshift, insertions/deletions), fold change > 10, high predicted affinity (IC50 < 500 nM) and predicted peptide of 9-10 amino acids in length. **Result:** Totally, 14 cases with matched lung primary lesions and metastases were enrolled, including 10 patients with liver metastases and 4 with brain metastases. A wide range of TNB were identified in both primary lesions (median 157, range 21-1156) and metastases (median 135, range 35-1902). We observed a large discrepancy of TNB between primary lesions and matched metastases with a median unique percentage of 82.2% (74.03%-95.24%) in primary lesions and 84.50% (77.45%-97.14%) in metastases. In patients with brain metastases, primary lesions had a percentage of 90.98% (79.57%- 97.24%) unique tumor neoantigens, while metastases had 86.03% (77.45%-97.14%). For those with liver metastases, the median unique percentage of tumor neoantigens was 80.58% (74.03%-88.66%) in primary lesions and 83.35% (78.49%-91.14%) in metastases. Smoking history and histological types had no impact on the discrepancy of TNB (P > 0.05, P > 0.05; respectively). TMB of primary lesions was similar to matched metastases (P = 0.733). However, primary lesions of brain metastases had a significantly higher percentage of unique tumor neoantigens than that of liver metastases (P = 0.025). **Conclusion:** There is a large percentage of different tumor neoantigens between primary lesions and matched metastases in lung cancer. Whether this discrepancy could affect the efficacy of following personalized vaccine on primary lesions or matched metastases need further investigation.

**Keywords:** non-small cell lung cancer, metastasis, neoantigen

**MA12.01 THE INFORMATION PATHWAY TO RANDOMISATION: PATIENTS EXPERIENCE OF THE MESOTHELIOMA AND RADICAL SURGERY (MARS2) FEASIBILITY TRIAL**

A. Tod1, C. Warnock2, K. Lord3, L. Darlison4

1School of Nursing and Midwifery, The University of Sheffield, Sheffield/GB, 2Weston Park Hospital, Sheffield Teaching Hospital NHS Foundation Trust, Sheffield/GB, 3Glenthera Hospital, Mesothelioma UK/university Hospitals of Leicester NHS Trust, Leicester/GB, 4Mesothelioma UK, University Hospitals of Leicester NHS Trust, Leicester/GB

**Background:** The Mesothelioma and Radical Surgery (MARS2) trial was established in the UK to evaluate the role of radical surgery, (Pleurectomy/decortication), for the treatment of malignant pleural mesothelioma (MPM). It compares chemotherapy and surgery to chemotherapy alone. The feasibility trial included a nested qualitative sub-study. The sub-study aimed to 1) understand the patient experience of MARS2 trial process and interventions and 2) Identify any information and support needs required by patients. We present here the results related to MARS2 participant’s information experiences and needs at the point of randomisation. Implications for information provision to enhance patient experience and overcome recruitment barriers within MPM trials are considered. **Method:** 41 in-depth longitudinal qualitative methods were used with 15 participants following randomisation. 9 participants received chemotherapy and surgery and 6 received chemotherapy alone. Interviews were conducted following randomisation, and at 6 and 12 months after the initial interviews. Participants randomised to surgery also had an interview after post-operative discharge. Data was collected between August 2015 and March 2017 and analysed using Framework

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MA12.03 THE IMPACT OF MALIGNANT PLEURAL MESOTHELIOMA HISTOLOGY ON THE USE OF SURGERY AND SURVIVAL IN A POPULATION-BASED ANALYSIS

C. Yang1, N. Mayne2, J. Deng3, S. Commander1, T. D’Amico4, M. Berry4

1Duke University Medical Center, Durham/NC/US, 2Section of General Thoracic Surgery, Duke University Medical Center, Durham/NC/US, 3Thoracic Surgery, Duke University, Durham/NC/US, 4Stanford University, Palo Alto/US

Analysis: The findings provide insight into the challenging context within which potential participants have to assimilate knowledge about a trial such as MAPS2. Prior to hearing about the trial participants had encountered a diverse range of new and concerning experiences. These included worrying symptoms, diagnostic tests, investigations and the drainage of litres of fluid from the lung. They had to absorb an array of life-changing facts in a short time including that they had a rare incurable cancer with a poor prognosis; their illness was an occupational disease with legal and financial implications due to asbestos exposure. Participants attended their trial consultation soon after this challenging diagnostic information was provided. This study reveals variations in understanding of the trial procedures, specifically decision-making regarding treatments, equipoise and the process of randomisation. Motivations for participating in the trial were identified along with preferences for information formats. Conclusion: This study provides useful insights into the information pathways of MPM trial participants, from diagnosis to randomisation. Results suggest that improvements in presentation of trial information and the development of formats that can be tailored to individual needs and preferred ways of learning, many enhance experience of and recruitment to MPM trials. Working with patients to co-produce information that communicates challenging concepts effectively, (such as randomisation and equipoise), may be a useful approach to meeting this challenge.

Keywords: Longitudinal qualitative research, Mesothelioma, patient experience

MA12.05 PHASE 1 STUDY OF HSP90 INHIBITOR GANETESPIB WITH PEMETREXED AND CISPLATIN/ CARBOPLATIN CHEMOTHERAPY FOR PLEURAL MESOTHELIOMA

1University of Leicester, Leicester/GB, 2Sheffield Ecmc, University of Sheffield, Sheffield/GB, 3CRUK Lunker Cancer Centre of Excellence, University College London Hospitals, London/GB, 4Department of Oncology, University of Oxford, Oxford/GB, 5Department of Oncology, William Harvey Hospital, University of Kent, Ashford/GB, 6Cancer Research Uk and UCL Cancer Trials Centre, University College London, London/GB, 7University Hospitals of Leicester NHS Trust, Leicesterc/GB, 4Aberdeen Royal Infirmary, Aberdeen/GB, 5Wythenshawe Hospital, Manchester University NHS Foundation Trust, Manchester/GB

Background: There have been no new licenced therapies for mesothelioma in over a decade. A Phase I/II dose-finding trial assessed the maximum tolerated dose of ganetespib in patients with malignant pleural mesothelioma with ECOG 0–1. Ganetespib was combined with standard pemetrexed/platinum therapy, using either cisplatin (GCip3), or carboplatin (GCarbP). Three ganetespib cohorts were: 100, 150 & 200mg/m² given days 1 and 15, every 21 days. GCip3 and GCarbP were administered using a 3+3 design. GCarbP followed an accelerated titration run-in using single patients, switching to a 3+3 design after one dose limiting toxicity (DLT). DLT was assessed during cycles 1-2 for GCip3 and cycle 1 for GCarbP. Gemcitabine instability was assessed by array-based analysis of somatic copy number. Result: 27 patients were treated (GCip3, n=16; GCarbP, n=11). Median age 66 (range 37-76), 6 PS-0/21 PS-1, and 25 male. Only 3 patients experienced DLTs, all at 200mg/m²: grade 3 nausea (GCip3, n=1; GCarbP, n=2); grade 2 infusion-related reaction (GCarbP, n=1); grade 3 neutropenia (GCip3, n=2; GCarbP, n=1). The maximum tolerated dose. Partial tumour response rate was 61% (14/23 evaluable patients); 7 patients had tumour burden reduction of >50% (Figure). PFS was better using 200mg/m² versus 100mg/m² (hazard ratio 0.32, 95%CI 0.11-0.95, p=0.04). One patient remains progression-
free even after 37 months. Total loss of heterozygosity (LOH) was correlated with increased tumour burden (n=7, correlation=0.7, p=0.078).

Figure. Best tumour response (% change in tumour burden from baseline)

Conclusion: Ganetespib plus pemetrexed and platinum chemotherapy was well-tolerated in patients with pleural mesothelioma, with evidence of activity, particularly at the recommended dose of 200mg/m2. LOH correlated with poorer response to this triplet combination.

MA12.06 STELLAR – FINAL RESULTS OF A PHASE 2 TRIAL OF TTFields WITH CHEMOTHERAPY FOR FIRST-LINE TREATMENT OF MALIGNANT PLEURAL MESOTHELIOMA

G. Ceresoli1, J. Aerts2, J. Madrak3, R. Dziedziszko4, R. Ramla5, S. Cedres6, B. Hiddinga7, J. Van Meerbeeck7, M. Mencoboni8, D. Gdansk/PL, 5Oncology, Poznan University of Medical Science, Poznan/PL, 6Vall d’Hebron University Hospital, Barcelona/ES, 7Thoracic Oncology, University Hospital Antwerp, Edegem/BE, 8Oncology Unit, Villa Scassi Hospital, Asl 3 Genovese, Genova/IT, 9Medical Oncology, Gustave Roussy, Villejuif/FR, 10Pneumology Universitaria, Ospedale Di Pisa, Pisa/IT, 11Thoracic Oncology Group, Istituto Cliniche Humanitas Gavazzeni, Department of Oncology, Bergamo/IT, 12Erasmus MC, Rotterdam/NL, 13Medical University of Graz, Graz/AU, 14Epidemiology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 15Tissue microarrays comprising 6 tumoral and 3 stromal cores from 265 patients with MPM (216 epithelioid, 26 biphasic, and 23sarcomatoid, 1989-2010) were investigated by immunohistochemistry for gC1qR expression (Intensity and distribution by H-score, range 0-300), and CD4 T-cell infiltration. Overall survival (OS) was analyzed by the Kaplan-Meier method (high versus low gC1qR expression delineated by median score). Multi-variable analysis included clinical, pathological factors and stage (T, N).

Result: In comparison to patients without NAC, high gC1qR was associated with better survival, (26 vs. 11 months, Fig1A), among patients who received neoadjuvant chemotherapy (NAC), high gC1qR was associated with better median OS (25 vs. 11 months, Fig1B), and 3) in multivariate analysis, high gC1qR was an independent factor for better OS (26 vs. 11 months, Fig1C).

Background: Tumor Treating Fields (TTFields) are an anti-miticotic, regional treatment modality, utilizing low intensity alternating electric fields delivered non-invasively to the tumor using a portable, medical device. In-vitro, human mesothelioma cells were highly susceptible to TTFields to standard chemotherapy. These results support the addition of TTFields to standard chemotherapy in the treatment of first-line malignant pleural mesothelioma.

Keywords: TTFields, Tumor Treating Fields, malignant pleural mesothelioma

MA12.07 GC1QR EXPRESSION IS INDEPENDENTLY PROGNOSTIC FOR SURVIVAL BENEFIT FOLLOWING CHEMOTHERAPY IN MESOTHELIOMA

Background: Overexpression of gc1qr, a multicompartamental and multifunctional cellular protein, has been shown to promote chemotherapy-induced apoptosis in cancer cells, but compromise CD4 T-cell proliferation in viral infections. The goal of this study was to investigate the overexpression of gc1qr, and its prognostic association with chemotherapy and CD4 T-cell infiltration in malignant pleural mesothelioma (MPM). Method: Tissue microarrays comprising 6 tumoral and 3 stromal cores from 265 patients with MPM (216 epithelioid, 26 biphasic, and 23sarcomatoid, 1989-2010) were investigated by immunohistochemistry for gc1qr expression (Intensity and distribution by H-score, range 0-300), and CD4 T-cell infiltration. Overall survival (OS) was analyzed by the Kaplan-Meier method (high versus low gc1qr expression delineated by median score). Multi-variable analysis included clinical, pathological factors and stage (T, N).

Result: In comparison to patients without NAC, high gC1qR was associated with better median OS (25 vs. 11 months, Fig1A), and 3) in multivariate analysis, high gC1qR was an independent factor for better OS (26 vs. 11 months, Fig1C).

**Background:** Photodynamic therapy (PDT) following lung-sparing extended pleurectomy (EPD) for malignant pleural mesothelioma (MPM) has been investigated as a potential means to kill residual microscopic cells. High expression of folate receptor 1 (FOLR1) has been reported in MPM, and targeting the FOLR1 has been considered as a new potential strategy. We have developed FOLR1-targeting porphysome-lipid nanoparticles (folate-porphysome: FP) for PDT. The inhibition of survival pathways of activated epidermal growth factor (EGFR) also enhance the PDT efficacy. Here, we have combined these approaches by using FP based PDT together with an EGFR-tyrosine kinase inhibitor (EGFR-TKI).

**Method:** The frequency of FOLR1 and EGFR expression in MPM was analyzed using tissue microarrays. Confocal microscopy and a cell viability assay were performed to confirm the specificity of FOLR1-targeting cellular uptake and photocytotoxicity in vitro. In vivo fluorescence activation and the therapeutic efficacy were then examined. The effect of EGFR-TKI was assessed in vitro. Folic acid based PDT shows selective destruction of MPM cells based on FOLR1 targeting, and pre-treatment with EGFR-TKI further enhances the therapeutic response.

**Conclusion:** FOLR1 is overexpressed on MPM cells. MPM patients with high FOLR1 expression have a significant survival benefit particularly following chemotherapy; or in the presence of high CD4 T-cell infiltration.

**MA12.10 LONG-TERM IMPACT OF RADIOTHERAPY BEFORE SURGERY FOR MESOTHELIOMA ON THE DISTRIBUTION OF MEMORY T CELL SUBSETS**

J. Murakami, L. Wu, M. Kohno, M. Chan, Y. Zhao, Z. Yun, M. De Perrot

**Latner Thoracic Surgery Research Laboratories, Toronto General Research Institute, Toronto/CA**

**Background:** Postoperative recurrence remains one of the critical issues in treatments for mesothelioma. We previously reported that non-ablative, hypo-fractionated radiation before surgery generated an antigen-specific activation of the immune system and could provide an in situ vaccination with long-term protection against mesothelioma in our murine model. An effective immunological protection depends on memory T cell subset diversification. However, limited work has been done to address the distribution of memory T cell subsets and its effects on the immune system after radiotherapy followed by surgery for mesothelioma.

**Method:** C57BL/6 mice bearing AE17-OVA tumor were treated with local radiotherapy (LRT). LRT 5Gy was delivered on days 0, 3, 10. The mice were re-challenged under the skin or into thoracic cavity with AE17-OVA 28 days after surgery and defined as immunological protective antigen-specific activation of the immune system and could provide an in situ vaccination with long-term protection against mesothelioma. The mice were re-challenged under the skin or into thoracic cavity with AE17-OVA 28 days after surgery and defined as immunological protective memory model if the tumors were completely rejected. Memory model received subcutaneous tumor inoculation once again (second re-challenge), samples were harvested on day 0, 3, 10. We investigated memory T cell subsets using flow cytometry. In addition, the harvested total splenocytes (effector) were co-cultured with CFSE-labeled AE17-OVA (target) for three days. Each of their cytotoxic potential was analyzed by evaluating a number of AE17-OVA and its early or late apoptosis.

**Result:** 8 out of 10 mice completely rejected the subcutaneous tumor in mice treated with LRT and surgery after re-challenged. We observed significantly better survival in the memory model re-challenged into the thoracic cavity compared with no treatment mice. After subcutaneous
tumor inoculation, central memory T cells (CD44+CD62L+KLRG1-) on day 0, effector memory T cells (CD44+CD62L-KLRG1-) and terminal effector T cells (CD44+CD62L-KLRG1-) increased significantly in CD8+ splenocytes of model compared with no treatment mice. This observation was also seen in draining and non-draining lymph nodes. The MPI of CFSE reflecting a number of AE17-OVA cells decreased in proportion of early (Annexin V(-)7E12D0(low)) or late (Annexin V(+)/7E12D0(high)) apoptotic cells in CFSE(+) cells increased, depending on time passage and effector/target ratio after tumor inoculation in both memory model and naive mice. However, during time passage, memory model always had a stronger cytotoxicity (even at Day 0) as compared to naive mice. Conclusion: Our data raise an important possibility that non-ablative, hypo-fractionated radiotherapy followed by surgery for mesothelioma contributes to the development and long-term maintenance of memory T cell subsets, which could remain poised to rapidly recall effector functions upon antigen re-exposure.

MA12 MESOTHELIOMA SURGERY AND NOVEL TARGETS FOR PROGNOSIS AND THERAPY
TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MAI2.11 ANALYSIS OF ANGIOGENIC AND STROMAL BIOMARKERS IN A LARGE MALIGNANT MESOTHELIOMA COHORT
P.L. Chia1, P. Russell1, K. Asadi2, C. Murone3, M. Walkiewicz3, U. Eriksson4, A. Scott2, T. John1
1Olivia Newton-John Cancer Research Institute, Melbourne/AU, 2Anatomical Pathology Department, St. Vincent's Hospital, Melbourne/AU, 3Department of Anatomical Pathology, Austin Health, Melbourne/AU, 4Karolinska Institute, Solna/SE

Background: Malignant mesothelioma (MM) is an aggressive malignancy of the pleura and other mesothelial membranes. Agents targeting vascular endothelial growth factor (VEGF) receptor such as bevacizumab; and multi-kinase inhibitors like nintedanib (angiokinase inhibitor of VEGF, platelet-derived growth factor (PDGF) receptor and fibroblast growth factor receptor (FGFR)) have recently demonstrated efficacy in MM. In the setting of these new therapies, it is important to evaluate angiogenic and stromal markers in MM to assess their associated prognostic implications.

Method: Tissue microarrays (TMAs) were created from formalin-fixed, paraffin-embedded tissue samples obtained from 326 patients who underwent surgical resection or biopsy for MM between 1988 and 2014. PDGF-CC, FGFR-1, VEGF and CD31 expression were analysed by immunohistochemical (IHC) staining. The H-score method assigned a score of 0–300 to each sample, based on the percentage of cells stained at different intensities. The discriminatory threshold was set for each IHC stain (usually the median score) and samples were classified as low (below median) or high expression (above median). CD31 was evaluated via Chalkley’s method to evaluate microvessel density. We evaluated the association between expression of the biomarkers, clinicopathological factors and outcomes, in patients with MM. Result: The histological subtypes comprised of 203/325 (62.5%) epithelioid; 72/325 (22.2%) biphasic; 42/325 (12.9%) sarcomatoid, or indeterminate. The median age was 67 (range 24-88) with Male: Female ratio of 266:53. CD31 high (≥5) was seen in only 31/302 (10.3%) irrespective of histology (13/31 (42%) epithelioid; 10/31 (32%) sarcomatoid; 7/31 (23%) biphasic; 1/31 (indeterminate)). PDGF-CC high (≥150) was seen in 203/310 (65%) of all samples but was higher in epithelioid subtype (129/203 (64%)). VEGF high (≥80) was seen in 219/322 (68%) of all MM with 143/209 (68%) of epithelioid histology. FGFR-1 high (≥40) was seen in 127/310 (41%) of all MM and 73/127 (57.5%) are of epithelioid histology. There was no association of VEGF and FGFR-1 IHC with survival nor differences between histological subtypes. There was a non-significant trend towards poorer survival in epithelioid tumours with increased PDGF-CC expression (OS 18% vs 67%, HR 0.708, 95% CI 0.595 to 1.015, P = 0.063 vs 11%). High CD31 score was associated with significantly poorer survival (OS 12 vs 8.6 months; HR 0.48; 95%CI 0.287 to 0.7941, P = 0.0044). Of the 31 patients with high CD31 scores; 23/31 (74%) were also high for PDGF-CC and 20/31 (64%) with high VEGF scores. Conclusion: High PDGF-CC expression and CD31 scores are associated with poor survival in MM. Abrogating these pathways may have prognostic implications.

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

MA13.01 CT-GUIDED TRANSTHORACIC NEEDLE BIOPSY FOR EVALUATION OF PD-L1 EXPRESSION: COMPARISON OF 22C3 AND SP263 ASSAYS
K. Beck1, K.Y. Lee2, S.J. Hong3
1Radiology, Seoul St. Mary’s Hospital, College of Medicine, the Catholic University of Korea, Seoul/KR, 2Pathology, Seoul St. Mary’s Hospital, College of Medicine, the Catholic University of Korea, Seoul/KR, 3Radiology, Hanyang University Guri Hospital, Hanyang University College of Medicine, Guri/KR

Background: Although there are a few studies about concordance of different assays testing PD-L1 expression using surgical specimens, there hasn’t been any such concordance study using real-world biopsy specimens. However, many of the patients requiring immunotherapy and thus PD-L1 testing have unresectable lung cancer and have to rely on small biopsy results. Although phase 2 of Blueprint phase 2 does include core biopsy results, they are mixed with bronchial biopsy specimens and the absolute number is very small (n=20). We sought to evaluate the concordance of 22C3 and SP263 assays in a larger number CT-guided transthoracic needle biopsy (TNB) specimens. The purpose of this study was to assess the concordance of two commercially available diagnostic assays (22C3 and SP263) in evaluating programmed cell death ligand-1 (PD-L1) expression using specimens from CT-guided TNB in a routine clinical setting.

Method: This retrospective analysis reviewed 202 non-small cell lung cancer (NSCLC) patients who underwent CT-guided TNB at our institution from April 2017 to February 2018. Among these, 60 biopsy specimens tested with both 22C3 and SP263 assays were included for review. Concordance of PD-L1 expression levels determined by the two assays was assessed using intraclass correlation coefficient, and the agreement of dichotomized values at various cut-offs (1%, 25%, 50%) were assessed using Cohen’s κ coefficient of agreement. Clinical characteristics and biopsy-related factors were also assessed for the association of concordance of PD-L1 expression detected by different assays

Result: In total, 80 patients (M:F = 47:33, mean age: 68±0.9 years) were included in the study. Concordance of PD-L1 expression levels was high (intraclass coefficient: 0.892) between 22C3 and SP263 assays. Agreements at cut-off levels of 1%, 25%, and 50% were also good, with κ values of 0.878, 0.698, and 0.790 respectively. Positive percent agreement was 92.2%, 100.0%, and 95.2% for agreements at 1%, 25%, and 50%. At multivariate analysis, the presence of emphysema was significantly related to discordant PD-L1 results (odds ratio: 0.059, p = 0.005). Conclusion: There is a high concordance of PD-L1 expression evaluated with 22C3 and SP263 assays using CT-guided TNB specimens.

Keywords: CT-guided biopsy, PD-L1 assay

MAI3.02 PD-L1 EXPRESSION IN EBUS-GUIDED CYTOLOGY SPECIMENS OF NON- SMALL CELL LUNG CANCER IS NOT AFFECTED BY TYPE OF FIXATION: A STUDY OF MATCHED PAIRS
J. Gosney1, A. Haragan2, C. Chadwick1, T. Giles1, S. Grundy3, V. Tippett1, K. Gumparty1, A. Wight4, H. Tan5
1Cellular Pathology, Royal Liverpool University Hospital, Liverpool/GB, 2Royal Liverpool University Hospital, Pathology Department, Floor 6, Duncan Building, University of Liverpool, Liverpool/GB, 3Respiratory Medicine, Aintree University Hospital, Liverpool/GB, 4Histopathology, Wirral University Hospital, Wirral/GB, 5Respiratory Medicine, Wirral University Hospital, Wirral/GB

Background: Previous trials of immune modulators (IMs) to treat non-small cell lung cancer (NSCLC) have included ‘cytology’ specimens, dispersed cells aspirated from a tumour deposit or body cavity, for immunohistochemical assessment of PD-L1, a useful companion diagnostic test. This has led to the widely held view that, in the absence of such validation, cytology specimens cannot be used to assess it. In many centres, endobronchial ultrasound (EBUS)-guided aspiration of the tumour or intra-thoracic lymph nodes is the preferred means of diagnosing and staging of NSCLC and such specimens account for the majority received for analysis. Failure to assess them has serious implications for appropriate management and might deny patients effective therapy. Much of this reluctance centres on the alleged effect of fixation in alcian blue-based fixatives and other methods of cytopathologists, rather than formalin, the standard fixation medium for tissue specimens, on the expression of PD-L1 on the cell surface.

Method: We compared expression of PD-L1 in 50 paired specimens of NSCLC, one fixed in an alcohol-based fixative and one in a formalin-based fixative, taken from the same tumour deposit or lymph node during the same procedure. All were spun down and formed into a cell block before assessment for PD-L1 expression, which was by two appropriately-
trained pathologists with extensive experience in its interpretation.

**Result:** In none of the 50 pairs studied was there any significant difference, qualitative or quantitative, in the pattern or extent of PD-L1 expression and, in the great majority, it was identical irrespective of fixation. **Conclusion:** There is no evidence from this study that the use of alcohol-based fixatives has any effect on the expression of PD-L1 or its interpretation. Notwithstanding the general challenges in accurately assessing such expression, which are common to specimens of tissue as well as dispersed cells, pathologists should feel able to interpret cytology specimens with confidence and clinicians able to rely on the results.

**Keywords:** EBUS-cytology, Fixation, PD-L1

TUESDAY, SEPTEMBER 25, 2018 - 10:30-12:00

**MA13.03 HETEROGENEITY ANALYSIS OF EBUS-TBNA-DERIVED SPECIMENS FOR EVALUATION OF PD-L1 EXPRESSION AND COPY NUMBER ALTERATIONS IN PATIENTS WITH NSCLC**

K. Yoshimura1, Y. Inoue1, K. Tsuchiya1, M. Karayama1, Y. Iwashita1, T. Kahyo1, A. Kawsae1, M. Tanahashi1, H. Ogawa1, K. Yokomura1, N. Inui1, K. Fun1i1, K. Shinmura2, H. Niwa2, T. Suda2, H. Sugimura2

1Second Division, Department of Internal Medicine, Hamamatsu University School of Medicine, Hamamatsu/JP, 2Department of Thoracic Surgery, Hamamatsu University School of Medicine, Hamamatsu/JP

**Background:** Most patients with non-small cell lung cancer (NSCLC) are diagnosed at advanced stages and only small biopsy specimens are available for diagnosis in the majority of the patients. Endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) is a useful diagnostic modality and is becoming more relevant and essential procedure in the real-world clinical setting. However, it is poorly elucidated whether EBUS-TBNA-derived small specimens are suitable for evaluation of biomarkers such as PD-L1 alterations, because heterogeneity of PD-L1 expression limits the power as a guide to select patients who are likely to benefit from the PD-1/PD-L1 blockade therapy. In addition, PD-L1 copy number alterations (CNAs) have been proposed to potentially complement the predictive performance of PD-L1 expression. We here evaluated the utility of EBUS-TBNA-derived specimens in the assessment of PD-L1 protein and CNAs focusing on the heterogeneity with other biopsies/resected samples. **Method:** PD-L1 protein expression and CNAs in 71 EBUS-TBNA specimens of NSCLC were assessed. Corresponding 68 transbronchial biopsy (TBB) specimens, 13 resected primary tumors, and 6 resected metastases were comparatively analyzed. PD-L1 expression on tumor cells was assessed by immunohistochemistry (E1L3N). Positivity of ≥1% was used as the cut-off. PD-L1 CNAs were assessed with fluorescent in situ hybridization, and were classified into three categories: amplification, polysomy, and disomy. Concordance between EBUS-TBNA and other specimens were calculated. **Result:** The median age was 68 years (38-90 years). The cohort comprised 48 men (67.6%), 15 never-smokers (21.1%), and 39 adenocarcinomas (54.9%). The concordance of PD-L1 positivity between EBUS and the other specimens was moderate; κ = 0.63 for EBUS vs TBB, κ = 0.68 for EBUS vs the resected primary tumors, and κ = 1.00 for EBUS vs the resected metastases. The concordance of PD-L1 CNA statuses was comparable with that of PD-L1 expression; κ = 0.60 for EBUS vs TBB, and κ = 0.74 for EBUS vs the resected primary tumors. When the PD-L1 copy number was assessed as a continuous variable, the correlation was also good/moderate; ρ = 0.60 for EBUS vs TBB specimens, ρ = 0.56 for EBUS vs the resected primary tumors, and ρ = 0.80 for EBUS vs the resected metastases. Intratumorally, PD-L1 expression was significantly heterogeneous in whole sections of resected tumors, but PD-L1 CNAs was less heterogeneous than protein expression. **Conclusion:** EBUS-TBNA-derived specimens can be used for the assessment of PD-L1 alterations including CNAs. The concordance of PD-L1 CNAs between EBUS-TBNA and TBB/resected specimens were comparable with that of PD-L1 expression. However, spatial heterogeneity should be taken into account to interpret both PD-L1 protein expression and CNAs.

**Keywords:** PD-L1, EBUS-TBNA, copy number alteration

**MA13.05 THE CANADA LYMPH NODE SONOGRAPHIC SCORE: NATIONAL VALIDATION OF A SONOGRAPHIC SCORE TO DETERMINE MEDIASTINAL LYMPH NODE MALIGNANCY**

D. Hylton1, J. Huang2, S. Turner3, D. French1, C. Wen4, J. Masters5, B. Kidane6, J. Spicer4, J. Taylor5, C. Finley4, Y. Shargail2, C. Fahim4, F. Farrokhyar1, K. Yasufuku7, J. Agazar1, W. Hanna8

1Department of Health Research Methods, Evidence, and Impact (Hei), McMaster University, Hamilton/ON/CA, 2Division of Thoracic Surgery, McMaster University, Hamilton/ON/CA, 3Division of Thoracic Surgery, University of Alberta, Edmonton/AB/CA, 4Division of Thoracic Surgery, Dalhousie University, Halifax/NS/CA, 5Division of Thoracic Surgery, University of British Columbia, Surrey/BC/CA, 6Division of Thoracic Surgery, Laurentian University, Sudbury/ON/CA, 7Division of Thoracic Surgery, University of Manitoba, Winnipeg/MB/CA, 8Division of Thoracic Surgery, McGill University, Montreal/QC/CA

**Background:** At the time of endobronchial ultrasound (EBUS) staging for Non-Small Cell Lung Cancer (NSCLC), 6 ultrasonic criteria (Fig. 1) are used to assign a Lymph Node Sonographic Score (LNSS) that is predictive of malignancy. The LNSS has not gained widespread use due to lack of research demonstrating its validity and reliability among endoscopists. We hypothesized that LNSS correlates well with the probability of malignancy, potentially guiding decisions for lymph node (LN) biopsy.

**Method:** We conducted a prospective study to assess the validity and reliability of the LNSS. The validation cohort comprised LN that were video-recorded from patients with NSCLC, and assigned a LNSS by an experienced endoscopist. Videos were then circulated to thoracic surgeons and interventional respirologists across Canada, who were asked to assign a score to each LN. All raters had demonstrated proficiency using our online education module, were blinded to staging information, and to each other. Each LN was scored by at least 3 independent raters. Pathological specimens were used as the gold standard for determination of malignancy. Regression, receiver operator curve (ROC), and Gwet’s AC1 analyses were used to test LNSS score performance, discriminatory capacity, and inter-rater reliability. **Result:** A total of 300 LNs (18% malignant) from 140 patients were analyzed by 11 endoscopists across 7 Canadian centres. LNSS ≤ 0.5 was strongly predictive of benign LN (NPV=95.6%, OR=49.2, p=0.001). LNSS ≤ 2.5 (OR=44, p=0.001) was determined as the cutoff for malignancy based on ROC analysis (c= 0.7757, 95%/CI: 0.70281-0.84853). Inter-rater reliability for LNSS=0 was 0.8953 (95%/CI:0.8158-0.8947, p=0.0001) and 0.46 for LNSS ≤ 2.5 (95%/CI:0.3521-0.5012, p=0.00001). **Conclusion:** The Canada LNSS shows excellent performance in identifying benign LN at the time of EBUS. A cutoff ≤ 2.5 has the potential to inform decision-making regarding biopsy or repeat mediastinoscopy if the initial results are inconclusive. Further teaching and education are required to improve inter-rater reliability.

MA12.06 ENDOSONOGRAPHY WITH LYMPH NODES SAMPLING FOR RESTAGING THE MEDIASTINUM IN LUNG CANCER: A SYSTEMATIC REVIEW AND POOLED-DATA ANALYSIS

L. Jiang1, J. Liu1, W. Shaol, K. Harris2, L. Yarmus3, W. Huang1, J. He1
1Thoracic Surgery, The First Affiliated Hospital of Guangzhou Medical University, Guangzhou/ CN; 2Section of Interventional Pulmonology, Division of Pulmonary and Critical Care Medicine, Johns Hopkins University, Baltimore/US

Background: Mediastinal restaging after induction treatment is still a difficult and controversial issue. We aimed to investigate the diagnostic accuracy of endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) and endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) for restaging the mediastinum after induction treatment in patients with lung cancer. Method: Embase and PubMed databases were searched from conception to July 2017. Data from relevant studies were analyzed to assess sensitivity and specificity of EBUS-TBNA and EUS-FNA, and to fit the Hierarchical Summary Receiver-Operating Characteristic curves. Result: A total of nine studies consisting of 542 patients fulfilled the inclusion criteria. All patients were restaged by EBUS-TBNA, EUS-FNA or both. Negative results were confirmed by subsequent surgical approaches. There were no complications reported during any endosonography approaches reviewed. The pooled sensitivities of EBUS-TBNA and EUS-FNA were 66%(95% CI, 60%-72%) and 73%(95% CI, 52%-87%), respectively; and specificities were 100%(95% CI, 98%-100%) and 99%(95% CI, 93%-100%), respectively. The area under the HSROC curves(AUC) were 0.84(95% CI, 0.81-0.87) for EBUS-TBNA and 0.99(95% CI, 0.98-1) for EUS-FNA. Moreover, for patients who received chemotherapy alone, the pooled sensitivity of endosonography with lymph node sampling for restaging was 69%(95% CI, 63%-75%), and specificity was 100%(95% CI, 97%-100%); and for patients who received combined therapy, the results seemed similar with sensitivity of 65%(95% CI, 50%-78%) and specificity of 100%(95% CI, 96%-100%).

If negative Likelihood Ratio(LR-) is smaller: essentially a definite diagnosis when negative result. Conclusion: Endosonography with lymph node sampling is an accurate and safe technique for mediastinal restaging of lung cancer. For nondiagnostic results, a further more invasive approach should be thoroughly considered.

MA13.07 DIAGNOSTIC YIELD OF N3 HILAR STAGING BY ENDOBRONCHIAL ULTRASONOGRAPHY (EBUS) IN LUNG CANCER

J. Bordas Martinez1, J. L. Vercher Conejero2, G. Rodriguez Gonzalez2, C. Martin Cabeza1, N. Cubero De Frutos3, R. Lopez Lisbona4, M. Díez Ferrer1, P. Notta1, R. Llatjos Sanuy5, J. Dorca Sargatal5, A. Rosell Gratacos5
1Department of Pulmonology, Bellvitge University Hospital, Idiell, Hospitalat-Barcelona/ES, 2NM-PET/CT Unit, ICS-IDI, Barcelona University, Hospitalat-Barcelona/ES, 3Department of Pulmonology, Bellvitge University Hospital, Idiell, Ciber of Respiratory Diseases (Cibers), Hospitalat-Barcelona/ES, 4Department of Anatomic Pathology, Bellvitge University Hospital, Hospitalat-Barcelona/ES, 5Department of Pulmonology, Bellvitge University Hospital, Idiell, Ciber of Respiratory Diseases (Cibers), Barcelona University, Hospitalat-Barcelona/ES

Background: Systematic lung cancer staging with EBUS has proven to be equivalent to cervical mediastinoscopy. Nevertheless, in the daily practice it is common to explore and sample negative PET-CT hilar N3 lymph nodes (LN). This study aims to explore if there is enough evidence to support this clinical practice. Method: Retrospective study from our database including 1,013 explorations over the last 5 years. Including criteria were patients with lung cancer staged by PET-CT and EBUS-TBNA. Mediastinal and hilar N3 LN with a short axis ≥ 10mm were sampled with a 21G needle and assessed by rapid on site evaluation (ROSE). A single nuclear medicine expert reviewed blindly all PET-CT scans and determined the SUVmax of every LN. Those that were ≥ 5 SUVmax by PET-CT and/or ≥ 10mm in short axis by EBUS were considered abnormal. Result: 87 patients were included, of which 87% were male with a mean age of 66 years (SD 12.6). The final histopathology diagnoses were adenocarcinoma (46%), squamous cell carcinoma (39%) and other histology (14%). EBUS-TBNA was performed 30 days (SD 16.9) after PET-CT. None of the 61 normal hilar and normal mediastinal N3 LN, and none of the 7 normal N3 hilar LN with abnormal mediastinal LN (3 by PET-CT, 3 by EBUS and 4 for both) resulted positive for lung cancer. Of the 19 patients with abnormal N3 hilar LN (6 by PET-CT, 8 by EBUS and 6 for both) malignancy was found in 16.7% , 25% and 60% for both techniques, respectively.

Conclusion: In absence of abnormal N3 hilar LN (PET: SUVmax<5; EBUS<10mm in short axis) it seems there is not enough evidence to sample them, regardless of N3 mediastinal status.

MA13.09 ELECTROMAGNETIC NAVIGATION BRONCHOSCOPY AS AN INTEGRATED APPROACH TO AID IN DIAGNOSIS AND TREATMENT OF PULMONARY LESIONS

S. Khandhar1, S. Murgu1, K. Hogarth1, W. Krimsky1, J. Flanders2, O. Rickman1, M. Wahidi1, E. Sztejman2, P. Linden3, S. Benzaquen4, S. Bansal5, E. Falch6
1Inova Health System, Falls Church/VA/US, 2The University of Chicago Medicine, Chicago/IL/US, 3Pulmonary and Critical Care Associates of Baltimore, Baltimore/MD/US, 4Tis-Fundacion Jimenez Diaz University Hospital, Ciberes, Madrid/ES, 5Vanderbilt University Medical Center, Nashville/TN/US, 6Duke University Medical Center, Durham/NC/US, 7Virtua Pulmonary Group, Marlton/NJ/US, 8University Hospitals Cleveland Medical Center, Cleveland/Ohio/US, 9University of Cincinnati Physicians Company Llc, Cincinnati/Ohio/US, 10University of California, San Francisco Highland Health Care, Dubois/US, 11University of Cincinnati Physicians Company Llc, Cincinnati/Ohio/US, 12University of Cincinnati Physicians Company Llc, Cincinnati/Ohio/US

Background: Electromagnetic navigation bronchoscopy (ENB) is an image-guided localization approach to guide endoscopic tools to lung targets. In a single procedure, ENB aids in localizing lung lesions for biopsy or molecular profiling, fiducial placement for stereotactic body radiation therapy (SBRT), or dye marking for surgical resection. The
multidisciplinary utility of ENB in a large, prospective, multicenter study is unknown. **Method:** NAVIGATE (clinicaltrials.gov, NCT02410837) is a prospective, multicenter, observational cohort study of ENB using the superDimension™ navigation system. From April 2015 to August 2016, 1,215 consecutive subjects were enrolled at 29 United States sites. Two-year follow-up is ongoing. A prespecified 1-year interim analysis is presented. **Result:** ENB was used to aid in lung lesion biopsy (n=1157 subjects), fiducial placement (n=258), pleural dye marking (n=23), and/or lymph node biopsy (n=30). EBUS-guided lymph node staging was conducted in the same procedure in 448 subjects. The median lesion-to-patient distance was 9mm. The median lesion size was 20mm; most were in the middle (30%) and peripheral (67%) thirds of the lung. Pathology results were malignant in 44.3% (484/1092) (54.1% Stage I, 11.1% Stage II, 17.0% Stage III, 17.7% Stage IV). Molecular testing was attempted in 30.7% (80/261) of adenocarcinoma or NSCLC-not otherwise-specified cases overall and 57.9% (33/57) of Stage IIIB/IV cases. Tissue was adequate in 87.5% (70/80) of cases. EGFR mutations (14.7%) and ALK translocations (4%) were the most frequently observed genetic alterations. The ENB procedure was well-tolerated; 2.9% of subjects had procedure-related pneumothorax requiring hospitalization or intervention, lower than published rates for CT-guided core biopsy (25%) and CT-guided fine needle aspiration (19%). Subject-reported impact of ENB on daily activities was 0.9 out of 10 (0 = no impact).

**Conclusion:** In the largest prospective, multicenter study to date, ENB aided in lesion biopsy in the middle and periphery of the lung and tissue collection for molecular testing, with a very low morbidity. ENB facilitates a multidimensional approach to lung biopsy and mediastinal/hilar staging, creating the opportunity for multiple sites/tissues to be safely sampled in one anesthetic event.

**MA13.10 COMPARISON OF PULMONARY NODULE LOCATION BETWEEN PREPROCEDURAL CT AND INTRA-PROCEDURAL CONE-BEAM CT DURING GUIDED BRONCHOSCOPY**
M. Pritchett
Pinehurst Medical Clinic and Firsthealth Moore Regional Hospital, Pinehurst/NC/US

**Background:** Electromagnetic navigation bronchoscopy relies on pre-procedural CT scans to create a virtual airway reconstruction that is used as a roadmap during bronchoscopy. These systems assume similarity between the pre-procedural CT and the nodule during bronchoscopy and the pre-procedural CT scan. However, there are multiple factors that suggest that such assumption maybe inaccurate. These include differences in positioning, breathing motion, and the presence of atelectasis. In this study, we evaluated whether the lung nodule position would be between pre-procedural CT to interprocedural cone-beam CT (CBCT). In addition, we assessed the ability of a novel augmented endobronchial fluoroscopic guidance system (LungVision, Body Vision Medical Ltd, Israel) to overcome those differences in position. **Method:** This was a prospective study of 21 patients with 23 peripheral pulmonary nodules. CT scans were imported into the planning software and the physician identified the nodule and navigation pathway. CBCT (Philips Allura Xper FD20) was used to scan the patient during the procedure. Lung/vision was used for real-time navigation and guidance during biopsy. The divergence in nodule location between the pre-procedural CT and the interprocedural CBCT was measured. **Result:** The average patient age was 69 ± 8.6, median nodule size was 18mm with 74% of the nodules in the upper lobes. The average divergence of the nodule was 14.11 ± 9.9mm. Successful navigation was verified by CBCT in 91% of cases. Malignancy was diagnosed in 20 of 23 nodules for a diagnostic yield of 87%. No adverse events were reported. **Conclusion:** This study demonstrates a significant divergence in the nodule location between pre-procedural CT and intra-procedural CBCT during guided bronchoscopy. This finding indicates that the change in nodule position between the CT and bronchoscopy could have a great impact on the diagnostic success of the procedure. This movement, sometimes greater than the size of the nodule itself, can lead to an inaccurate localization when relying solely on virtual bronchoscopic or electromagnetic navigation. CT to patient divergence does not appear to influence the accuracy of this novel navigation platform. The system is capable of tracking the nodules dynamically and can compensate for changes in patient positioning and respiratory motion during both navigation and biopsy which leads to a high diagnostic yield.

**MA13.11 PHOTODYNAMIC THERAPY FOR PERIPHERAL-TYPE LUNG CANCER IN A MULTI-CENTER CLINICAL TRIAL**
J. Usuda
Thoracic Surgery, Nippon Medical School, Tokyo/JP

**Background:** Photodynamic therapy (PDT), is a treatment modality for non-small cell lung cancer, and uses a tumor-specific photosensitizer and laser irradiation. Recently, we have developed a new minimally invasive laser device using a 1.0 mm in diameter composite-type optical fiberscope (COF), which could transmit laser energy and images for observation in parallel. In this study, we aimed to develop a new endobronchial treatment for peripheral cancer using PDT and a COF, and evaluated the feasibility of PDT using COF for peripheral lung cancer. **Method:** This phase I study enrolled 3 patients with peripheral lung cancers (primary tumor: 20 mm, stage IA), which were definitively diagnosed by bronchoscopic modalities such as EBUS-GS and bronchoscopic navigation system. We conducted irradiation using a diode laser (664 nm) and a COF 4 hours after the administration of NPe6 40 mg/m². We evaluated the tumor lesions using EBUS, and then we introduced the COF into the peripheral lung cancer, and irradiated of red light 664 nm (120 mW, 50 J/cm² or 100J/cm²). **Result:** We performed PDT for 3 patients with c-stage IA peripheral lung cancer, using a laser dose (120mW, 50J/cm²), and confirmed the feasibility of the dose. We escalated the laser dose and performed 4 patients using a laser dose (120mW, 100J/cm²). Seven patients met our criteria, and 5 cases were adenocarcinoma and 2 case squamous cell carcinoma. We were able to observe the cancer lesions at the peripheral lung by the COF, and feasibly irradiated. Two weeks and 3 months after NPe6-PDT, complications such as pneumonia and pneumothorax were not found, but mildly found light skin photosensitivity. Six months later, we found CR in 3 cases and SD in 4 cases. **Conclusion:** The 1.0 mm COF was a very useful device of NPe6-PDT for peripheral lung cancers, and PDT was a feasible and non-invasive treatment for a peripheral type early lung cancer. In the future, for non-invasive adenocarcinoma such as AIS, NPe6-PDT will become a treatment modality.

**MA14.01 LIFE SUSTAINING PROCEDURES, PALLIATIVE CARE AND HOSPITAL COST TRENDS IN DYING LUNG CANCER PATIENTS IN U.S. HOSPITALS: 2005-2014**
J. Hwang¹, J.W. Yoo², J. Shen³, S.J. Kim⁴, S.Y. Chun⁵
¹Korea University Ansan Hospital, Gyeonggi-Do Ansan-Si/KR, ²University of Nevada Las Vegas School of Medicine, Las Vegas/US, ³University of Nevada Las Vegas, Las Vegas/US, ⁴Soon Chun Hyang University, Asan, Chungcheongnam-Do, Korea, Asan/ KR

**Background:** Little is known about the extent to which dying patients with lung cancer receive life-sustaining treatments and palliative care services at the end-of-life in U.S. hospitals. We examine hospital cost trends and the impact of palliative care utilization on the use of life-sustaining procedures in this population. **Method:** Retrospective nationwide cohort analysis was performed using National Inpatient Sample (NIS) data from 2005 and 2014. We examined the receipt of both palliative care and life-sustaining procedures, defined as systemic procedures, local procedures, or surgeries using the International Classification of Diseases, 9th revision (ICD-9-CM). **Result:** Figure 1. We used compound annual growth rates (CAGR) to determine temporal trends and multilevel multivariate regressions to identify factors associated with hospital cost. Among 77,394,755 hospitalizations, 120,144 patients were examined during 10 years, the CAGR of hospital cost was 7.05% (p<.0001). In contrast, the CAGR of hospital lengths of stay was -3.77% (p<.0001). The CAGRs of hospital cost and hospital length of stay were -3.77% and -3.77%, 50.6%, 7.4%, 50.6%, 4.6% respectively (each p<.001). Palliative care was associated with decreased hospital cost and lengths of stay by 28.6% and 7.4%, 50.6%, 4.6% respectively (each p<.001). Palliative care was associated with decreased hospital cost and lengths of stay by 28.6% and 7.4%, 50.6%, 4.6% respectively (each p<.001).

**Keywords:** palliative care, end of life, lung cancer

(See next page)
Conclusion: The volume of life-sustaining treatments is the biggest driver of cost increase although there is a cost-saving effect from greater palliative care utilization at the end-of-life in dying lung cancer patients.

Keywords: lung cancer, hospital cost, palliative care

MA14.02 USE AND IMPACT OF A SYSTEMATIC ADVANCED CARE PLANNING IN HOSPITALIZED LUNG CANCER PATIENTS: A PROSPECTIVE STUDY
A.C. Toffart1, N. Denis1, M. Giaj Levra1, L. Sakhri2, M. Duruisseaux1, J. Pinsolle3, L. Ferrer1, D. Moro-Sibilot1, J. Timis1
1Centre Hospitalier Universitaire Grenoble Alpes, Grenoble/FR, 2Institut Daniel Holland, Grenoble/FR, 3Hospices Civils de Lyon, Louis Pradel, Bron/FR, 4CHU Bichat, Aphp, Paris/FR

Background: End-of-life communication is crucial, particularly for cancer patients. In usual practice, advanced care planning discussions with the patients are uncommon and rarely documented. The aim of this study was to investigate the impact of advanced care planning on intensity of care in cases of organ failure in lung cancer patients. Method: This prospective study was performed at the Grenoble University Hospital in France. Consecutive patients hospitalized in thoracic oncology unit between 01/28/2014 and 03/31/2016 were included and followed up to 12/31/2016. At each hospital admission, lung cancer patients benefited from advanced care planning. We defined 3 intensities of care: intensive care, maximal medical care and exclusive palliative care. The propositions of care could be modified during the hospitalization. Patients’ wishes should be received.

Result: Data of 715 hospitalizations corresponding to 473 patients were studied. Hundred fifty nine patients had a second hospitalization and 69 a third. At first admission, 247 (52%) patients had a performance status of 0 to 2. 186 (39%) were not yet treated for the cancer and 165 (35%) in progression. Main reasons of admission were an acute disease (n=208, 44%) and supportive care in cancer symptoms (n=167, 35%). During the first three admissions, 173 (25%) patients developed an organ failure. Among them, 56 (32%) had intensive care, 104 (63%) maximal medical care, and 13 (7%) exclusive palliative care. Median time between admission and organ failure was 9 days (IQR 25%-75%, 3-13). All patients benefited from intensity of care equal or lower than the proposed intensity of care. Among patients planed for intensive care, 17 (30%) patients received intensive care, 22 (39%) maximal medical care and 17 (30%) exclusive palliative care. Thirteen of the 39 patients not admitted in ICU despite organ failure and previous proposition of intensive care were considered too well by the oncologist. Patients’ wishes were recorded for 158 (91%) patients, and a discussion about end of life conditions was led with 116 (73%) patients or families.

Conclusion: In case of organ failure, an advanced care planning appears helpful to provide reasonable intensity of care. The proposition of care seems to be adapted to the patient’s general condition and cancer characteristics. 3/4 of the patients with an organ failure benefited from a discussion about end of life conditions. ClinicalTrials.gov identifier: NCT02852629 Funding from the publicly funded nonprofit organization Cancéropole Lyon Auvergne Rhône-Alpes (CLARA).

Keywords: advanced care planning, end of life conditions, lung cancer

MA14.03 AGGRESSIVENESS OF CARES ON THE MONTH BEFORE DEATH OF PATIENTS WITH LUNG CANCER: A FRENCH NATIONAL DATABASE SURVEY
O. Bylicki1, C. Tournier2, F. Canouil-Potrin3, C. Blein4, C. Chouaid4
1Pneumology, Hia Percy, Clamart/FR, 2Heva, Lyon/FR, 3Department of Public Health and Clinical Research Unit, Creteil/FR, 4CHU Pitié Salpêtrière, Paris/FR

Background: Prior studies have demonstrated that high-intensity end of life (EOL) cares improves neither survival nor quality of life for cancer patients. The National Quality Forum endorses markers of poor EOL care for cancer patients but there is little data’s concerning lung cancer patients (1). The aim of this study was to assess, the quality of management during the last month of life of lung cancer patients managed in France and factors associated EOL aggressiveness. Method: Using a French hospital discharge database (PMSI, Programme de Médicalisation des Systèmes d’Information), all patients with lung cancer who died between January 1, 2010 and December 31, 2011 (cohort 1) and between January 1, 2015 and December 31, 2016 (cohort 2) were identified through the International Classification of Diseases 10th version (ICD-10). Aggressiveness of EOL cares was assessed by the following criteria’s: 1) chemotherapy administrated within last 14 days of life (DOL); 2) ≥ 1 hospitalization within 30 DOL; 3) ICU admission within 30 DOL; and 4) Palliative care < 3 days before death. Multivariate analysis was performed to identify individual determinants EOL aggressiveness.

Result: A total of 90,827 incident adult patients were identified. Among them, 56 (32%) had intensive care (DOL 1: 43,662, cohort 2: 46,965); men: 74%, median age: 67 years), metastatic at diagnosis: 70%; 57% have at least one marker of aggressiveness of EOL cares (repeated hospitalizations: 49%, ICU admissions: 12%, chemotherapy within 14 DOL: 9%, palliative care < 3 days before death: 10%). A significant increase was observed between 2010/2011 and 2015/2016 for repeated hospitalizations (48% vs 51%, p<.001) and ICU admissions (11% vs 13%, p<.001); the two other markers have remained stable. In multivariate analysis of cohort 2, the risk of aggressiveness of care in EOL was increased by the presence of COPD (OR: 1.08, 95%CI: 1.02-1.14) and a management in an anti-cancer center (OR: 2.32,95%CI: 2.05-2.61) while advanced age (OR: 0.51, 95%CI:0.47-0.55), female sex (OR: 0.86 95%CI: 0.82-0.90), malnutrition (OR: 0.72, 95%CI:0.68-0.76) were protective factors for EOL aggressiveness of cares. Despite growing focus on providing appropriate EOL cares, in this analysis 57% of deceased lung cancer patients in France received aggressive EOL cares. Research must be undertaken to better identify patients at risk of aggressive EOL cares and to improve the quality of cares of last days of life these patients. 1.McNiff K K . Measuring supportive care in medical oncology practice: lessons learned from the quality oncology practice initiative. JCO 2008;

MA14.05 SOCIAL ISOLATION INCREASES PSYCHOLOGICAL DISTRESS IN PATIENTS WITH NSCLC
B. Leung1, J. Wu1, J. Laskin1, H. Rennie1, A. Bates1, C. Ho1
1Medical Oncology, BC Cancer, Vancouver/BC/CA, 2Radiation Oncology, BC Cancer, Vancouver/BC/CA, 3Patient Experience and Interprofessional Practice, BC Cancer, Vancouver/BC/CA, 4Psychosocial Oncology, BC Cancer, Vancouver/BC/CA

Background: The Psychosocial Screen for Cancer (PSSCAN-R) questionnaire is a validated screening tool used to identify the psychosocial needs of patients with cancer. The questionnaire assesses patients’ perceived social supports and identifies patients at risk for developing psychological distress. The study goal was to examine patients with NSCLC who reported risk factors for social isolation and their risk for developing psychological distress. Method: All patients with NSCLC referred to BC Cancer from 2011-2015 who completed a prospective PSSCAN-R questionnaire at the time of first visit were included in the study. Perceived social support questions include: if patients live alone, lost a life partner recently, have no help with IADLs, have no regular contact with friends and family or have no emotional support from others. Demographics were collected retrospectively. The Chi-squared test and logistical regression were used to compare patient groups based on age, gender and perceived social support factors.

Result: The study cohort was comprised of 4428 patients who completed the PSSCAN-R questionnaire. Female 50%, patients ≥65 years 69%, live alone 29%, lost life partner 13%, no help with IADLs 9%, no regular contact 3% and no emotional support 5%.
## MA14.06 PREDICTORS OF FINANCIAL TOXICITY, AN UNDER-RECOGNIZED PATIENT-REPORTED OUTCOME

1. University Health Network, Toronto/CA
2. Medical Oncology, British Columbia Cancer Agency, Vancouver/CA
3. Princess Margaret Cancer Centre, Toronto/ON/CA
4. Dept of Medical Oncology and Hematology, Princess Margaret Cancer Centre and University of Toronto, Toronto/ON/CA
5. Medical Oncology, Princess Margaret Cancer Centre, Toronto/CA

**Background:** In contemporary cancer care, financial distress has been established as a clinically relevant patient-reported outcome (PRO) associated with worse mortality and quality of life, but remains under-recognized by health care providers. Our goal was to define predictors of patient financial toxicity (FT) in a public healthcare system.

**Method:** Patients with advanced lung cancer were recruited from outpatient clinics at the Princess Margaret Cancer Centre (Toronto, Canada). FT was measured with the validated Comprehensive Score for Financial Toxicity (COST) instrument, an 11-item survey scored from 0-44 with lower scores reflecting worse financial well-being. Data on patient and treatment characteristics, total out-of-pocket costs (OOP) and extended insurance coverage (EIC) were collected. Associations between variables and COST score were evaluated using multivariable regression analyses.

**Result:** Of 249 patients approached, 200 (80%) participated. Median age of the cohort was 65 years; 44% were male, 36% immigrants, 67% employed or on pension, with median OOP between $1000-5000 CAD. Median COST score was 21 (range 0-44). FT was associated with age, with patients <65 years reporting greater FT than older patients (COST 18 vs 25; P=0.001). Employed patients or those receiving pension income reported less FT than unemployed patients (22 vs 19; P=0.01). Less FT occurred in patients with EIC compared to those without (23 vs 19; P=0.03). Patients with higher OOP reported more FT (P=0.0001). Patients on clinical trials reported less FT than others (25 vs 20; P=0.04). In multivariable linear regression, younger age was a predictor of higher FT, when adjusting for income, employment status, OOP and EIC (P=0.0001).

**Conclusion:** Age is a predictor of FT in the Canadian (Ontario) public healthcare system, with younger lung cancer patients reporting greater financial distress. This study highlights priority patient populations where FT should be routinely assessed and appropriate resources for support offered.

**Keywords:** patient-reported outcome, financial toxicity

---

## MA14 SURVIVORSHIP, SOCIOECONOMIC AND END-OF-LIFE CONSIDERATIONS

### MA14.07 THE IMPACT OF SOCIOECONOMIC STATUS AND GEOGRAPHIC LOCATION ON PALLIATIVE CHEMOTHERAPY UPTAKE IN PATIENTS WITH METASTATIC NSCLC

1. Medical Oncology, BC Cancer Agency, Vancouver/BC

**Background:** Socioeconomic status (SES) and geographic factors may impact patient treatment choices. Canada has a publically funded health care system and in BC, there are 35 community oncology network sites that deliver treatment in patients’ local communities. We studied the impact between SES and geographic location upon delivery of chemotherapy/survival in metastatic NSCLC.

**Method:** All patients with metastatic NSCLC referred to BC Cancer Centres from 2011-2015, who completed a prospective Canadian Problem Checklist questionnaire at the time of their first visit and for which chemotherapy data was available were included in the study. The CPC assesses patient distress in 6 domains including practical aspects of cancer care. The Postal Code Conversion File Plus uses data from Statistics Canada 2011 census to determine population size and income quintiles. Baseline characteristics and chemotherapy treatments were collected retrospectively. Univariate analysis using the Chi-squared test and Fisher’s exact test were used for analysis. Result: 1113 patients were included with median age of 69 years, 54% female and 77% were former/current smoker and 47% received palliative chemotherapy. Uptake of chemotherapy did not differ between lowest vs mid-lowest 44%, middle 51% (mid-highest – highest 49% income quintiles (P=0.18). Chemotherapy use was also similar between patients reporting financial concerns 50% versus none 47% (P=0.51). Uptake of chemotherapy was lower in patients who lived in rural communities population<10 37% (P 0.00), 10K-1.5M 41%, >1.5 million 53% (P<0.001). Chemotherapy use was lower for patients with concerns about getting to appointments (39% vs 49%, p=0.008) or accommodations (33% vs 48%, p=0.012).

**Conclusion:** This dataset provide evidence that patients from rural communities were less likely to receive palliative chemotherapy treatment for metastatic NSCLC in BC despite the availability of multiple local community oncology services. SES did not appear to impact the proportion of patients treated, congruent with a government funded health care system. An in depth assessment of distances to local cancer services and treatment delivery is warranted to investigate these differences and their effect on mortality.

**Keywords:** socioeconomic, geographic, non-small cell lung cancer
MA14.09 MORTALITY OF LUNG CANCER AS A SECOND PRIMARY MALIGNANCY AMONG CANCER SURVIVORS: A STUDY OF SURVEILLANCE, EPIDEMIOLOGY, AND END RESULTS DATABASE

L. Deng1, H. Song1, Z. Xiao1, C. Jiang3, Q. Wang3, H. Cheng4, D. Lu5
1Department of Medicine, Jacobi Medical Center, Bronx/NY/US, 2Center of Public Health Sciences, Faculty of Medicine, University of Iceland, Reykjavik/IS, 3Department of Internal Medicine, Icahn School of Medicine at Mount Sinai, New York/NY/US, 4Albert Einstein College of Medicine/montefiore Medical Center, Bronx/US, 5Department of Medical Epidemiology & Biostatistics, Karolinska Institutet, Stockholm/SE

Background: Cancer survivors are at increased risk of developing a second primary malignancy, including lung cancer. However, the prognosis of lung cancer as a second primary malignancy (lung-2) remains largely unknown. Method: Primary lung cancer patients diagnosed from 1988 to 2014 in the SEER program were included. Lung-2 was ascertained by a previous diagnosis of primary malignancy in SEER. Hazard ratios (HRs) of overall and lung cancer specific mortality were estimated among patients with lung-2 compared to lung-1. Result: 679,541 (88.8%) and 85,758 (11.2%) patients were identified as lung-1 and lung-2, respectively. The median time from first primary malignancy to lung-2 diagnosis was 4.8 years. Compared to lung-1, patients with lung-2 were more likely to be diagnosed at localized stage, with smaller primary tumor, and treated with surgery. Lung-2 patients were at lower risk of lung cancer specific mortality in the first five years (HR 0.77, 95% CI 0.76 - 0.78 at < 1 year; HR 0.87, 95% CI 0.86 - 0.89 from 1 to < 5 years) but at higher risk thereafter. Patients with lung-2 were associated with reduced risk of overall mortality during the first year after diagnosis (HR 0.91, 95% CI 0.91 - 0.92), but with significantly increased risks thereafter. Table Hazard ratios (HRs) of overall and lung cancer specific mortality among patients with lung-2

N, number of deaths; IR, incidence rate per 100 person-years.^ HR was adjusted for age and calendar period at diagnosis, sex, race, cohabitation status, percentile of cost of living and high-school education in county of residence, tumor stage, histology, tumor grade, surgery, radiation therapy, and chemotherapy. Conclusion: Lung-2 is associated with favorable lung cancer specific and overall survival within early period of diagnosis. Inferior overall survival afterwards cannot be attributed to aggressiveness of lung-2, highlighting the importance of managing first malignancy and comorbidities.

MA14.10 QTc INTERVAL-PROLONGING MEDICATIONS IN LUNG CANCER: IMPLICATIONS FOR CLINICAL TRIAL ELIGIBILITY AND ROUTINE CLINICAL CARE

D. Gerber
Hematology/Oncology, UT Southwestern, Dallas/TX/US

Background: Concomitant medication use, including agents that prolong the QTc interval, may exclude cancer patients from clinical trials. To estimate potential impact on accrual, we determined the prevalence of QTc-prolonging medication prescriptions in a national patient cohort.

Method: We identified adult patients in the United States Veterans’ Affairs system diagnosed with lung cancer 2003-2016. QTc-interval prolonging medications and risk category were obtained from CredibleMeds®. We calculated prevalence of prescriptions for QTc-prolonging medications with known or possible risk of torsades de pointes (the most common criteria employed as trial exclusion criteria) in the 3 months up to and including date of cancer diagnosis. Rates across patient groups and time periods were compared using Chi-square test. Result: 280,068 patients were included in the study. Mean age was 70 years, 98% were male, and 72% were white. Overall, 29.7% were prescribed a QTc-prolonging medication. Patients receiving QTc-prolonging medications were marginally younger (mean age 68.9 years versus 70.9 years; P<0.001) and more likely to be black (14.1% versus 11%; P<0.001). The most commonly prescribed QTc-prolonging medications were antimicrobials (14.0%), psychiatric agents (10.2%), antiemetics (2.6%), and cardiovascular medications (1.7%). Seven percent of patients were prescribed two or more QTc-prolonging medications. Over the period of study, the rate of QTc-prolonging medication use increased 20% (25% in 2004 versus 31% in 2016; P<0.001). Conclusion: A substantial and growing proportion of individuals with lung cancer are prescribed QTc-prolonging medications. These prescriptions may limit eligibility for clinical trials and complicate the administration of standard cancer therapies. Given the prevalence of chronic and/or multiple QTc-prolonging medication prescriptions, it may be challenging to address this obstacle to trial enrollment simply through prescription substitution or discontinuation. Further research into the actual clinical risks and optimal management of QTc-prolonging medications in cancer populations is warranted.

Conclusion: Our findings from a real-world population identify several factors which affect the risk of early mortality in NSCLC patients following SACT, and establish a 30-day mortality benchmark for Canadian NSCLC populations. Evolving SACT modalities may facilitate an increased use of SACT at EOL and associated early mortality; however, in this cohort, decreased early mortality risk in the 2010-2014 timeframe suggests concomitant evolution of decisions regarding EOL SACT and/or palliative and EOL care may be underway at our centre, but represents an area for ongoing investigation.

MA15.01 STRONG PD-L1 EXPRESSION PREDICTS POOR RESPONSE AND DE NOVO RESISTANCE TO EGFR TKIS AMONG NON-SMALL CELL LUNG CANCER PATIENTS WITH EGFR MUTATION
S. Su1, Z. Dong2, X. Zhi3, J. Su1, Z. Chen1, J. Yang1, H. Tu1, Q. Zhou1, W. Zhong1, X. Zhang1, Y. Wu1
1Guangdong Lung Cancer Institute, Guangdong General Hospital, Guangzhou/CN, 2Department of Radiation Oncology, Nanfang Hospital, Southern Medical University, Guangzhou/CN

Background: This study evaluated whether tumor expression of programmed death-ligand 1 (PD-L1) predicted the response of EGFR-mutated non-small cell lung cancer (NSCLC) to epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKIs). Method: We retrospectively evaluated patients who received EGFR-TKIs for advanced NSCLC between April 2016 and September 2017 at the Guangdong Lung Cancer Institute. None of them were enrolled in clinical studies, and their EGFR and PD-L1 statuses were simultaneously evaluated. Result: Among the 101 eligible patients, strong PD-L1 expression significantly decreased the objective response rate (ORR) compared with those with weak or negative PD-L1 expression (35.7% vs 63.2% vs 67.3%, P = 0.002) as well as shortened progression-free survival (PFS, 3.8 months vs 6 months vs 9.5 months, P < 0.001), regardless of EGFR mutation types (19del or L858R). Furthermore, positive PD-L1 expression was predominantly observed among patients with de novo resistance rather than acquired resistance to EGFR-TKIs (66.7% vs 30.2%, P = 0.009). Notably, patients with de novo resistance had a high proportion of dual positive for PD-L1 and CD8 (46.7%, 7/15). Finally, one patient with de novo resistance to EGFR-TKIs and dual positivity for PD-L1 and CD8 experienced a favorable response to anti-PD-1 therapy.

Conclusion: This study uncovered the adverse impact of PD-L1 expression on the efficacy of EGFR-TKIs, especially in those with de novo resistance NSCLC, which inclined to reshape an inflamed immune phenotype of dual positive for PD-L1 and CD8 and showed potential therapeutic sensitivity to PD-1 blockade.

Keywords: de novo resistance, EGFR, PD-L1

MA15.02 LONG-TERM SAFETY AND CLINICAL ACTIVITY RESULTS FROM A PHASE IIB STUDY OF EROLITINIB PLUS ATEZOLIZUMAB IN ADVANCED NSCLC
1Memorial Sloan Kettering Cancer Center, New York/NY/US, 2University of Valencia, Valencia/ES, 3University Hospitals Case Medical Center, Cleveland/ OH/US, 4Gustave Roussy, Villejuif, France and University of Paris-Sud, Orsay/FR, 5Phase I Clinical Trial Center, Chinese University of Hong Kong, Hong Kong/CN, 6Beth Israel Deaconess Medical Center, Boston/MA/US, 7Barts Cancer Institute, London/GB, 8Massachusetts General Hospital, Boston/MA/US, 9Northwestern University, Chicago/IL/US, 10Genentech, Inc., South San Francisco/CA/US, 11Yale Cancer Center, New Haven/CT/US

Background: Patients with EGFR mutation–positive non-small cell lung cancer (NSCLC) achieve favorable outcomes with EGFR tyrosine kinase inhibitors (TKIs); however, the long-term efficacy of these agents is limited by development of acquired resistance. Atezolizumab (anti–PD-L1 mAb) monotherapy has shown tolerability and durable clinical activity in NSCLC. By selectively targeting PD-L1 to block its interaction with receptors PD-L1 and B7.1, atezolizumab can reinvigorate anti-cancer T-cell activity. Thus, combining atezolizumab and erlotinib could result in improved anti-tumor immunity and durable anti-tumor effects. Somatic and preliminary clinical activity from a Phase I study of erlotinib plus atezolizumab in locally advanced or metastatic NSCLC have been previously reported (Rudin, et al. WCLC 2016). Here we describe updated findings from this study (NCT02013219). Method: EGFR TKI-naïve patients with NSCLC were enrolled into a safety-evaluation stage (Stage 1) regardless of EGFR status, and an expansion stage (Stage 2) enrolled patients with EGFR-mutant NSCLC who were previously untreated or treated with 1 prior non–EGFR TKI therapy. A 7-day run-in period with erlotinib 150 mg PO QD was followed by addition of atezolizumab 1200 mg IV q3w. The primary endpoint was safety/tolerability of the combination; secondary endpoints included clinical activity per RECIST v1.1. Result: At data cutoff (August 18, 2017), 28 patients (Stage 1, n = 8; Stage 2, n = 20) were evaluable for safety, and the median survival follow-up was 26.0 months (range, 7.8–32.0; Stage 2). The median age was 61 years (range, 47–84), and the most common EGFR mutation type was exon 19 deletion (44%). Grade 3 treatment-related AEs (TRAEs) were reported in 43% of patients; no Grade 4 or 5 TRAEs occurred. The most common TRAEs were increased ALT, pyrexia, rash and diarrhea (2 patients each). Serious TRAEs occurred in 54% of patients; treatment-emergent AEs led to atezolizumab discontinuation in 18% and erlotinib discontinuation in 11%. Clinical activity was evaluated in Stage 2 patients. ORR was 75% (95% CI: 50.9, 91.1), with a median DOR of 27.0 months (range, 4.2–26.0+). Median PFS was 15.4 months (95% CI: 8.4, not estimable [NE]), and median OS was 32.7 months (95% CI: 32.7, NE). Conclusion: Atezolizumab plus erlotinib demonstrated a tolerable safety profile and compared favorably with prior reports of efficacy with erlotinib monotherapy. OS data are expected to mature and improve with longer follow-up; updated clinical and biomarker data will be presented. Future investigation of the combination is warranted to assess its full potential.

MA15.03 PD-L1 EXPRESSION IN UNTREATED EGFRM ADVANCED NSCLC AND RESPONSE TO OSMERTINIB AND SOC EGFR-TKIS IN THE FLAURA TRIAL
1Precision Medicine Laboratories, Precision Medicine and Genomics, Imed Biotech Unit, Astrazeneca, Cambridge/GB, 2Respiratory Oncology Unit (Respiratory Diseases), University Hospital KU Leuven, Leuven/BE, 3Department of Medical Oncology, Kindai University School of Medicine, Osaka/GP/JR, 4Medical Oncology Department, University Regional Hospital of Málaga, Ibiza, Málaga/ES, 5Olivia Newton-John Cancer Research Institute, Austin Health, Melbourne/VIC/AU, 6Oncology Companion Diagnostics Unit, Precision Medicines and Genomics, Imed Biotech Unit, Astrazeneca, Cambridge/GB, 7Global Medicine Development, Biometrics and Information Sciences, Astrazeneca, Cambridge/GB, 8Global Medicines Development, Astrazeneca, Cambridge/GB, 9Translational Science, Oncology, Imed Biotech Unit, Astrazeneca, Wallaham/MA/US, 10Bioscience, Imed Biotech Unit, Astrazeneca, Waltham/MA/US, 11Hematology & Medical Oncology, Emory University School of Medicine, Winship Cancer Institute, Atlanta/GA/US

Background: The FDA recently approved osimertinib (AZD9291) for the treatment of patients with EGFR mutation-positive advanced NSCLC who are progressed on EGFR-TKIs, or who cannot tolerate prior EGFR-TKIs. This study investigated PD-L1 expression in patients treated with osimertinib and the impact of PD-L1 expression on clinical activity.

Methods: Patients treated with osimertinib from the FLAURA trial were split into the following groups: Group A (n = 94, PD-L1–negative), Group B (n = 55, PD-L1–positive). Patients were followed for a median of 24 months (range, 3–33). In the PD-L1–positive group, 15% of patients showed PD-L1 expression ≥50%, and approximately 5% showed PD-L1 expression ≥1%. Conclusion: In this exploratory analysis of patients treated with osimertinib, PD-L1 expression ≥1% was associated with better response rates and OS compared to patients without PD-L1 expression ≥1%. Further studies are warranted to confirm these findings.

**MA15.06 CIRCULATING TUMOR DNA PORTRAYS THE RESISTANCE LANDSCAPE TO A NOVEL THIRD GENERATION EGFR INHIBITOR, AC0010**

1Guangdong Lung Cancer Institute, Guangdong General Hospital and Guangdong Academy of Medical Sciences, Guangzhou/CN, 2Graduate School, Southern Medical University, Guangzhou/CN, 3Burning Rock Biotech, Guangzhou/CN

**Background:** In a Phase I/II dose-escalation and expansion study conducted at Guangdong Lung Cancer Institute, AC0010 demonstrated promising efficacy and good tolerability in advanced NSCLC patients with EGFR T790M-mediated resistance to previous EGFR TKIs (NCT02330367). As disease progression (PD) with EGFR T790M-directed therapy also emerges over time, we investigated the resistance mechanisms to AC0010 in this study. **Method:** Serial ctDNA samples obtained from patients who progressed on AC0010 (data cut-off October 14, 2016; figure1). Putative resistance mechanisms to AC0010 were identified in 19/23 patients (>1 putative resistance mechanism was detected in some patients). EGFR amplification was the predominant resistance mechanism (21.1% [4/19 patients]), followed by TP53 loss of heterozygosity (15.8% [3/19]). EGFR C797S mutation, Met amplification and mutations in the PI3KCA pathway each occurred in 10.5% of patients (2/19). SCLC transformation, ERBB2 amplification, CD79A_R80 mutation, and MLH1 amplification, Rb1 loss, and concurrent rise in the allelic fraction of tumor suppressor gene TP53 and Rb1 were each detected in 5.3% of patients (1/19). In a patient with PD following single-agent AC0010 and EGFR amplification as the putative resistance mechanism to AC0010, subsequent treatment with AC0010 plus nimotuzumab (EGFR monoclonal antibody) successfully overcame resistance, resulting in a response that lasted for 7.7 months.

(See next page)
MINI ORAL ABSTRACT SESSIONS
TUESDAY, SEPTEMBER 25, 2018

**Conclusion:** The resistance landscape to AC0010 appears to differ from that described previously with osimertinib. In this cohort of patients in China, EGFR amplification was the predominant resistance mechanism to AC0010 and could be potentially overcome by EGFR dual inhibition.

**Keywords:** Resistance, Circulating Tumor DNA, third generation EGFR inhibitor

**MA15.07 DIFFERENT RESPONSES TO OSIMERTINIB IN PRIMARY AND ACQUIRED EGFR T790M-MUTANT NSCLC PATIENTS**

S. Wang, B. Zhang, B. Han
Department of Pulmonary Medicine, Shanghai Chest Hospital, Shanghai/CN

**Background:** Primary EGFR T790M could be occasionally identified by routine molecular testing in tyrosine kinase inhibitor TKI-naive non-small cell lung cancer (NSCLC) patients. This study was aimed to compare clinical characteristics of primary and acquired T790M mutations and their responses to Osimertinib in NSCLC patients. **Method:** We collected clinical characteristics of patients diagnosed with epidermal growth factor receptor (EGFR) mutation from 2012 to 2017 in Shanghai Chest Hospital. For patients with primary and acquired T790M mutations, the responses to Osimertinib were analyzed. **Result:** Primary T790M was identified in 1.03% (61/5900) of TKI-naive patients. Acquired T790M was detected in 45.50% (96/211) of TKI-treated patients. T790M always coexisted with sensitizing EGFR mutations. Primary T790M was always coexisted with 21L858R (45/61) whereas acquired T790M was coexisted with 19del (61/96). Among them, 18 patients with primary T790M mutation acquired Osimertinib and 75 patients with acquired T790M mutation received Osimertinib. The objective response rate (ORR) of patients with low baseline CTC level (<20.5 FU/3 mL) were significantly higher than those with high baseline CTC level (≥20.5 FU/3 mL) (55.8% vs 38.5%, P = 0.030). Moreover, patients with low baseline CTC level had a markedly longer progression-free survival (PFS) than those with high baseline CTC level (HR = 0.50, P < 0.001). This difference remained significant after multivariate analysis (P = 0.003). Dynamic change of CTC value was significantly associated with partial response (PR) (P = 0.042) and stable disease (SD)/progression disease (PD) (P = 0.032). Of note, dynamic monitoring of CTC provided evidence of resistance to EGFR-TKIs before CT scanning, median: 113 days; range: 45 to 169 days.

**Conclusion:** Primary and acquired T790M-mutation patients showed different molecular characteristics. Both of them may respond to Osimertinib. However, primary T790M patients showed greater survival benefits from Osimertinib than acquired T790M patients.

MA15 COLLIDING APPROACHES - EGFR AND IMMUNOTHERAPY
TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA15.10 LOSS OF T790M MUTATION IS ASSOCIATED WITH EARLY PROGRESSION TO OSIOMERTINIB IN CHINESE ADVANCED NSCLC PATIENTS HARBORING EGFR T790M
S. Zhao1, T. Jiang1, X. Li2, C. Zhao2, C. Su3, S. Ren1, C. Zhou3
1Department of Medical Oncology, Shanghai Pulmonary Hospital, Thoracic Cancer Institute, Tongji University School of Medicine, Shanghai/CH; 2Department of Lung Cancer and Immunology, Shanghai Pulmonary Hospital, Thoracic Cancer Institute, Tongji University School of Medicine, Shanghai/CH

Background: Osimertinib has demonstrated striking superior efficacy in non-small cell lung cancer (NSCLC) patients detected acquired T790M mutation as resistant mechanism to upfront early-generation EGFR-TKIs. However, not all the T790M positive tumors are homogeneously sensitive to osimertinib, and the duration of response often varies. Previous studies suggest that loss of T790M mutation upon progression is related to decreased therapeutic benefit from osimertinib. The aim of this study is to investigate the association of T790M-mutant status and clinical outcomes after osimertinib treatment in Chinese NSCLC patients harboring acquired EGFR T790M mutation.

Method: We reviewed the electronic medical records of all patients receiving osimertinib monotherapy after detected acquired T790M mutation in rebiopsy resistant to prior EGFR-TKIs, and underwent re-biopsy again upon progression to osimertinib at our hospital. Detailed clinicopathologic characteristics and response data were collected for all patients. Result: From January 2014 to December 2017, 236 patients were confirmed T790M positive for acquired resistance to early-generation EGFR-TKIs (gefitinib, erlotinib, afatinib and icotinib). Among them, 90 patients received osimertinib monotherapy as subsequent treatment. Out of the patients, 84 (93.3%) with scanned tumor tissues for osimertinib resistance analysis, and 31 (34.4%) patients underwent T790M detection in biopsy after disease progression to osimertinib. The most commonly used biopsy sample were tumor tissue, peripheral blood and hydrothorax. 16 patients remained T790M positive, while 15 patients lost T790M mutation in their re-biopsy samples. Loss of T790M upon progression was significantly associated with shorter duration of response to osimertinib (median time 5.93 vs 11.87 m, HR:0.325, 95%CI: 0.087 to 0.45, p=0.0005), while overall survival (OS) was not statistically different between T790M-loss and -remain groups. The objective response rates were also similar in two groups (85% and 100%, respectively). In multivariate analysis, T790M mutation was significantly associated with early progression to osimertinib. Conclusion: Loss of T790M mutation was associated early progression to osimertinib in Chinese NSCLC patients harboring acquired T790M mutation. Dynamic detection during osimertinib treatment may be a potential strategy to timely reveal disease progression.

Keywords: EGFR T790M mutation, early progression to osimertinib, non-small cell lung cancer

MA15.11 REAL WORLD BIOMARKER TESTING AND TREATMENT PATTERNS IN PATIENTS WITH ADVANCED NSCLC RECEIVING EGFR-TKI
A. Chiang1, A. Fernandes2, M. Pavilack2, J. Wu3, F. Laliberté3, M.S. Duh4, N. Chehab2, J. Subramanian5
1Guardant Health, Redwood City/US; 2Department of Thoracic/Head & Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 3Massachusetts General Hospital, Boston/MA/US

Background: In patients who progress on treatment with first- or second-generation EGFR-TKI, mutation analysis is recommended to identify potential resistance mechanisms to upfront early-generation EGFR-TKIs. However, 60% will have a T790M mutation. We sought to observe how many patients in the real world underwent biomarker testing on EGFR Ex19del/L858R positive advanced NSCLC. We aimed to investigate the association of T790M-mutant status and clinical outcomes after osimertinib treatment in Chinese NSCLC patients harboring acquired EGFR T790M mutation.

Method: We reviewed the electronic medical records of all patients receiving osimertinib monotherapy after detected acquired T790M mutation in rebiopsy resistant to prior EGFR-TKIs, and underwent re-biopsy again upon progression to osimertinib at our hospital. Detailed clinicopathologic characteristics and response data were collected for all patients. Result: From January 2014 to December 2017, 236 patients were confirmed T790M positive for acquired resistance to early-generation EGFR-TKIs (gefitinib, erlotinib, afatinib and icotinib). Among them, 90 patients received osimertinib monotherapy as subsequent treatment. Out of the patients, 84 (93.3%) with scanned tumor tissues for osimertinib resistance analysis, and 31 (34.4%) patients underwent T790M detection in biopsy after disease progression to osimertinib. The most commonly used biopsy sample were tumor tissue, peripheral blood and hydrothorax. 16 patients remained T790M positive, while 15 patients lost T790M mutation in their re-biopsy samples. Loss of T790M upon progression was significantly associated with shorter duration of response to osimertinib (median time 5.93 vs 11.87 m, HR:0.325, 95%CI: 0.087 to 0.45, p=0.0005), while overall survival (OS) was not statistically different between T790M-loss and -remain groups. The objective response rates were also similar in two groups (85% and 100%, respectively). In multivariate analysis, T790M mutation was significantly associated with early progression to osimertinib. Conclusion: Loss of T790M mutation was associated early progression to osimertinib in Chinese NSCLC patients harboring acquired T790M mutation. Dynamic detection during osimertinib treatment may be a potential strategy to timely reveal disease progression.

MA15 NOVEL MECHANISMS FOR MOLECULAR PROFILING
TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA16.01 FREQUENCY AND GENOMIC CONTEXT OF EMERGING MARKERS FOR MOLECULAR TESTING IN LUNG ADENOCARCINOMA IN CELL-FREE DNA NGS ANALYSIS
L. Kiedrowski1, V. Lam2, Z. Piotrowska3, A. Tsao4, A. Wells1, R. Lanman1, V. Papadimitrakopoulou5, R. Nagy2
1Guardant Health, Redwood City/US; 2Department of Thoracic/Head & Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 3Massachusetts General Hospital, Boston/MA/US

Background: The recently updated CAP/IASLC/AMP lung cancer molecular testing guidelines recommend several genes be analyzed by next-generation sequencing (NGS) in lung adenocarcinoma including EGFR, ALK, BRAF, KRAS, and other genes. A recent study of 20 emerging markers (EMs) for molecular testing suggests practitioners remain aware of these and other genes between guideline updates. We investigated the frequency of genomic alterations (GAs) in several of these EMs in a cohort of patients with advanced lung adenocarcinoma who underwent clinical cell-free DNA (cfDNA) NGS analysis and assessed co-occurrence with canonical driver GAs. Method: Genomic data was reviewed from 6530 patients with at least one GA detected on clinical Guardant360 cfDNA NGS testing (Guardant Health, Inc) with an indicated diagnosis of lung adenocarcinoma from 11/25/16-3/1/18. Synonymous alterations were excluded from further analyses. Result: 2600 patients (40%) had at least one nonsynonymous alteration in the EMs assessed; excluding GAs classified as variants of unknown significance (VUS), 1350 patients (21%) had at least one characterized alteration. Table 1 shows number and frequency of GAs observed per patient by gene and alteration type. Of EMs assessed, GAs were observed most commonly in RAF1, PIK3CA, EGFR, KIT, and AKT1. Multiple EMs, including RIT1, NRAS, FGFR2-3, NTRK1, KIT, and AKT1 were observed co-occurring with established driver GAs, often in a genomic context consistent with resistance to targeted therapy at allele fractions suggestive of subclonality.

MA16.02 PROSPECTIVE CLINICAL VALIDATION OF THE INVISIONFIRST™ CTDNA ASSAY FOR MOLECULAR PROFILING OF PATIENTS WITH ADVANCED NSCLC

R. Govindan1, M. Pritchett1, D.R. Camidge1, M. Patel1, J. Khatri1, S. Bonito1, E.K. Friedman2, A. Khomani3, S. Dalia4, K. Baker-Neblett1, V. Plagnol1, K. Howarth1, N. Rosenfeld1, C. Morris1
1Washington University School of Medicine, St. Louis/MO/US, 2Pinehurst Medical Clinic, Pinehurst/NC/US, 3University of Colorado Cancer Center, Aurora/CO/US, 4Jackson Oncology Associates, Pllc, Jackson/MS/US, 5Christiana Care Health Services Inc, Newark/DE/US, 6Christus Cancer Treatment Center, Shreveport/LA/US, 7Virginia Cancer Institute, Richmond/VA/US, 8Gibbs Cancer Center & Research Services Inc, Spartanburg/SC/US, 9Invision, Spartansburg/SC/US, 10Inivata, Research Triangle Park/NC/US, 11Inivata, Cambridge/MA

Background: Clinical practice guidelines advocate molecular profiling as a part of the evaluation of advanced NSCLC, with ctDNA based profiling being an option for those with insufficient tissue. Thorough prospective clinical validation studies of NGS based ctDNA assays are lacking. Here we report the multi-centered prospective clinical validation of a ctDNA NGS panel for stratification of patients with advanced untreated NSCLC.

Method: InVisionFirst™ (Inivata) is a ctDNA NGS assay for detection of genomic alterations in 36 genes commonly mutated in NSCLC and other cancers. 264 patients with untreated advanced NSCLC were prospectively recruited by 41 US centers. 178 patients had tumour tissue available for molecular profiling (predominantly by NGS) and the remaining 86 patients without tissue were included to compare ctDNA profiles obtained from patients with and without tissue for profiling. Result: A total of 204 patients (77.3%) had detectable ctDNA alterations. Using tissue results as the reference, overall concordance for the full 36 genes in the InVisionFirst™ panel with matched tissue profiling was 97.8% with 82.9% PPV, 98.5% NPV, 70.6% sensitivity and 99.2% specificity. Excluding patients with undetectable ctDNA, these figures become 93.7% PPV, 98.4% NPV, 87.3% sensitivity and 99.3% specificity. The observed pattern of genomic changes seen in ctDNA was consistent across patients with and without tissue for profiling. Across the whole study, 44 patients with actionable alterations were identified by ctDNA testing compared to only 36 by tissue testing. 47% of patients tested by ctDNA had an actionable alteration or an alteration that is generally mutually exclusive for such actionable changes such as KRAS or STK11. Conclusion: The InVisionFirst™ assay demonstrates excellent concordance with tissue profiling in this multi-centered prospective clinical validation study. The performance of this assay in terms of overall sensitivity and specificity appears comparable if not higher than other established commercial ctDNA assays. Utilization of InVisionFirst™ ctDNA testing led to the detection of 22% more actionable alterations than standard of care tissue testing in this study supporting its use for the molecular stratification of patients with advanced NSCLC. Further analyses on the features associated with detectable ctDNA signatures are ongoing.

Keywords: NSCLC, ctDNA, InVisionFirst™

MA16.04 CLINICAL AND MOLECULAR CHARACTERISTICS OF EGFR MUTANT LUNG CANCERS WITH CONCURRENT TP53 AND RB1 MUTATIONS.

1Medical Oncology, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Pathology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 3Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US, 4Department of Pathology - Molecular Diagnostics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 5Department of Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US

Conclusion: Effective therapies are continually emerging for a growing number of molecular biomarkers in lung cancer. Comprehensive genomic profiling with ctDNA NGS can identify GAs in referred patients and inform recommended and EM genes to guide therapeutic decision-making and catalyse clinical trial enrollment. Further investigation of mutual exclusivity and co-occurrence of established drivers and EMs may reveal novel resistance mechanisms and facilitate identification of rational combination therapeutic strategies.

MA16 NOVEL MECHANISMS FOR MOLECULAR PROFILING TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA16.05 MET KINASE DOMAIN REARRANGEMENTS (KDRE) IN NON-SMALL CELL LUNG CANCER (NSCLC) IDENTIFIED THROUGH COMPREHENSIVE GENOMIC PROFILING (CGP)

A. Schrock1, D. Pavlick1, M. Rosenzweig1, R. Erlitch1, L. Albacker1, G. Frampton1, J. Ross1, V. Miller5, S. Ali5, O. Ou2
1Foundation Medicine, Cambridge/MA, 2University of California at Irvine, Orange/CA/US

Background: MET is a known oncogenic driver in NSCLC, and activation via various means including gene amplification, exon 14 skipping, and fusion has been reported to be targetable in the clinical setting. However, the prevalence and characteristics of NSCLCs harboring MET kinase fusions as well as diverse KDRE have not been comprehensively assessed. Microwave CGP, a hybrid-capture based CGP with 5 megabases (Mb) of sequenced DNA and is reported as mutations/Mb. MET KDRE cases harbored at least one targetable NSCLC fusions was 0.03%). MET KDRE cases harbored at least one targetable NSCLC cancer, Lineage Plasticity
Keywords: NSCLC, ctDNA, InVisionFirst™

MA16.04 CLINICAL AND MOLECULAR CHARACTERISTICS OF EGFR MUTANT LUNG CANCERS WITH CONCURRENT TP53 AND RB1 MUTATIONS.

1Medical Oncology, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Pathology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 3Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US, 4Department of Pathology - Molecular Diagnostics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 5Department of Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US

Background: 20% of patients with metastatic lung adenocarcinoma have activating EGFR-mutations. EGFR-mutant lung cancers can undergo histologic transformation to small cell lung cancer (SCLC) as a response to the selective pressure of EGFR-TKIs in ~5% of patients after earlier-generation EGFR-TKIs and have been reported after osimertinib. SCLC nearly universally harbor TP53/RB1-alterations which are rarely seen in EGFR-mutant lung adenocarcinomas. We sought to identify this subset of patients, describe their clinical course and likelihood of SCLC transformation. Method: Retrospective review of targeted next generation sequencing (NGS, MSK-IMACT) at Memorial Sloan Kettering (MSK) was performed to identify patients with concurrent EGFR-activating mutations and TP53/RB1-wildtype in the sputum tumor sample from NGS between April 2014 to February 2018 with a data cutoff of March 2018. For comparison, consecutive patients with lung cancers harboring EGFR-mutations who were EGFR-TKI naive and TP53/RB1 wildtype were also collected during that time-period. Result: Of the 21% of lung cancer patients with activating EGFR-mutations (759/3662), 5% (40/759) had concurrent TP53/RB1-mutations. 43% (17/40) were female, 58% former-smokers (23/40, median pack-years: 8), and median age of 68 (range 25-86 years). 88% (35/40) were adenocarcinoma at diagnosis, of which 11% (4/35) transferred to SCLC during treatment; 10% (4/40) were de-novo SCLC at diagnosis, and 1 was large cell neuroendocrine. The transformation rate was significantly higher compared to previous work from MSK evaluating EGFR-mutant patients showing 4% (4/115) transformation (p=0.04). Concurrent PIK3CA mutations were more frequently seen in the EGFR/TP53/RB1 mutant group compared to the TP53/RB1-wildtype group (17% (n=6/35) vs 7% (n=4/60), p=0.11). 20 patients were EGFR TKI-naive at the time of NGS; the median time on EGFR-TKIs (TOT) was 7.6 months versus 14.2 months in the TP53/RB1-wildtype group (HR 4.48, p=0.0003). The overall survival (OS) of this cohort versus TP53/RB1-wildtype was not different (4.3 vs 4.1 years, HR 1.35, p=0.51). In the 4 patients with SCLC transformation, the median transformation was 2.4 years after a median of 1.5 EGFR-TKI therapies (range 1-5 lines). Median OS from time of transformation was 7 months. 63% (25/40) of the EGFR/TP53/RB1-mutant cohort had brain metastases during their disease course as compared to 50% (n=30) in the TP53/RB1-wildtype group (p=0.04). Conclusion: TP53/RB1-wildtype tumors harboring MET KDRE, are enriched in EGFR/TP53/RB1-mutant lung cancers, occurring in 11% of patients. Once SCLC transformation occurs, overall survival is short. Patients with EGFR/TP53/RB1 have a shorter time on EGFR-TKI. Further investigation into optimal treatment for this subset of EGFR/TP53/RB1 mutant lung cancers is critical.

Shanghai Jiao Tong University, Shanghai, China. 2Cancer Hospital of Shantou University Medical College, Shantou, China. 3The First Affiliated Hospital of Guangzhou Medical University, Guangzhou, China. 4The First Affiliated Hospital of Wenzhou Medical University, Wenzhou, China. 5The Second Affiliated Hospital of Nanchang University, Nanchang, China. 6The First Affiliated Hospital of Guangxi Medical University, Nanning, China. 7Huzhou Cancer Hospital, Huzhou, China. 8Shanghai Changzheng Hospital, Shanghai, China. 9Ningbo No.2 Hospital, Ningbo, China. 10Shanghai Ninth People’s Hospital, Shanghai Jiao Tong University, Shanghai, China. 11Geneplus-Beijing Institute, Beijing, China. 12Geneplus-Beijing, Beijing, China.

Background: TKI has significantly improved survival time of NSCLC pts with sensitive mutation. However, pts present different outcome while receiving TKI treatment. We conduct a prospective multicenter clinical trial to determine whether clonality of sensitive mutation is related to the efficacy of TKI. We also evaluate the consistency of TMB between tissue and blood in this cohort. Method: Paired tumor and plasma samples at diagnosis were obtained from systemic treatment naïve pts with advanced NSCLC. DNA was sequenced by target-capture deep sequencing of 1021 previously annotated genes related to solid tumors. Clonal EGFR mutation was defined if EGFR mutation was in the cluster with the highest mean variant allele frequency with Pyclone, and otherwise subclonal EGFR mutation. TMB of tissue (tTMB) and blood (bTMB) analysis interrogated single nucleotide variants, small insertion and deletion, with VAF ≥ 3 % and > 0.1%, respectively. TMB-high pts were identified with ≥ 8 mut/Mb (upper quartile of data from geneplus). Result: During February 2017 to April 2018, 127 advanced NSCLC pts were enrolled from 9 centers. A total of 653 somatic variations were detected in tissues. Mutations occurred most frequently in EGFR (57 %), TP53 (54 %), KRAS (9 %), ALK (8 %), and PIK3CA (2 %). In matched plasma, 405 (62 %) tumor-derived mutations were detected by pan-cancer panel sequencing. A total of 90 EGFR mutations were detected in 73 pts, most of which occurred in tyrosine kinase domain (L858R, 41%; E19Del, 33%). Most EGFR mutation were clonal in tissue and plasma, with a consistency of 83 % in paired samples. In addition, tTMB was significantly correlated to bTMB (Pearson r= 0.85, p-value= 1.8e-30), with a consistency of 89 %. Interestingly, high tTMB was observed in a small fraction of patients (8 %) with driver mutations, such as mutations in EGFR, ALK fusion, ERBB2 and PIK3CA. Conclusion: Deep sequencing with the pan-cancer panel can effectively detect mutations and evaluate TMB in both tissue and blood with high consistency. EGFR mutations can be clonal or subclonal in both tissue and blood. Prospective multicenter study is ongoing to determine the EGFR clonality as a predictive factor for the TKI efficacy in NSCLC (TRACELIB-NSCLC, NCT03059641).

Keywords: TMB, advance NSCLC, ctdna sequencing
Method: ALK- and ROS1-translocated advanced NSCLC patients, were prospectively enrolled from October 2015 to April 2018 in 9 French institutions. ALK or ROS1 positivity was as confirmed by immunohistochemistry and FISH or RNAseq. ALK (EML4 variants v1, v2, v3), ROS1 (CD74, SLC34A2, SDC4 and EZR) fusions, and mutations in a panel of 36 NSCLC-associated genes were investigated in ctDNA using InVisionFirst™ (Plagnol V PLoS ONE, 2018). Result: A total of 120 patients were included: 96 ALK and 24 ROS1. 30 samples were collected from patients who were TKI-treatment-naive, 257 during follow-up and 73 at progressive disease (PD) under TKI. The median age was 55 years-old (range 23-75); most patients were female (57%) and had a non-smoking history (59%). At diagnosis, 20% of patients presented with brain metastasis. All patients received at least 1 ALK-TKI (median: 1.6; range:1-6). Preliminary results are available for the first 54 patients: 21 at diagnosis and 33 at PD under TKI. ALK/ROS1 fusions were detected in 13/21 patients (62%) at diagnosis: 12/20 ALK-fusions (7 v1, 2 v2 and 3 v3) and in 1/1 ROS1-fusion (CD74-ROS1). No fusion was detected in 8 patients, which may be due to partner genes or variants not covered by this panel. However, 5 of these 8 patients had exclusive thoracic or brain PD. Liquid biopsies collected at the radiographic evaluation under therapy revealed complete ctDNA clearance of the fusion when patients experienced PR (n=4). In samples at PD, fusion was detected in 44% of patients (24/55) with evidence of acquired resistance in patients both positive and negative for fusion. Results for the remaining samples, correlation between fusion variant and survival, fusion variant and mechanism of resistance will be presented at the Congress. Conclusion: Our results suggest that ctDNA profiling is a promising non-invasive tool for identification of ALK/ROS1 fusions and monitoring of response in advanced NSCLC patients. Systematic identification of the fusion partner may help to better understand the heterogeneity and evolution (sensitivity profile to targeted inhibitors and associated-mechanisms of resistance) of NSCLC driven by ALK and ROS1 rearrangement.

Keywords: ALK/ROS1-rearrangement, ctDNA

**MA16 NOVEL MECHANISMS FOR MOLECULAR PROFILING**

**TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00**

**MA16.10 CLINICAL UTILITY OF CEREBROSPINAL FLUID CELL-FREE DNA FOR CLARIFYING GENETIC FEATURES OF LEPTOMENINGEAL METASTASES IN ALK REARRANGEMENT NSCLC**

M. Zheng1, Y. Li1, B. Jiang1, H. Tu1, X. Zhang1, J. Ye2, W. Tang1, S. Chuaï2, Y. Wu1

1Oncology Center, Guangdong Lung Cancer Institute, Guangzhou/CN, 2Burning Rock Biotech, Guangzhou, China, Guangzhou/CN

**Background:** Leptomeningeal metastases (LM) were associated with a poor prognosis in non-small cell lung cancer (NSCLC). LM were much more frequent in EGFR mutant patients, and cerebrospinal fluid (CSF) cell-free DNA (cfDNA) has shown unique genetic profiles of LM in patients harboring EGFR mutations in our previous studies. However, studies in ALK positive NSCLC patients with LM are scarce. **Method:** Lung cancer patients with ALK rearrangement were screened from Sept 2011 to Feb 2018 at our institute. Leptomeningeal metastases were diagnosed by MRI or CSF cytology or next-generation sequencing (NGS) of CSF cfDNAs. Paired plasma were also tested by NGS. **Result:** LM were diagnosed in 22 (7.6%) of 288 ALK rearrangement patients with lung cancer. A total of 11 ALK positive patients with LM were enrolled with CSF cfDNA tested by NGS (one case used CSF precipitates instead of CSF cfDNA). Paired plasma were available in 11 patients. Driver genes were detected in 75.0% CSF samples and 45.5% plasma respectively (P=0.214). Max allele fractions were higher in CSF cfDNA than in plasma (40.8% versus 0%, P=0.021). ALK variant 2 (E20:A20) was identified in 5 cases of CSF and 1 paired plasma. Multiple copy number variants (CNV) were mainly found in CSF cfDNA, including EGFR copy number gains. Resistance mutations including gatekeeper gene ALK G1202R was identified in CSF cfDNA with ALK variant 1 and ALK G1269A was detected in plasma. The detection rate of TP53 was 45.4% versus 27.3% in CSF cfDNA and plasma.

**Conclusion:** CSF cfDNA was more sensitive than plasma to reveal genetic features of ALK-fusion LM, confirming its role as a liquid biopsy medium for LM in driver gene positive NSCLC.

**Keywords:** Leptomeningeal metastases, non small cell lung cancer, Cerebrospinal fluid
MA17.01 A SENSE OF UNDERSTANDING AND BELONGING WHEN LIFE IS AT STAKE – OPERABLE LUNG CANCER PATIENTS’ LIVED EXPERIENCES OF PARTICIPATION IN EXERCISE

M. Misse1, M. Schoena2, B. Borregaard2
1Dept. of Thoracic Surgery, University Hospital of Copenhagen, Copenhagen/DK; 2J. Department of Cardiothoracic and Vascular Surgery, Odense University Hospital, University of Southern Denmark, Odense/DK

**Background:** Exercise has been introduced to improve physical capacity and quality of life and to reduce symptoms and side effects of treatment in surgically treated non-small cell lung cancer (NSCLC) patients. The effects of an exercise programme for this patient group have been tested in a randomized controlled trial – the PROLUCA study. The questions though, of how patients experience participation in group-based exercise studies and the impact of the shared community with fellow patients has not been previously examined. The objective was to explore lived experiences and social benefits among patients with operable NSCLC who participated in an exercise programme (the PROLUCA study) post-surgery.

**Method:** Nineteen patients enrolled in an exercise intervention two weeks post-surgery participated in qualitative interviews at three time points. A phenomenological hermeneutical approach comprised the epistemological stance and the methodological basis was Ricoeur’s narrative philosophy. The goal of the analysis and interpretation was to provide descriptions that captured the meaning of the lived experiences of the patients. Narrative analysis using a hermeneutical approach was used to make sense of the patient accounts and to identify the personal experiences and social benefits of taking part in the group-based exercise intervention. The patients experienced themselves as part of a community, and the physical exercise intervention was significant in terms of the patients’ social capital. In this sense, patients gained access to resources that derived from human interaction in the exercise group, and their illness and treatment became easier to manage when shared with others in the same situation. The exercise intervention helped to create a community for patients after lung cancer surgery, and the patients experienced a feeling of belonging and equality with the other participants.

**Conclusion:** The group-based exercise intervention created opportunities for mutual understanding between patients, making illness and treatment easier to manage. The participants supported each other in renewed balance in life during the exercise intervention in the interaction with peers in the group. It is relevant to inform operable NSCLC patients about the potential community of understanding and belonging in group-based exercise interventions.

**Keywords:** NSCLC, Surgery, exercise

MA17.02 EARLY ACCURACY TO A PRECISION LUNG CANCER SURVIVORSHIP INTERVENTION: THE KENTUCKY LEADS COLLABORATIVE LUNG CANCER SURVIVORSHIP CARE PROGRAM

J. Studts1, J. Burris2, M. Andrykowski3, T. Schapmire1, B. Head1, M. Rigney4, A. Criswell1, S. Arnold1, A. Yates5, C. Blair2, A. Christian3
1Department of Behavioral Science, University of Kentucky College of Medicine, Lexington/US; 2Department of Psychology, University of Kentucky, Lexington/DK; 3Medical Outreach, Lung Cancer Alliance, Washington/DC/US; 4Medical Outreach, Lung Cancer Alliance, Washington/DC/US; 5Department of Internal Medicine, University of Kentucky College of Medicine, Lexington/KY/US; 6University of Kentucky Markey Cancer Center, Lexington/US; 7Behavioral and Community-Based Research Shared Resource Facility, University of Kentucky Markey Cancer Center, Lexington/KY/US

**Background:** Recent advances in early detection and treatment of lung cancer have created a need for survivorship care interventions to reduce the psychosocial and symptom burden of lung cancer, but few interventions address the unique experience of lung cancer survivors and their caregivers. Leveraging shared decision-making and motivational interviewing, the Kentucky LEADS Collaborative developed a precision psychosocial intervention addressing the unique experiences and challenges of individuals diagnosed with lung cancer and their caregivers. This paper describes the demographic, diagnostic, and psychosocial characteristics of the initial participants in the Kentucky LEADS Collaborative Lung Cancer Survivorship Care Program.

**Method:** Participants include 61 lung cancer survivors across 9 lung cancer care sites in Kentucky, USA. Data were drawn from baseline surveys of demographic characteristics, disease/treatment information, symptom burden, psychosocial functioning and quality of life administered to lung cancer survivors and caregivers enrolled in the single-arm lung cancer survivorship trial. **Result:** Of the first 61 LC survivors enrolled, 32 had a caregiver join them as participants in the intervention (53%). Participants had a mean age of 62 years. Approximately 20% of LC survivors did not have a caregiver available to participate, and 27% declined to involve a caregiver join the program. Most participating caregivers were spouses (63%), but siblings (10%) and children (19%) were also included. Most survivors were female (66%), Caucasian (97%), and covered by health insurance (93%), and 59% were married or living in a committed relationship. Most participants had been diagnosed with non-small cell lung cancer (84%) and late-stage disease (IIIb-IV; 53%). Most participants had a history of smoking (95%); 30% had smoked within the past 30 days, and 29% were current smokers. Among current smokers, participants reported very high quit planning (9.2±1.77) and quitting confidence (9.4±2.89). Finally, approximately 55% reported clinically significant distress, with a mean level of distress of 3.98 (2.99) on a scale from 0-10.

**Conclusion:** Early accrual to the trial has exceeded expectations. Most survivors had advanced disease and reported significant distress. A substantial minority continued to use tobacco. Data suggest that modifications made to the survivorship approach emphasizing empathy and patient preference may help improve intervention acceptability and feasibility. Subsequent analyses will evaluate the impact of the intervention on quality of life, psychosocial functioning, and symptom burden. Data will also be collected regarding acceptability of the intervention and potential program changes to optimize benefits.

**Keywords:** survivorship, behavioral oncology, quality of life

MA17.03 SHARED DECISION-MAKING FOR PATIENTS WITH ADVANCED NON-SMALL CELL LUNG CANCER

M. Jensen1, K. Pihl2, G. Persson1, S. Langer1, M. Vinter3, K. Winther3, S. Peters-Haché1, M. Pahl1
1Department of Oncology, Copenhagen University Hospital, Rigshospitalet, Copenhagen/DK; 2The Danish Cancer Society, Copenhagen/DK; 3Finsen Center, Copenhagen University Hospital, Copenhagen/DK

**Background:** Lung cancer is the leading cause of cancer-related death in the world and more than half of the patients have metastatic disease at the time of diagnosis. Although, treatment options are developing rapidly, most patients are facing a poor prognosis. The role of 3rd or 4th line treatment with chemotherapy remains controversial with sparse evidence of efficacy. Therefore, the patient’s preferences become central. Shared decision-making enables the patients to be actively involved in choosing the treatment option that best reflects both medical evidence and individual preferences. This study examines how patients with lung cancer and their relatives are empowered and supported when they have made informed choices regarding 3rd or 4th line of treatment. The aim was to develop a model for shared decision-making and to test decision aid tools that enable a collaborative process that takes into account the best available scientific evidence, as well as the patient’s values and preferences.

**Method:** Patients diagnosed with advanced non-small cell lung cancer, their relatives and the health care professionals were involved in the process that included: 1) Multidisciplinary workshops and workshops with patients and relatives, 2) Training course in communication on existential issues and shared decision-making for health care professionals, 3) Designing and testing five decision aid tools, 4) Creating a Podcast and 5) Evaluation by patient satisfaction surveys.

**Result:** Three strategic focus areas were identified: 1) The meaningful service, 2) Considerations in end-of-life care and 3) Patient involvement in decision making. The patient reported quality of communication was increased during the study period. The patient satisfaction surveys (n=77 before intervention and n=60 final evaluation at the end) demonstrates that improvements from baseline to final evaluation in regard to:1) involving patients in the treatment decisions to the extent they prefer (Pearson Chi-Square, P=0.048) and 2) encouraging patients to ask questions (Pearson Chi-Square, P=0.008). The study improved the healthcare professionals understanding of the importance of incorporating patients in shared decision-making processes in clinical practice. However, some barriers for implementation were identified, such as changing established behaviour among healthcare professionals. For the next step, the findings indicate that decision aid tools are useful and related to significant changes in patient experience of the quality of communication. We suggest investigating the feasibility and potential concerns of integrating these tools to a larger extent in clinical practice.

**Keywords:** Patient involvement, shared decision-making, Advanced Non-Small Cell Lung Cancer
MA17.05 DEVELOPMENT OF A TELEPHONE CLINIC FOR PATIENTS UNDERGOING LONG TERM FOLLOW-UP AFTER THORACIC SURGERY
J. Mitchell1, C. Buchanan2, S. Malone3, F. Di Chiara1, D. Stavroulias1, E. Belcher1
1Thoracic Surgery, Oxford University Hospitals NHS Trust, Oxford/GB, 2Cardiothoracic Surgery, Oxford University Hospitals NHS Trust, Oxford/GB

Background: Patients undergoing long term follow-up after lung cancer surgery in our institution follow an imaging based follow-up programme. Protocol led CT imaging followed by an out-patient appointment is undertaken every 6 months for two years after surgery then annually until year 5. Feedback from patients indicated they find their visits to the hospital burdensome and they frequently requested results of surveillance imaging over the telephone. Limited capacity in the thoracic surgery clinics led to long waits for an appointment to be informed of imaging results. To address these issues, we developed a model of nurse led telephone follow-up after surveillance imaging. Method: A proposal to hold one telephone clinic per week was made to commissioners in the autumn of 2016. Following approval, the telephone clinic commenced in April 2017. Patients are triaged by the specialist nurse when CT results are available and allocated to the telephone clinic if appropriate. They are given a timed appointment and the telephone number they will be contacted on is confirmed prior to the appointment. A database is completed during the appointment, a record of the consultation is returned in both paper and electronic patient records and a letter is sent to the GP and other teams who have contact with the patient. Patients with significant abnormalities on CT imaging are referred for discussion by the multidisciplinary team and seen in a face to face clinic. Result: In the first twenty months (April 2017 to March 2018) there were 254 patient appointments in 51 telephone clinics. Average call length is 10 minutes with a range of 3 to 22 minutes. One patient scheduled for a telephone appointment was not contactable at the appointed time (0.4%). Satisfaction with the clinic is high with 98% of patients requesting their next follow-up appointment in the telephone clinic. Clinic capacity was increased at reduced cost to commissioners as a telemedicine appointment is charged at £25.34 compared to £70.16 for a face to face appointment. Conclusion: Early results suggest nurse led telephone clinics are an effective way of providing follow-up to patients on an imaging based follow-up programme after surgery. They are well received by patients. We aim to introduce an online tool to objectively assess symptoms in this patient group. Further evaluation of patient experience in this clinic would be beneficial, along with an evaluation of the impact of introduction of telephone follow-up on the rest of the service.

Keywords: Surgery, Follow-up, Nurse-led

MA17.06 THE SPECIALIST LUNG CANCER NURSE AND SELF-MANAGEMENT FOR PEOPLE LIVING WITH LUNG CANCER: A MODEL OF ENGAGEMENT
V. Brunelli, P. Yates, C. Windsor
Institute of Health and Biomedical Innovation, Queensland University of Technology, Red Hill/AU

Background: There is increasing evidence that patient self-management strategies, used as adjuncts to traditional pharmacological interventions, can improve symptom control for people living with lung cancer. While it is acknowledged that the specialist lung cancer nurse (SLCN) is well positioned in the multidisciplinary team to facilitate patient self-management education (PSME), limited guidance is available to SLCNs on this role. The aim of this study was to understand the knowledge and skills required of SLCNs to facilitate PSME and how such skills might best be developed. The intent was to develop a pedagogy that enhances SLCN-patient interactions so that patients can be better supported to make self-care decisions and to act on these decisions. Method: The epistemological lens of the study drew on the sociocultural works of Vygotsky and Leontiev. Fifteen participants were purposively recruited through the Australia and New Zealand Lung Cancer Nurses Forum. The sample comprised Australian registered nurses employed at the level of clinical nurse consultant. Eligibility for the study required participants have a minimum of 5 years lung cancer nursing experience. Of the sample, the average was 13 years’ experience. Through individual, face to face interviews, a biographical approach to data collection focused on the participants’ experiences from patients’ perspective. The theoretically informed analysis generated understanding about the salient influences on SLCN learning and how and why these influences shaped PSME. Result: PSME is an inherently complex activity. Although seeking to facilitate patient learning to empower patients to self-manage, the SLCN experiences challenges in the contemporary health care environment. Entrenched power relations, professional boundaries, minimal practice guidelines and issues of resourcing of lung cancer and lung cancer nursing are key factors that shape PSME. A model of engagement was designed to reflect the pedagogy that underpins optimal interactions between SLCNs and patients. The model brings forth the socially situated contexts of the SLCN and patient as central to the interaction. A reflective mode of practice creates a teaching and learning environment inclusive of sociocultural and individual processes on learning and the mechanisms of co-constructing knowledge for the purpose of shaping patient behaviour. Conclusion: The study assumes the strategic importance of addressing how best the SLCN workforce can support people living with lung cancer to self-manage. A key strength of the research is the focus on understanding the individual and social nature of SLCN’s work and how the factors that impact their work are understood and managed. This will assist the SLCN in understanding their role and the role of the multidisciplinary team in supporting the patient. The model brings forth the socially situated contexts of the SLCN and patient as central to the interaction. A reflective mode of practice creates a teaching and learning environment inclusive of sociocultural and individual processes on learning and the mechanisms of co-constructing knowledge for the purpose of shaping patient behaviour.

Keywords: nurse education, patient self-management, nurse-patient interaction

MA17.07 NURSE-LED TELEHEALTH CLINIC IN TREATMENT MONITORING AND FOLLOW UP
S. Cubbin1, M. Brada2
1Oncology, Clatterbridge Cancer Centre NHS Foundation Trust, Wirral/GB, 2Radiation Oncology, Clatterbridge Cancer Centre, Wirral/GB

Background: A clinical consultation is usually physician led and traditionally carried out in a direct person-person interaction in an outpatient clinic. The alternative is replacing it through electronic means via telehealth. This has already been exploited as a phone consultation and is gaining momentum as a video based consultation although it has not been widely introduced into oncology. Method: The aim was to ascertain the acceptance of the video consulting technology in real clinical settings and the effectiveness of video consultation in replacing conventional consultation. Eligible patients who attended a pre-existing nurse led clinic completed a satisfaction questionnaire to ensure its use. Those that were willing to participate were asked to replace two nurse led appointments with nurse led telehealth appointments using iKonsult video consultation platform. After each consultation a satisfaction questionnaire was completed. Result: Patients were recruited from a protocolised nurse led clinic for evaluation driven NSCLC on oral tyrosine kinase inhibitors (TKI). 42 patients were approached over a three month period; only 6 agreed and were followed up via the telehealth platform. 4 patients considered it as a possibility, 4 did not feel confident and 3 did not have the correct equipment. The remaining patients cited numerous reasons for not taking up this service. In the satisfaction analysis of 17 initial telemedicine consultations 5/6 patients (81%) were very satisfied with telemedicine follow up. 4 patients (66%) found the platform extremely easy and 2 (34%) easy to use. Conclusion: On treatment monitoring of oral TKI therapy could be effectively carried out using video consultation platform reducing the number of hospital visits. The consultations provided necessary information and allowed for adequate clinical assessment. However the initial take up rate is low mostly due to patient reluctance rather than unavailable technology. The overall feedback from participants was very positive and accepting of the service. The iKonsult video consultation is being introduced into other oncology settings.

MA17.09 REMOTE SYMPTOM REPORTING FOR TELE-NURSING TEAM IN THORACIC ONCOLOGY CLINICS: ENVIRONMENTAL SCAN AND STAKEHOLDER ENGAGEMENT
S. Kooner1, J. Harris2, S. Lee1, C. De Guia1, D. Howell3, G. Liu4

MA17 NEW METHODS TO IMPROVE LUNG CANCER PATIENTS OUTCOMES TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA17.10 THE USE OF TECHNOLOGY IN THE DELIVERY OF SUPPORTIVE CARE OF LUNG CANCER PATIENTS AFTER TREATMENT P. Rose1, H. Quail1, J. Mcphelim2, M. Simpson3
1Cancer Services, NHS Lanarkshire, G/GB, 2Cancer Services, NHS Lanarkshire, Rg/GB, 3Cancer Services, NHS Lanarkshire, Ls/GB

Background: The NHS Lanarkshire Lung Cancer Project is part of the Transforming Care after Treatment (TCAT) programme. During phase one 58 patients participated in the project. 88% of patients opted for a telephone consultation, which was more time effective taking only on average 20 minutes compared to 48 minutes for a face to face consultation. 90% of patients rated the service as excellent and a review of additional Patient Reported Outcome Measures demonstrated an improvement in overall quality of life. Further funding was secured as part of phase 3 of the TCAT programme allowing for continued testing.

Method: Between November 2017 – May 2018 lung cancer patients living in Lanarkshire were offered two monthly SPARC assessments on completion of treatment. This was followed up with and a telephone consultation from a lung cancer clinical nurse specialist, the provision of a personalised care plan and access to self-management information.

The choice of an electronic or paper SPARC assessment was offered. To support the evaluation a Functional Assessment of Cancer Therapy – Lung (FACT-L), Memorial Symptoms Assessment Scale (MSAS) and Supportive Care Needs Assessment – Lung (SPARC) were completed prior to their first and after their final assessment. A patient experience questionnaire was also provided on completion of their final assessment.

Result: 24 patients participated in phase 3. 53% opted to complete their assessment electronically with 47% preferring the paper option. 15 patients (63%) completed both assessments resulting in a total of 582 concerns being identified. Data analysis of these patients shows a 27% reduction in concerns with the number of high concerns falling by 62% between the first and second assessment. The average length of time for telephone review remained similar phase one at 22 minutes ranging from 7 minutes to 55 minutes. Patient satisfaction in the project continued to be high with 82% rating the service as excellent and 18% as good. Data analysis for 15 patients who had completed 2 FACT-L, MSAS and SCNS yielded a significant reduction in symptom burden and psychological distress with a significant improvement in quality of life.

Conclusion: Findings from this project are encouraging that this model of working is not only acceptable to patients but time efficient and clinically effective. However, a limitation of this project is its small sample size. Therefore, further work is needed to explore its transferability and cost effectiveness to allow it to be considered for implementation in standard practice.

</tbody>
</table>

Conclusion: This audit provides a broad overview of the pattern and trend of readmission rates within 30 days post discharge following lung cancer resection. Whilst not every readmission can be avoided, there is opportunity to identify and prevent patient readmission. Listening to patient’s assessment of their readiness for discharge is crucial to facilitating patient compliance with discharge and confidence in community carers.

MODEL: DEVELOPMENT AND VALIDATION

Background: Lung cancer is a heterogeneous disease with many clinically important subtypes. Given the complexity of classification, there is room for innovative risk assessment tools to help ascertain prognosis and management. In this work we tested an Artificial Neural Network (ANN) to stratify patients into clinically significant low and high risk categories.

Method: CT imaging, survival, and cancer staging data was extracted for a sample of 311 patients with Stage-I (n = 186) and Stage-II (n = 125) non-small cell lung cancer (NSCLC) from the comprehensive Boston Lung Cancer Survival (BLCS) cohort. Median follow-up from time of diagnosis was 3.5 years, with 86% 2-year survival. A deep convolutional neural network pretrained on ImageNet was used, with fine-tuning of the last convolutional layers, dense layers, and softmax for stratification. Inputs of this model were 50 x 50 mm² image patches. Training was performed on 182 labeled CT scans (112 Stage-I and 70 Stage-II). 46 cases were used for initial cross-validation, with an independent test set of 83 cases. The median prediction probability from the ANN was used as a cutoff to divide patients into low and high risk groups. Result: The model was able to perform classification of cancer stage on the heterogeneous test set (AUC = 0.73, p < 0.0005). The test set was split evenly into low risk (n = 42) and high risk (n = 41) groups based on model predictions. There was statistically significant separation in the Kaplan Meier—estimates for survivorship in the two stratified groups (p = 0.02).

Conclusion: ANNs can be effective tools for quantitative risk stratification in NSCLC. In addition to the potential for real-time clinical decision support, ANNs may also help create new paradigms in lung cancer risk assessment. The models have the capacity to perform suprahuman computations, which can help meet future demands of clinical practice, supporting ANNs may also help create new paradigms in lung cancer risk assessment. The models have the capacity to perform suprahuman computations, which can help meet future demands of clinical practice, given expanding digital-imaging volumes.

MA18.05 CHARACTERISTICS AND LONG-TERM OS OF NON-SMALL CELL LUNG CANCER PATIENTS RECEIVING EGFR TYROSINE KINASE INHIBITOR TREATMENT

M. Bergqvist1, H. Nordahl Christensen2, F. Wiklund1, S. Bergström1
1Department of Radiation Sciences, Umed University, Umeå/SE, 2Nordic Baltic, Astrazeneca, Södertälje/SE, 3Statisticon Ab, Statisticon, Stockholm/SE, 4Department of Oncology, Gävle Hospital, Gävle/SE

Background: Epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (TKIs) are important therapeutic agents in treatment of EGFR mutation-positive non-small cell lung cancer (NSCLC) patients. However, long-term follow-up and knowledge of clinical factors and TKI treatment patterns, which may be associated with longer OS, remains unclear. Using nationwide registry data, the aim was to investigate survival, prognostic factors for OS, and first line TKI treatment pattern of stage IIIIB/IV NSCLC patients in Sweden. Method: In this cohort study, data on all patients diagnosed with stage IIIIB-IV NSCLC during 2010–2015 from the nationwide Cancer Registry of Sweden were linked with data on dispensed EGFR-TKIs drugs, comorbidity, and mortality data from Swedish national health registries. OS was defined as the interval from date of diagnosis until date of death. Survival rates were estimated using the Kaplan-Meier method. Assessment of predictive factors for OS was performed in multivariable Cox regression. Result: Of 9,992 stage IIIIB/IV NSCLC patients, 2,917 (29%) died during the observation period (n=177), 65% quit after diagnosis. Among all, few patients were aware that smoking negatively impacts treatment-related outcomes. Univariable and multivariable logistic regression models assessed factors associated with awareness and whether awareness was associated with cessation of smoking. Conclusion: This is the first nationwide study on NSCLC patients receiving first-line EGFR TKIs in routine clinical practice in Sweden. In addition to the reported prolonged TKI treatment length and TKI switching/re-challenging during the observation period, improvements and extension of EGFR testing targeting the appropriate NSCLC patient population may further have contributed to the observed relatively long overall survival.

MA18.06 PATTERNS OF LUNG CANCER CARE IN THE UNITED STATES: DEVELOPMENTS AND DISPARITIES

E. Blom1, K. Ten Haaf2, D. Arenberg3, H. De Koning1
1Department of Public Health, Erasmus MC, Rotterdam/NL, 2Division of Pulmonary & Critical Care Medicine, University of Michigan, Ann Arbor/MI/US

Background: The level of adherence to lung cancer treatment guidelines is unclear. The aims of this current study were to provide an overview of current patterns of lung cancer care in the United States and to identify possible disparities in receiving standard of care. Method: Using the National Cancer Database, we evaluated the first course therapy of 468,422 lung cancer cases diagnosed between 2010-2014. We used a series of multivariate logistic regression models to identify relationships between patient, tumor, and health care provider characteristics and receiving predefined stage-specific standards of care. Result: Most common treatments were surgery only (15.2%), radiotherapy only (12.8%), chemotherapy only (13.5%), and radiotherapy and chemotherapy (26.2%). 22.1% of subjects received no treatment. Between 2010-2014, the use of Video-Assisted Thoracoscopic Surgery among surgically treated cases increased from 24.6% to 42.3%, while the use of conversions to thoracotomy decreased from 17.7% to 4.0%. Among stage IA non-small cell lung cancer patients treated with thoracic radiotherapy, the use of Stereotactic Body Radiotherapy increased from 53.4% to 73.0%. Overall, only 63.3% of subjects received standard of care. Receiving surgery for early-stage non-small cell lung cancer was less likely with increasing age (for those 80 and over: odds ratio [OR], 0.08; 95% confidence interval [95%CI], 0.07-0.09), for non-Hispanic Blacks (OR, 0.59; 95%CI, 0.57-0.62), and for squamous cell histology (OR, 0.50; 95%CI, 0.45-0.47). These disparities were also present in other stages. Conclusion: Particularly elderly lung cancer patients, non-Hispanic Blacks, and those with squamous cell histology are less likely to receive standard of care. These disparities may have consequences for lung cancer screening, as the effectiveness depends on adequate treatment of lung cancer.

Leigh1, F. Shepherd1, A. Bejzak1, D. Howell1, J. Jones1, W. Xu1, D. Goldstein1, W. Ebbeling1, P. Selby5, M. Giuliani5, M. O’Hara6
1Dept of Medical Oncology and Hematology, Princess Margaret Cancer Centre and University of Toronto, Toronto/ON/CA, 2Princess Margaret Cancer Centre, Toronto/CA, 3Radiation Oncology, Princess Margaret Cancer Centre, Toronto/CA, 4Medical Oncology, Princess Margaret Cancer Centre, Toronto/CA, 5Oncology, McMaster University, Hamilton/CA, 6Center for Addiction and Mental Health, Toronto/CA

Background: Continued smoking after a LC diagnosis is associated with poorer cancer outcomes including increased risk of treatment-related side-effects, reduced treatment efficacy and poorer prognosis. Smoking cessation is an integral part of LC survivorship by improving both cancer and non-cancer outcomes. To enhance survivorship education, clinicians should understand patient awareness of the harms of continued smoking. Method: LC survivors from Princess Margaret Cancer Centre, Toronto (2014-2017) were surveyed with respect to self-awareness of the harms of continued smoking on cancer-related outcomes. Univariable and multivariable logistic regression models assessed factors associated with awareness and whether awareness was associated with cessation of smoking. Result: Of 553 patients, 181 were living with their LC diagnosis who were surveyed. 37% of patients were ever-smokers. Among those who were surveyed after their diagnosis period (n=177), 65% quit after diagnosis. Among all, few patients were aware that smoking negatively impacts treatment-related outcomes [complications from cancer surgery (only 41% aware), radiation side-effects (30%), quality-of-life on chemotherapy (44%) and treatment efficacy (36%)]. Half were aware that smoking negatively impacts cancer prognosis (51% aware) and risk of developing secondary primaries (50%). Compared to ex-smokers/current-smokers at diagnosis, current smokers at diagnosis were less aware of the impact of smoking on radiation side-effects (22% vs 31% aware, P=0.01), prognosis (44% vs 55%, P=0.02) and risk of secondary primaries (42% vs 55%, P=0.007). Among sociodemographic variables, only those speaking English at home were consistently more likely unaware that smoking negatively impacts these outcomes (OR=1.52-2.20, P<0.04). Patients with early stage disease were more likely unaware that smoking negative impacts radiation side-effects (OR=1.60, 95%CI[1.09-2.35], P=0.02); while patients on curative treatment (OR=1.53[1.08-2.17], P=0.02) and those exposed to second-hand smoke (SHS) were more likely unaware that smoking impacts quality-of-life on chemotherapy (OR=1.64[1.05-2.58], P=0.03). Exposure to SHS, treatment intent and stage were not associated with awareness of impact on prognosis or secondary primaries (P>0.11). Among smokers in the peri-diagnosis period, awareness of the impact of smoking on surgical complications (aOR=2.09 [0.96-4.54], P=0.06), quality-of-life while receiving chemotherapy (aOR=2.60[1.7-5.79], P=0.02) and on treatment efficacy (aOR =2.24[0.97-5.20], P=0.06) were each associated with subsequent smoking. Multivariable analyses demonstrated that smoking status, pack-years, self-rated health and SHS exposure. Conclusion: Many LC patients are unaware of the harms of continued smoking on cancer outcomes, particularly those smoking at diagnosis. Awareness of some of these outcomes was associated with subsequent tobacco cessation. Patient education on the harms of continued smoking may increase quit rates and improve outcomes for LC patients.

MA18 MODELLING, DECISION-MAKING AND POPULATION-BASED OUTCOMES TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00
MA18 MODELLING, DECISION-MAKING AND POPULATION-BASED OUTCOMES TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA18.09 PREDICTORS OF HEALTH UTILITY SCORES (HUS) IN ADVANCED EGFR-MUTATED NSCLC.
1Dept of Medical Oncology and Haematology, Princess Margaret Cancer Centre, Toronto/ON/CA, 2AstraZeneca Canada, Toronto/CA, 3Princess Margaret Cancer Centre, Toronto/ON/CA, 4Institut Universitaire de Cardiologie Et de Pneumologie de Quebec, Division of Respiriology and Thoracic Surgery, Quebec/CA, 5Department of Medical Oncology and Haematology, Princess Margaret Cancer Centre, Toronto/CA

Background: Advanced NSCLC patients with EGFR mutations (EGFRm) are currently treated with first - to third-generation tyrosine kinase inhibitors (TKIs). In the advanced setting, quality of life is an important goal; therefore we evaluated determinants of HUS in this population.

Method: In a prospective, observational study, patients with advanced EGFRm NSCLC completed EQ-SD surveys at outpatient visits generating HUS (range 0-1). Patients were allowed to enrol at any point in their disease course. Baseline clinical characteristics and outcome data were extracted from chart review. Patient imaging was reviewed and health states (stable/progressing) at each encounter recorded. Univariable analyses conducted using ANOVA and multivariable regression analyses with generalized estimating equations identified factors associated with HUS. Result: From November 2014 to July 2017, 782 encounters (follow-up visits) were collected for 244 patients. Median age at first encounter was 64 years (range:29-96); 54% were female and 54% Asian. Median time from diagnosis of stage IV NSCLC to first encounter was 23 months (range:0-67). The median number of HUS collected per patient was 2 (range:1-34). For patients with multiple visits the median time between completed questionnaires was 1.8 months (1-18). 105 patients (43%) presented with or developed brain metastases during the study period. In a univariable analysis, regardless of treatment line, mean HUS (mHUS) on osimertinib was 0.85 (standard deviation (SD): 0.15) (n=33 patients; 114 encounters) compared to mHUS = 0.80 (SD: 0.17) on gefitinib (n=147, 351 encounters); mHUS = 0.72 (SD: 0.16) on chemotherapy (n=32, 76 encounters); and mHUS = 0.79 (SD: 0.15) on other TKIs (n=49, 133 encounters); p<0.001. In a multivariable analysis, disease progression (p=0.04) and ECOG performance status >0 (p=0.001) were associated with lower HUS. In contrast, treatment with osimertinib (when compared to a reference group of first-generation TKIs, gefitinib/erlotinib) was associated with improved HUS (p<0.01), while line of therapy and number of metastatic sites of disease were not associated with HUS. In addition, brain metastases had no significant impact on HUS (p=0.33).

Conclusion: Progressive disease and worse performance status associate with lower HUS in patients with EGFRm NSCLC. Patients treated with osimertinib had the highest HUS when compared with a reference group of first-generation EGFR TKIs regardless of line of therapy. These results may help in the choice of EGFR-TKI, especially in patients with a poor performance status.

MA18 MODELLING, DECISION-MAKING AND POPULATION-BASED OUTCOMES TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA18.10 EVOLVING IMMUNOTHERAPY PRACTICE PATTERNS IN ADVANCED NSCLC: ANALYSIS OF AN ONLINE TREATMENT DECISION TOOL
D. Gandara1, T. Quill1, M. Edelman3, S. Ramalingam4, H. Wakelee1, H. (.
1Division of Hem-Oncology, UC Davis Comprehensive Cancer Center, Sacramento/CA/US, 2Clinical Care Options, Reston/VA/US, 3Fox Chase Cancer Center Philadelphia/US, 4Medical Oncology, Emory University Winship Cancer Institute, Atlanta/US, 5Medicine (Oncology), Stanford Cancer Institute/stanford University, Stanford/CA/US, 6Swedish Cancer Institute, Seattle/WA/US

Background: Checkpoint immunotherapy (IO) is revolutionizing NSCLC therapy. We have previously published results of an online decision support tool designed to provide clinicians with education and expert guidance (Chow et al: JTO 2015). Here we present a recently updated version of this online tool, capturing the impact of emerging IO options. Method: From June 2016 to July 2017, the NSCLC decision tool was updated to incorporate new treatment options for 280 different case scenarios. Briefly, oncologists entered patient and disease characteristics and then their planned treatment into the tool. Afterwards recommendations from 5 lung cancer experts were provided for that specific patient scenario. Result: This analysis includes 1481 individual cases entered by 863 practicing oncologists between June 2016 and April 2018 (USA 19%, Europe 33%, Rest of World 48%). During this time, treatment choices for EGFR and ALK cancers by oncologists closely resemble those of experts. After approval of 1st-line pembrolizumab for patients with high PD-L1 expression, oncologists recommended pembrolizumab less often than experts (67% vs 95%). In the 2nd-line setting following platinum chemotherapy, both tumor histology and PD-L1 expression level impacted treatment recommendations (see Table). For PD-L1 expression < 1%, recommendations between oncologists and experts differed substantially.

Second-line setting after platinum chemotherapy

Conclusion: This updated analysis of an online NSCLC decision-making tool integrates recent changes to the treatment landscape in 2017, capturing emerging patterns in IO therapy. Compared to earlier versions, practicing oncologist’s choice of 1st-line EGFR- and ALK- targeted therapy more closely tracked with experts during this period, while selection of IO differs from expert recommendations. A detailed analysis of expert versus online user data will be presented.

MA18 MODELLING, DECISION-MAKING AND POPULATION-BASED OUTCOMES TUESDAY, SEPTEMBER 25, 2018 - 13:30-15:00

MA18.11 IMPLEMENTING A COMPREHENSIVE NATIONAL AUDIT OF LUNG CANCER SURGERY: THE ENGLISH NATIONAL LUNG CANCER CLINICAL OUTCOMES PUBLICATION (LCCOP) PROJECT
D. West1, R. Page1, N. Navani2, S. Harden1, A. Khakwani1, R. Hubbard1, P. Beckett1
1The Society for Cardiothoracic Surgery, London/GB, 2The Royal College of Physicians of London, The National Lung Cancer Audit, London/GB, 3Clinical Effectiveness and Evaluation Unit, Royal College of Physicians of London, London/GB, 4Department of Epidemiology and Public Health, University of Nottingham, Ng Pb/GB, 5Department of Epidemiology and Public Health, University of Nottingham, Nottingham/GB, 6Division of Respiratory Medicine, Derby Teaching Hospital NHS Foundation, Derby/GB

Background: We report the establishment of a national audit of outcomes after lung cancer resection (LCCOP) in the English National Health Service (NHS), a government healthcare system providing the great majority of lung cancer surgery. LCCOP is a compulsory audit commissioned by NHS England. Method: Unusually, for a surgical audit, data is initially obtained from the cancer registry, and matched to national Hospital Episode Data (HES), before local validation by clinical teams. After case mix adjustment, unit level survival rates at 30, 60 and 90 days, and length-of-stay data are published online and in an annual report. The first annual report was released in 2014. Survival is adjusted for age, sex, performance status, stage, laterality, FEV1 percentage, comorbidity and socioeconomic status Result: The number of resections rose by 21% between 2015-2017 (4892 to 5936). Median annual activity per surgeon rose from 30 to 49 cases and, length-of-stay data are published online and in an annual report. The first annual report was released in 2014. Survival is adjusted for age, sex, performance status, stage, laterality, FEV1 percentage, comorbidity and socioeconomic status. The number of resections rose by 21% between 2015-2017 (4892 to 5936). Median annual activity per surgeon rose from 30 to 49 cases and, length-of-stay data are published online and in an annual report. The first annual report was released in 2014. Survival is adjusted for age, sex, performance status, stage, laterality, FEV1 percentage, comorbidity and socioeconomic status. The number of resections rose by 21% between 2015-2017 (4892 to 5936). Median annual activity per surgeon rose from 30 to 49 cases and, length-of-stay data are published online and in an annual report. The first annual report was released in 2014. Survival is adjusted for age, sex, performance status, stage, laterality, FEV1 percentage, comorbidity and socioeconomic status. The number of resections rose by 21% between 2015-2017 (4892 to 5936). Median annual activity per surgeon rose from 30 to 49 cases and, length-of-stay data are published online and in an annual report. The first annual report was released in 2014. Survival is adjusted for age, sex, performance status, stage, laterality, FEV1 percentage, comorbidity and socioeconomic status.
Conclusion: Using routinely collected NHS activity data for surgical audit is feasible, and reduces the data collection burden for hospital teams. Clinical validation remains important to correct discrepancies. Surgical activity has risen significantly. Increases in individual surgeon case volume may reflect increasing subspecialisation. Significant inter-provider variation remains, particularly in length of stay. More lung cancer surgery is being done in the English NHS. Surgeons are increasingly subspecialising, with higher case volumes. Local variation remains, particularly around length of stay. A mixed model of routinely collected data with local validation appears acceptable to clinical units.

Keywords: Surgery, audit, outcomes

MA19 GENOMIC MARKERS OF IO RESPONSE
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA19.01 EFFICACY AND GENOMIC CORRELATES OF RESPONSE TO ANTI-PD1/PD-L1 BLOCKADE IN NON-SMALL CELL LUNG CANCERS HARBORING TARGETABLE ONCOGENES
N. Vokes1, E. Jimenez Alguilar2, A. Adeni3, R. Umerton1, L. Sholl1, H. Rizvi1, M. Hellmann1, M. Awad1, E. Van Allen1
1 Dana Farber Cancer Institute, Boston/US, 2 University Hospital 12 de Octubre, Madrid/ES, 3 Pathology, Brigham and Women's Hospital, Boston/MA/US, 4 Memorial Sloan Kettering Cancer Center, New York/US, 5 Broad Institute, Cambridge/US

Background: Immune-checkpoint inhibitors (ICIs) are associated with improved outcomes in a subset of patients with advanced non-small cell lung cancer (NSCLC). NSCLCs with targetable oncogenes are thought to be less responsive to ICI therapy, possibly due to associations with never-smoking status and reduced tumor mutational burden (TMB), but this has not been comprehensively characterized. We evaluated the responsiveness of NSCLCs with targetable oncogenes to ICIs, and if mutation type or TMB influence response. Method: Clinicopathologic, radiographic response, and sequencing data for patients with advanced NSCLC treated with ICI therapy was acquired from two separate cohorts (DFCI Oncopanel, n=296; MSKCC MSK-IMPACT, n=202). Durable clinical benefit (DCB) was defined as responsive/stable disease > 6 months. Samples with activating mutations in EGFR, ALK, ROS, BRAF, MET, and RET were identified. TMB was calculated as the sum of nonsynonymous mutations divided by the coding region captured in each panel. Objective response rates (ORR), DCB, and TMB were compared in targetable oncogene positive (TOP) vs oncogene negative (TON) patients. TMB response rates (ORR), DCB, and TMB were compared in targetable mutations divided by the coding region captured in each panel. Objective response rates (ORR), DCB, and TMB were compared in targetable oncogene positive (TOP) vs oncogene negative (TON) patients. TMB response rates (ORR), DCB, and TMB were compared in targetable mutations divided by the coding region captured in each panel. Objective response rates (ORR), DCB, and TMB were compared in targetable mutations divided by the coding region captured in each panel.

Result: Targetable oncogenes were identified in 16% (419/2614) of patients: 44% (96/219) EGFR, 15% (34) MET exon 14 splice site mutated, 8% (23) BRAF V600E, 6% (11) ROS1 rearranged, 5% (1) ALK rearranged, and 4% (1) RET rearranged. Response to ICIs was similar in TOP vs TON patients, with ORR of 18% and 20%, and median PFS of 2.7 vs 2.8 months in TOP vs TON patients respectively. Among TOP patients, response rates differed by mutation type: ORR rate was 11% (5/44) in EGFR mutated, 40% (6/15) in MET mutated, 25% (2/8) in BRAF mutated, 33% (2/6) in ROS1 rearranged, and 0% in RET and ALK rearranged cancers (0/4, 0/5 respectively). Compared to WT, TMB was lower in TOP tumors (OncoPanel median 9 vs 11, p=0.0064; IMPACT median 4 vs 8, p=0.256-0.6). TMB did not correlate with objective response or DCB in TOP tumors when considered collectively or by mutation type (OncoPanel median TMB 10 vs 8 in DCB vs NDB, p=0.52; IMPACT median TMB 3 vs 5 in DCB vs NDB, p=0.31)[Mann-Whitney U for all]. Conclusion: Despite lower TMB in oncogene positive NSCLC, these patients still derive clinical benefit from ICIs. ICI responsiveness is likely mutation specific, and is most pronounced in MET and BRAF mutated cancers. Among targetable oncogene positive NSCLC, TMB did not distinguish benefit. Taken together, low TMB in the presence of oncogenic driver mutations should not preclude ICI therapy.

MA19.02 PRIOR THERAPY AND INCREASED EXPRESSION OF PD-L1 IN NSCLC TUMOR SAMPLES
A. Boothman1, M. Scott1, M. Ratcliffe1, J. Whiteley1, P. Dennis2, C. Wadsworth3, A. Sharpe1, N. Rizvi2, M. Garassino5, J. Walker1
1 Astrogenesa, Cambridge/GB, 2 Astrogenesa, Gaithersburg/MD/US, 3 Astrogenesa, Macclesfield/GB, 4 Columbia University Medical Center, New York/NY/US, 5 Fondazione IRCCS Istituto Nazionale Dei Tumori, Milano/IT

Background: Tumor PD-L1 expression has been shown to enrich for response to immunotherapy in several indications, including advanced NSCLC. However, the stability of PD-L1 expression over time and its relationship with non-immunotherapy cancer treatment is currently uncertain. We hypothesized that prior chemotherapy or radiotherapy would increase PD-L1 expression. Method: In the Phase 2, open-label, single-arm durvalumab ATLANTIC study (NCT02087423), patients who had received ≥ 2 prior systemic regimens in the treatment of Stage IIIIB or IV NSCLC were screened for tumor PD-L1 expression by immunohistochemistry using the VENTANA PD-L1 (SP263) Assay (25% tumor cell [TC] cutoff). PD-L1 expression was assessed using either a recent (<3 months) or archival sample; a subset of patients provided both. The relationship between non-immunotherapy cancer treatment and prevalence of tumor PD-L1 expression ≥25% (TC ≥25%) was assessed in patients who received therapy prior to sample acquisition versus those who did not. Pearson's chi-squared test was used to examine the differences between patient subgroups. Result: Of the patients screened for participation in ATLANTIC, 1590 were successfully assessed for PD-L1 expression. PD-L1 TC ≥25% prevalence was higher in patients who had received prior radiotherapy or chemotherapy before sample acquisition, with prevalence noticeably higher in those who had received ≥2 lines of prior chemotherapy. Prior EGFR inhibitor treatment did not have any noticeable relationship to TC ≥25% prevalence (Table). In the subset of patients with paired recent and archival samples, TC ≥25% prevalence remained the same in 74% of cases, increased over time in 19.5%, and decreased in 6.5%.

Conclusion: PD-L1 expression may increase in response to chemotherapy or radiotherapy and is unlikely to decrease over time. Re-biopsy may provide a more accurate assessment of current tumor PD-L1 expression status, when a low/negative result is seen in an archival sample, particularly if the patient has received multiple lines of intervening radiotherapy or chemotherapy.

### MA19.04 THE CLINICAL IMPLICATION OF FRAMESHIFT INDEL MUTATION BURDEN IN NON-SMALL CELL LUNG CANCER (NSCLC)

Y.K. Chae1, W. Park2, D. Saravia3, V. Florou1, S. Chang1, S. Wang1, L. Chieo2, A. Rahbari1, N. Mohindra3, V. Villalflor1, L. C. Park4, G. Lopes5

1Northwestern University, Chicago/IL/US, 2Sylvester Comprehensive Cancer Center, University of Miami, Miami/US

**Background:** Tumor mutational burden (TMB) has been proposed as a potential predictive marker for immune checkpoint inhibitor (ICI) response in many cancers, including NSCLC. Recently, research has revealed frameshift indel (fsindel) of all mutations to be significantly associated with ICI response in melanoma patients. However, little is currently known regarding its clinical implication in NSCLC patients treated with PD1/ PD-L1 inhibitors (ICIs). **Method:** Next generation sequencing of 324 genes (FoundationOne™) was used to derive fsindel burden and TMB. A total of 128 patient data with NSCLC treated with ICIs were analyzed from Northwestern University (N=68) and the University of Miami (N=60). A total of 128 patients were divided into two groups with 0 fsindel (FS-) and more than 1 fsindel (FS+). Progression free survival (PFS) and overall survival (OS) were compared between FS+ and FS- groups. PFS and OS outcomes of TMB high group (H-TMB, upper¼) and TMB low group (L-TMB, lower¼) were also compared. **Result:** Among 128 patients, 51.6% belonged to FS+ group (N=66). Between FS/- FS+ groups, there were no significant differences in mean age (66.2/66.0) and performance status (0.9/0.9). Lines of ICIs used in the FS-/FS+ groups were 1st (19/19%), 2nd (47/56%), 3rd (24/11%), and 4th line or more (10%). FS+ group had significantly longer PFS compared with FS-group (median 6.2/2.7 months, P<0.02, Figure 1). No significant difference in OS was seen between the two groups (median 16.8/11.2 months, P>0.70). In contrast, however, H-TMB did not show any significant difference in PFS (median 5.6/4.0 months, P=0.14) and OS (median 15.8/15.1 months, P=0.69) compared to L-TMB. **Conclusion:** This is the first report to illustrate an association between fsindel and outcome in patients with NSCLC treated with ICIs. Our findings suggest its potential role as a predictive marker for immunotherapy.

**Keywords:** NSCLC, frameshift indel, immuno checkpoints inhibitor

### MA19.05 DIFFERENCE OF TUMOR MUTATIONAL BURDEN IS ASSOCIATED WITH DISTINCT IMMUNE MICROENVIRONMENT IN THE T CELL-INFLAMED LUNG ADENOCARCINOMA

T. Karasaki1, K. Kitano2, K. Nagayama3, J. Nitadori1, M. Sato1, M. Anraku1, K. Kasmii2, J. Nakajima3

1Thoracic Surgery, Graduate School of Medicine, the University of Tokyo, Tokyo/JP, 2Immunotherapeutics, The University of Tokyo Hospital, Tokyo/JP

**Background:** PD-L1 expression on tumor cells, tumor infiltrating lymphocytes (TILs), and tumor mutational burden (TMB) have been reported as predictive biomarkers for checkpoint inhibitor immunotherapies. However, little is known about the relationship between each biomarkers. The aim of this study was to assess the relationship between these biomarkers, especially TIL and TMB. **Method:** RNA-seq data of 533 primary lung adenocarcinoma were downloaded from The Cancer Genome Atlas (TCGA). Gene expression and gene set enrichment analysis were performed. Clinical information and somatic missense mutation data were also integrated. **Result:** Weak correlation between PD-L1 and CD8A expression (Spearman’s R=0.32, P<0.001), and PD-L1 expression and TMB (R=0.10, P=0.19) were seen, but not between CD8A expression and TMB (R=0.03, P=0.45). Next, we performed gene signature analysis related to cancer-immunity cycle (ref. Karasaki et al. J Thorac Oncol 2017). Hierarchical clustering resulted in 3 clusters: T cell non-inflamed phenotype with high antigenicity (Cluster 1), inflamed phenotype with low antigenicity (Cluster 2), and inflamed phenotype with high antigenicity (Cluster 3). (Figure 1) Compared with Cluster 3, Cluster 2 was featured by lower gene expression signature of cytolytic activity (P<0.0001, U-test), as well as lower expression of PD-L1 (P<0.0001, U-test). To further investigate the relationship between TMB and TILs, T-cell inflamed phenotype tumors were divided into four groups according to the quartiles of TMB. We estimated immune cell phenotypes of TMB-high (upper quartile) and TMB-low (lower quartile) groups using ssGSEA and CIBERSORT. Either analysis showed significant enrichment of activated CD4 T cells in TMB-high group (P<0.0001, T-test). **Conclusion:** Existence of Cluster 1 and 2 suggested that tumor antigenicity (TMB) does not necessarily correlate with TIL enrichment. Tumor-low tumors may form T-cell-inflamed tumors (Cluster 2), although the immune status may differ from TMB-high inflamed tumors (Cluster 3). Integrating multiple biomarkers for the assessment of tumor immune microenvironment is important for optimal immunotherapy.

### MA19.06 BLOOD BASED BIOMARKERS: RNA, KRAS AND PD-L1 STRONGLY MATCHING WITH TISSUE AND SHOWING CORRELATION WITH CLINICAL RESPONSES IN NSCLC PATIENTS

L. Raez1, J. Usher2, C. Habaue3, K. Danenberg4, B. Hunis1, Y. Jaimes2, S. Rabizadeh1, A. Castrellon1, P. Danenberg4

1Memorial Cancer Institute/florida International University, Pembroke Pines/FL/US, 2Liquid Genomics/nanth Health, Torrance/US, 3Memorial Cancer Institute, Pembroke Pines/FL/US, 4University of Southern California, Los Angeles/US

**Background:** Circulating cell-free tumor RNA (cfRNA) can be now safely isolated as cfDNA and used to measure changes in the tumor burden in the blood and changes in gene expression in non-small cell lung cancer (NSCLC) patients (pts). We are correlating these changes in cfRNA and PD-L1 with clinical response to therapy (chemotherapy, immunotherapy (IMMUNO) or targeted therapy) in stage IV NSCLC pts. Our group has been the first one to use cfRNA to detect PD-L1. **Method:** Blood was drawn from 31 pts under various treatments (tx) every 6-8 weeks, at the same time that CT scans were done. cfRNA was extracted from the resulting plasma and reverse transcribed with random hexamers to cDNA. Levels of cfRNA were quantitated by RT-qPCR and correlated with pts clinical response (CR/PR/SR/PD), as determined by CT scans. **Result:** A total of 31 lung cancer pts were enrolled in a 2-year clinical study. 25 of 31 pts completed already the first two cycles of tx and had CT scans done. Of these, 6/8 pts with progressive disease (PD) showed increased (INC) levels of cfRNA, 9/13 pts with stable disease (SD) showed either no change (NC) or decreased (DEC) cfRNA, and 4/4 pts with partial response (PR) had NC or DEC cfRNA, corresponding to 76% concordance between cfRNA and clinical responses. PD-L1 expression measured in plasma cfRNA matched the tissue expression in 7/10 pts. In the one pt where
PD-L1 was (-) in blood and (+) in tissue there was PD on IMMUNO. Among 8 pts treated with IMMUNO, 3/3 pts with PD showed INC PD-L1 cDNA expression, 3/3 pts with SD had NC in negative PD-L1 status, and 2 pts with PR showed DEC PD-L1 cRNA, corresponding to 100% correlation between PD-L1 expression levels and pt response. Of the 31 pts, 32% (10/31) harbored KRAS mutations in cDNA. Of those with KRAS+ status by tissue-based testing, 83% matched with cDNA results. Among KRAS+ pts, 80% (8/10) showed PD-L1 cDNA expression in same blood draws with KRAS+ cDNA, suggesting correlation between these cDNA and cRNA analyses. Conclusion: Significant association was observed between clinical response and changes in plasma cRNA levels in NSCLC pts (76%). There was concordance between tissue- and blood-based testing in both DNA (KRAS mutations, 83%) and RNA (PD-L1 expression, 70%). While on IMMUNO levels of PD-L1 expression could be used to monitor response to immunotherapy.

Keywords: PD-L1, cRNA, NSCLC

MA19 GENOMIC MARKERS OF IO RESPONSE TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA19.08 DETECTION OF PRIMARY IMMUNOTHERAPY RESISTANCE TO PD-1 CHECKPOINT INHIBITORS (PDICI) IN 2ND LINE NSCLC J. Aerts1, E. Smit2, M. Muller2, A. Niemeijer2, C. Oliveira4, H. Rodier4, J. Roder4
1Erasmus MC, Rotterdam/NL, 2NKI, Amsterdam/NL, 3YU Medical Centre, Amsterdam/NL, 4Biosieux, Boulder/US

Background: PDICI are capable of restoring immunity, but some patients do not benefit. While molecular tests like PD-L1 expression and TMB help in enriching response in respective subsets, a test identifying patients showing primary resistance to PDICI which does not require tissue samples could aid in optimizing treatment regimens. Method: Sophisticated mass spectrometry profiling data from a development set (S) of pre-treatment serum from 116 2nd line NSCLC patients treated with nivolumab were correlated with outcome data (PFS/OS) using multivariate and classification techniques related to deep learning. The resulting test stratified patients into three groups: group A having very poor outcomes, group B having intermediate outcomes, and group C having very good outcomes. Development results were obtained using out-of-bag estimators. Two additional patient cohorts treated with nivolumab were correlated with outcome data (PFS/OS) using out-of-bag estimators. Result: The proportions of patients in A, B, and C were 41:43:32 in S, 23:18:71 in V1, and 32:19:24 in V2. Median PFS/OS in the poor prognosis group A was 43/132 days in S, 105/189 days in V1, 90/278 days in V2, and in the good prognosis group c 276/528 days in S, 192/459 days in V1, and 155/ not reached days in V2. In a comparison with historical controls treated with single agent chemotherapy and analyzed with the same technique, nivolumab appeared substantially superior in the good prognosis group C, while there was no evidence of superiority in the poor prognosis group A. In multivariate analysis including performance status, smoking history, and histology, the test remained an independent predictor of outcome. The patterns of protein expression related to poor prognosis in group A were associated with elevated complement activation, coagulation, and acute phase reactants. Conclusion: We developed and validated a test stratifying patients into three groups with significantly different outcomes on nivolumab. The poor prognosis group showed little benefit from nivolumab, and other treatments may be needed, while in the good prognosis group outcomes were very good for a 2nd line population. Our results emphasize the important role of the host immune response in the prediction of PDICI efficacy. Data on PD-L1 IHC from these cohorts will be included in the multivariate analysis and presented at the meeting.

MA19 GENOMIC MARKERS OF IO RESPONSE TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

Memorial Sloan Kettering Cancer Center, New York/NY/US

Background: Targeted next generation sequencing (NGS) testing for lung cancer patients identifies recurrent patterns of co-mutations. STK11 is known to be associated with poor outcomes with immunotherapy. We have identified that STK11 is commonly co-mutated with KEAP1, but the impact of this pattern of co-mutation on response to immunotherapy is not known. Method: We identified 308 patients with advanced lung cancer treated at Memorial Sloan Kettering Cancer Center who underwent NGS testing with the IMPACT panel and received at least one dose of PD-(L)1 inhibitor. Progression free survival (PFS) and overall survival (OS) from treatment initiation of PD-(L)1 blockade were calculated using Kaplan-Meier methodology and compared using logrank method and t-test for continuous variables. Result: In a cohort of 308 patients with NSCLC treated with PD-(L)1 blockade, STK11 or KEAP1 mutations occurred frequently (23% and 22% respectively) and concurrent STK11 and KEAP1 mutations (STK11mut/KEAP1mut) were common (56% of all STK11 and KEAP1 mutant patients among 13% of all lung cancers). Fisher’s test of association p<0.0001. Other common co-mutations with STK11 included KRAS (50%) and TP53 (48%). STK11mut/KEAP1mut patients had higher TMB than STK11wt/KEAP1wt patients (median 9.4 vs 6.1, Mann-Whitney p=0.0002). STK11mut/KEAP1mut (n=39) patients had diminished PFS and OS compared to patients with STK11wt/KEAP1wt (n=210) (n=0.5, p=0.02: OS HR 2.3, p<0.001). As context, outcomes in STK11mut/ KEAP1mut patients were similarly poor to EGFR mutant patients (n=28) treated with PD-(L)1 blockade (PFS p=0.7) despite substantially different tumor mutation burden (9.4 vs 4.9 mut/Mb, p<0.0001). Among STK11mut/KEAP1mut patients, poor outcomes were unchanged irrespective of KRAS status (PFS p=0.8, OS p=0.5). Patients with mutations in STK11 alone (n=31) or KEAP1 alone (n=28) had outcomes that more closely mirrored STK11wt/KEAP1wt patients (PFS p=0.9 and 0.1 respectively, OS p=0.1 and 0.2 respectively). Conclusion: KEAP1 plus STK11 co-mutation is a common event in NSCLC that is distinctly associated with poor outcomes with PD-(L)1 blockade despite otherwise favorable molecular features.

Anderson Cancer Center, Houston/TX/US, 2Quantitative Research Computing, The University of Texas MD Anderson Cancer Center, Houston, TX/US, 3Dep. of Biostatistics, MD Anderson Cancer Center, Houston/US, 4Thoracic and Cardiovascular Surgery, MD Anderson Cancer Center, Houston/TX/US, 5Thoracic and Cardiovascular Surgery, The University of Texas MD Anderson Cancer Center, Houston/US

Background: Chemo-immunotherapy with pemetrexed/carboplatin/ pembrolizumab represents a standard of care for the first-line treatment of patients with metastatic non-squamous NSCLC, irrespective of tumor cell PD-L1 expression. Genomic determinants of response to chemo-immunotherapy in NSCLC have not been reported thus far. We previously identified STK11/LKB1 alterations as a major genomic driver of de novo resistance to PD-1/PD-L1 inhibitor monotherapy in NSCLC (Skoulidis et al., Cancer Discovery, 2018). Here, we examine the impact of STK11/ LKB1 mutations on clinical outcomes with chemo-immunotherapy with pemetrexed/carboplatin/pembrolizumab. Method: Patients with metastatic non-squamous NSCLC that received at least 1 cycle of pemetrexed/carboplatin/pembrolizumab at MD Anderson Cancer Center, were alive for ≥14 days thereafter and had available next generation sequencing- based comprehensive tumor genomic profiling were eligible. Results assessment was based on RECIST1.1. PD-L1 expression on tumor cells was evaluated using the FDA-approved 22C3 pharmDx assay. All patients consented to collection of clinical and molecular data as part of the GEMINI protocol. Result: Among 49 eligible patients (median age 61 years, 51% female, 96% adenocarcinoma histology, 34.7% STK11/LKB1-mutant) the objective response rate to pemetrexed/carboplatin/ pembrolizumab was 51% (25/49) for the overall population. The disease control rate (PR+SD: 6 months) differed significantly between STK11/ LKB1-mutant and STK11/LKB1-wild-type patients (P=0.13, Fisher’s exact test). The objective response rate was 31.3% for STK11/LKB1-mutant and 60.6% for STK11/LKB1 wild-type tumors (P=0.07, two-tailed Fisher’s exact test). 37.5% (6/16) of STK11/ LKB1-mutant tumors exhibited progressive disease as best overall response to chemo-immunotherapy compared with 6.1% (2/33) STK11/LKB1 wild-type tumors (P=0.011, two-tailed Fisher’s exact test). The objective response rate was 31.3% for STK11/LKB1-mutant and 60.6% for STK11/LKB1 wild-type tumors (P=0.07, two-tailed Fisher’s exact test). 37.5% (6/16) of STK11/LKB1-mutant tumors exhibited progressive disease as best overall response to chemo-immunotherapy compared with 6.1% (2/33) STK11/LKB1 wild-type tumors (P=0.011, two-tailed Fisher’s exact test). Patients bearing STK11/LKB1-mutant tumors exhibited shorter progression- free survival with chemo-immunotherapy (median PFS 4.4 months vs 11.3 months), P=0.039, log-rank test). STK11/LKB1-mutant tumors were less likely to be positive for PD-L1 expression (PD-L1 TPS ≥ 1%), although the difference did not reach statistical significance (43.8% vs 72%, P=0.1, two-tailed Fisher’s exact test). Conclusion: STK11/
MA20 IMPLEMENTATION OF LUNG CANCER SCREENING
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA20.01 LUNG CANCER SCREENEE SELECTION BY USPSTF VERSUS PLCOm2012 CRITERIA – PRELIMINARY ILST FINDINGS

1Health Sciences, Brock University. St. Catharines/ON/CA, 2Integrative Oncology, British Columbia Cancer Agency, Vancouver/MB/CA, 3Lungs for Living Research Centre, UCL Respiratory, University College London, London/GB, 4Division of Respiratory Medicine and Childhood Lung Research Centre, University of Calgary, Calgary/CA, 5Integrative Oncology, BC Cancer Research Centre, Vancouver/ BC/CA, 6Health Behaviour Research Centre, University College London, London/GB, 7Thoracic Medicine, Homerton University Hospital, London/Gb, 8Medical Imaging, Alberta Health Services, Calgary/CA, 9Medicine, University of Calgary Cumming School of Medicine, Calgary/CA, 10Surgery, University of Alberta, Edmonton/CA, 11Thoracic Surgery, Vancouver Cancer Centre Health, Vancouver/CA, 12Radiology, University of British Columbia, Vancouver/CA, 13Integrative Oncology, British Columbia Cancer Agency. Vancouver/BC/CA, 14Department of Thoracic Medicine, University of Queensland Thoracic Research Centre at the Prince Charles Hospital, Brisbane/AU, 15Integrative Oncology. British Columbia Cancer Research Centre, Vancouver/BC/CA

Background: The National Lung Screening Trial showed that lung cancer screening of high-risk individuals with low dose computed tomography can reduce lung cancer mortality by 20%. Critically important is enrolling high-risk individuals. Most current guidelines including the United States Preventive Services Task Force (USPSTF) and Center for Medicare and Medicaid Services (CMS) recommend screening using variants of the NLST eligibility criteria: smoking ≥ 30 pack-years, smoking within 15 years, and age 55–80 and 55–77 years. Many studies indicate that using accurate risk prediction models is superior for selecting individuals for screening, but these findings are based on retrospective analyses. The International Lung Screen Trial (ILST) was implemented to prospectively identify which approach is superior. Method: ILST is a multi-centred trial enrolling 4000 participants. Individuals will be offered screening if they are USPSTF criteria positive or have PLCOm2012 model 6-year risk ≥ 1.5%.

Result: Participants will receive two annual screenings and will be followed for six years for lung cancer outcomes. Individuals not qualifying by either criteria will not be offered screening, but samples of them will be followed for lung cancer outcomes. Outcomes in discordant groups, USPSTF+ve/PLCOm2012-ve and USPSTF-ve/PLCOm2012+ve, are informative. Numbers of lung cancers, abnormal suspicious for lung cancer scans (a marker of future lung cancers) and individuals enrolled, and sensitivity and specificity and positive predictive values of the two criteria will be compared. Result: As of March 2018, ILST centers in Canada (British Columbia and Alberta), Australia, and the United Kingdom had enrolled and scanned 1938 individuals. Study results are summarized in Figure 1.

Figure 1. ILST Interim Results (N = 1938)

The proportion of lung cancers in PLCOm2012+ve individuals was 15.9% higher than in those who were USPSTF+ve (2.31% vs. 2.01%, p<0.14).

The proportion abnormal suspicious for lung cancers scans in the PLCOm2012+ve were 11.3% higher than detected in those who were USPSTF+ve (9.83% vs. 8.86%, p<0.15).

Conclusion: Interim analysis of ILST data, suggests that classification accuracy of lung cancer screening outcomes support the PLCOm2012 criteria over the USPSTF criteria. Individuals who are USPSTF+ve and PLCOm2012-ve appear to be at such low baseline risk (0.46%) that they may be unlikely to benefit from screening.

Keywords: risk-based selection, lung cancer screenee selection

MA20.02 "REDUCED" HUNT LUNG CANCER MODEL FOR PREDICTING LUNG CANCER IN THE PROSPECTIVE DANISH LUNG CANCER SCREENING STUDY - COMPARISON WITH THE NLST

O. Reel1, M. Markaki2, I. Tsmardinos3, V. Lagan4, J. Pedersen5, Z. Sabq5, H. Ashraf5
1Clinical Cancer Research Center Department of Clinical Medicine, Aalborg University Hospital, Aalborg/DK, 2Department of Computer Science, University of Crete, Heraklion/GR, 3Foundation for Research and Technology - Hellas (FORTH), Institute of Applied Mathematics Science, Heraklion/GR, 4Gnosis Data Analysis Pc, Heraklion/GR, 5Cardiothoracic Surgery IR 2152, Rigshospitalet, Copenhagen University, Copenhagen/DK, 6Section of Pulmonary Medicine, Department of Medicine, Herlev-Gentofte Hospital, Copenhagen University Hospital, Herlev/DK, 7Department of Imaging, Akershus University Hospital, Oslo/N0

Background: Risk prediction is important for selection of individuals for lung cancer screening programs. We have recently published a validated Lung Cancer Risk Model (https://www. ebiomedicine.com/article/S2352-3964(18)30114-2/fulltext) for all ages and smoking patterns. The Danish Lung Cancer Screening Trial (DL CST) was a randomized prospective study that included 4104 heavy smokers with a median age of 57.6, 33.6 pack-years and maximum 9 years quit time. We tested the value of the HUNT model in this prospective Danish lung cancer study and compared with the NLST.

Method: The DL CST study only had 5 of the 7 variables in the original HUNT Model, so we trained a "reduced" HUNT Model in the Norwegian HUNT2 cohort of 12 091 ever-smokers ages between 49-71 years (as the age span in the Danish cohort) based on age, pack-years, smoking intensity, quit time and BMI where sex was added for adjustment. The model was applied blindly in the 4051 individuals of the Danish cohort that had all 5 variables. Result: In the population selected by the "reduced" HUNT Model, 148/149 (99.33%) lung cancer cases were predicted (sensitivity 99.33%, negative predictive value 99.23%), thus only one individual that developed lung cancer was lost among those 52 not selected for screening. If the the NLST criteria were used (age 55-74, >30 pack-years and <15 years quit time), less than half of the Danish cohort (n=1870) (46.2%) would have been considered eligible for screening, and 104/149 (69.80%) lung cancer cases would have been predicted. With these criteria, one would lose 45 (32.7%) lung cancer cases, and the sensitivity would be lower (69.80%). Conclusion: We were able to predict 99.33% of those that were diagnosed with lung cancer in 10 years, only one future lung cancer case was not included. Therefore, even the "reduced" HUNT model was highly sensitive in selecting persons at high risk for lung cancer in a screening cohort. The objection one could have for preferring the NLST criteria is that one screened about half of this population but at the same time lost 1/3 of the future lung cancers. In a health system that can afford to screen more people than those included by the NLST criteria, the HUNT model may be useful and preferably the validated HUNT Lung Cancer Model, for the selection of high risk individuals to a screening programme.

Keywords: NLST, HUNT Lung Cancer Model, Screening

MA20.03 SURPRISING IMPLICATIONS OF PROPOSED RISK-ThRESHOLDS FOR SELECTING US EVER-SMOKERS INTO CT LUNG-CANCER SCREENING

H. Kattk, C. Berg, A. Chaturvedi, R. Landy, H. Robbins, L. Cheung
Division of Cancer Epidemiology and Genetics, US National Cancer Institute, Rockville/MD/US

Background: Many studies show that using risk-models to select ever- smokers for screening may be more effective and efficient than current US Preventive Service Task Force (USPSTF) guidelines. Current National Comprehensive Cancer Network (NCCN) guidelines permit screening ever-smokers with at least 1.3% 6-year lung-cancer risk. Here we re-evaluate assertions, originally based on pre-2015 or non-representative data, that currently proposed risk-thresholds would screen no more ever-smokers than current USPSTF guidelines and at higher effectiveness and
MA20.06 LUNG CANCER SCREENING PILOT FOR PEOPLE AT HIGH RISK: EARLY RESULTS ON CANCER DETECTION AND STAGING
G. Darlingi, H. Schmidti, M. Yu1, M. Luettschwager2, B. Pylpenko1, T. Patel1, V. Rivera1, K. Pearson1, K. Larson3, M. Tammemagi3
1Division of Thoracic Surgery, University of Toronto, Toronto/ON/CA, 2Medical Imaging, Women's College Hospital, Toronto/ON/CA, 3Cancer Care Ontario, Toronto/ON/CA, 4Brock University, St. Catharines/CA

Background: In June 2017, Cancer Care Ontario initiated organized lung cancer screening for people at high risk for developing lung cancer, using annual low-dose computed tomography (LDCT), at three pilot sites in Ontario. A key indicator of pilot success is detection of lung cancers at early stages. Ontario Cancer Registry (OCR) is used to track lung cancer diagnosis, stage and histology. Method: Patient abstracts were created using Registry Plus CDC abstracting software for pilot participants and patient-level data were collected from hospital data submissions, hospital electronic medical records via remote access, OCR pathology database (emARc) and OCR clinical source records (Resolink). Confirmed lung cancer cases were reviewed by a team of cancer staging analysts to achieve consensus on stage group using AJCC TNM 8th edition. A post-staging review was conducted for all staged cases to ensure accuracy and completeness. Result: As of February 2018, 1086 participants received a baseline LDCT scan. 37% (n=404) of participants had Lung-RADS scores of 1; 45% (n=487) had Lung-RADS2 scores of ≥ 2; 10% (n=112) had Lung-RADS3 scores of 3; and 8% (n=83) had Lung-RADS3 scores of 4A, 4B or 4X, which triggered additional follow-up or diagnostic workup. 18 lung cancers were confirmed and 11 were fully staged. Of the 11 staged cases: 45% (n=5) was stage I; 9% (n=1) stage II; 9% (n=1) stage III; and 36% (n=4) stage IV. This represents a statistically significant increase in the proportion of early stage lung cancers (stage I and II) compared to historical proportions (p<0.05). 73% (n=8) were adenocarcinoma. The median risk score (i.e., PLCOm2012 risk prediction model probability of developing lung cancer in 6 years) was 8.1%, considerably higher than the median risk score of the overall pilot cohort (2.9%). 82% (n=9) had baseline Lung-RADS3 scores of 4X and 18% (n=2) had 4B. The average age at diagnosis was 67, 45% (n=5) were current smokers, and 85% (n=9) had high school education or less. In addition, the screening pilot facilitated the successful transition by the OCR from AJCC TNM 7th to TNM 8th edition in lung cancer staging. Results will be updated in the conference presentation. Conclusion: Early pilot results demonstrate success in detecting early stage lung cancers and a statistically significant stage shift to earlier cancer stages. We anticipate a greater proportion of early stage lung cancers on annual recall LDCT scans. The OCR efficiently enabled capturing important incidence, staging and histological pilot data.

MA20 IMPLEMENTATION OF LUNG CANCER SCREENING TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA20.05 WHO GETS SCREENED FOR LUNG CANCER? A SIMPLE ADJUSTMENT TO CURRENT GUIDELINES TO REDUCE RACIAL DISPARITIES
M. Aldrich1, S. Mercaldo2, K. Sandler2, W. Blot4, E. Grogan1, J. Blume5
1Thoracic Surgery, Vanderbilt University Medical Center, Nashville/TN/US, 2Massachusetts General Hospital, Boston/MA/US, 3Radiology and Radiological Sciences, Vanderbilt University Medical Center, Nashville/TN/US, 4Brock University, St. Catharines/CA, 5American Cancer Society, Atlanta/US

Background: The United States Preventive Services Task Force (USPSTF) recommends low-dose computed tomography screening for lung cancer in current or former smokers age 55-74 with no more than 30 pack-year history. However, the USPSTF guidelines were developed in the predominantly white population of the National Lung Screening Trial and therefore may not be generalizable to African Americans who have different smoking patterns. We evaluated USPSTF lung cancer screening guidelines in a predominantly African American prospective cohort with an elevated incidence of lung cancer. Method: The Southern Community Cohort Study (SCCS) is a prospective observational cohort of approximately 86,000 adults (two-thirds African American) aged 40-79 years enrolled at community health centers from 2002-2009 across 12 Southern U.S. states. Former and current smokers were included in the present study and were followed for up to 9 years. We examined the impact of race and smoking history on eligibility for lung cancer screening using USPSTF guidelines. Result: Among N=50,524 adult (67% African American, 33% white) ever smokers at baseline (64% current smokers, median age 50 years at enrollment) in the SCCS, we identified 1,359 incident lung cancers. Among lung cancer patients, 32% of African Americans were eligible for screening following USPSTF guidelines compared with 55% of whites (p<0.001). The lower percentage of eligible African Americans was primarily due to African Americans having smoked fewer pack-years than whites (14 vs 27 median pack-years, respectively, p<0.001). Lowering the smoking pack-year eligibility criteria to a minimum 20-29 pack-year history, increased the number of African Americans eligible for screening by 38%. With a lower smoking pack-year criterion for African Americans, sensitivity increased from 32% to 50% and specificity decreased from 87% to 78% yielding sensitivity and specificity values that were similar to whites (55% sensitivity, 78% specificity) using the USPSTF guidelines. Conclusion: Current lung cancer screening guidelines are too conservative for African Americans. A greater percentage of African Americans are excluded from screening opportunities primarily due to lower smoking histories. Adjustment of pack-years in lung cancer screening guidelines by race will result in more equitable screening for smokers at high risk for lung cancer.

MA20.07 LUNG CANCER SCREENING FOR LIMITED-RESOURCE PATIENTS: PRELIMINARY FINDINGS FROM A LOW-DOSE CT PILOT PROGRAM
L. Watson, M. Cotter, R. Smith, K. Sharpe
American Cancer Society, Atlanta/US

Background: Low-dose CT (LDCT) screening for lung cancer in adults at high-risk is associated with a reduction in lung cancer mortality in high-risk adults, yet screening rates remain low. Increasing access to high-quality lung cancer screening is critical to further reducing deaths from the disease. In 2015 the American Cancer Society implemented a pilot program to identify successful strategies for improving access to LDCT in Memphis, Tennessee and Charleston, West Virginia through partnerships with Federally Qualified Health Centers (FQHCs) that serve limited resource patients. The program focused on developing systems for FQHCs to identify and refer patients for LDCT, and helping FQHCs build relationships with local accredited screening facilities to deliver lung cancer screening and navigate patients through the screening process and any necessary follow-up. This program is novel because it brings emerging technology in lung cancer screening and early detection...
low-resource FQHCs that typically do not have access to state-of-the-art interventions. As such, the pilot affords important opportunities to illustrate facilitation and barriers to conducting LDCT in under-resourced areas. This presentation focuses on evaluation results for the program to-date, emphasizing barriers to implementation experienced by FQHCs and their screening partners. Method: Participating FQHCs submitted quarterly monitoring reports tracking the number of patients assessed for LDCT eligibility, shared decision-making (SDM) visits, patients screened, and screening results. Evaluators conducted site visits and stakeholder interviews with staff from FQHCs and their screening partners in summer 2017 and 2018 to capture nuanced information about program implementation. Result: Participating FQHCs conducted 387 SDM discussions and have screened 252 patients to date. Participants expressed uncertainty about the definition and process of SDM, and difficulty with tracking and billing for these patient-provider encounters. Through the pilot period, both sites established processes for follow-up screening and referrals based on initial screening results (LRADS 1-4). Interview data provided insight into the major challenges and successes to piloting and implementing a new protocol. Both sites struggled to agree on the correct follow-up for LRADS 3 and 4 patients. Through piloting and discussion with clinic leadership, one site successfully implemented clear, logical follow-up procedures based on staff capacity and clinical guidelines. Conclusion: Our evaluation findings, including key lessons learned and recommendations, will add to the growing knowledge base of effective lung cancer screening practices and may be used to inform and guide health systems looking to initiate similar programs, particularly those in low-resource settings.

MA20.09 IMPROVED LUNG CANCER AND MORTALITY PREDICTION ACCURACY USING SURVIVAL MODELS BASED ON SEMI-AUTOMATIC CT IMAGE MEASUREMENTS

A. Schneider1, C. Jacobs2, N. Lessmann3, E. Scholten1, I. Isgun2, M. Prokop2, C. Schaefer-Prokop1, B. Van Ginneken4

1Radboudumc, Nijmegen/NL, 2University Medical Center Utrecht, Utrecht/NL, 3Medical University of Göttigen, Goettingen/DE, 4Heidelberg University Hospital, Heidelberg/DE

Background: In a lung cancer CT screening setting, imaging biomarkers are typically extracted by experienced human readers. We found that adding semi-automatic computer-aided detection (CAD) measurements to a base model significantly improved lung cancer and mortality risk prediction accuracy. Method: Participants’ baseline CT scans, lung nodule characteristics, and 7-year follow-up outcomes were obtained from the National Lung Screening Trial. The selection included all 1810 deceased and a random selection of 4190 surviving participants from the same screened cohort with an image subset to which the latter subcohort was sampled with replacement up to 24432 to approximate the full CT arm. Seventeen patient characteristics variables endorsed by literature were considered for each model. CAD was used to automatically measure normalized emphysema score, coronary calcium volume, and thoracic aorta calcium volume. Pulmonary nodule consistency, volume, solid core volume (if part-solid), and upper lobe location were annotated by an experienced radiologist with CAD support. Only the largest noncalcified nodule was considered for the model; having no nodules was the reference. Cox proportional hazard regression was performed on patient characteristics variables only (base model) and combined with CAD variables (new model). This was done for three outcomes: lung cancer diagnosis, lung cancer mortality, and overall mortality. The average continuous net reclassification improvements (NRI) between the base and new models were calculated for each year following the baseline scan. To calculate NRI, the net percentages of subjects with and without the event of interest correctly reclassified as high and low risk, respectively, are summed (maximum range: -2 to 2); positive scores indicate that the new model is more accurate. Result: CAD measures were successfully computed for 5575 baseline scans. After sampling, the test cohort consisted of 24370 participants. 3.9% were diagnosed with lung cancer (940/24370) and 6.9% died (1681/24370), of which 24.9% due to lung cancer (418/1681). For all outcomes, the new models were significantly superior to the base model. With lung cancer diagnosis as the outcome, the NRI at 1, 4, and 7 years follow-up were 0.628 (95% confidence interval: 0.373–0.700), 0.331 (0.261–0.390), and 0.349 (0.293–0.389), respectively. The respective AUCs were 0.701 (0.686–0.717), 0.701 (0.674–0.728), and 0.720 (0.697–0.744). Conclusion: Automated measurements of emphysema and atherosclerosis and CAD-supported pulmonary nodule annotations are of added value for predicting lung cancer and mortality. These new models may be used to further personalize lung cancer CT screening follow-up protocols.

Keywords: CT, CAD, model

Ather4, M. Tsakok1, C. Arteta4, L. Pickup2, S. Hussain4, W. Hickes2, P. Novotny1, C. Santos5, E. Fay1, J. Declerck1, V. Potessil5, T. Kadir1, F. Gleeson5, T. Kadir1

1Radiology, University of Oxford Hospitals NHS Foundation Trust, Oxford/GB, 2University Medical Center Groningen, Groningen/NL, 3Department of Radiology, University of Groningen, University Medical Center Groningen, Groningen/NL, 4Heidelberg University Hospital, Heidelberg/DE, 5Optellum Ltd, Oxford/GB

Background: Artificial Intelligence software has shown promise in predicting malignancy in indeterminate CT detected pulmonary nodules. This study aimed to assess the accuracy of a convolutional neural network (CNN) based lung cancer prediction software on an independent dataset of indeterminate incidentally detected nodules in a retrospective European multicentre trial. Method: The software was trained using the US National Lung Screening Trial (NLST) dataset which was manually curated, such that each reported nodule and cancer was located, contoured and diagnostically characterised (9310 benign nodules, 1058 cancer patients). From this complete dataset, a training set was built by selecting all patients with solid and part-solid lesions of 6mm and above, where benign nodules and cancers could be confidently identified by clinicians (5972 patients, of which 575 were cancer patients). A CNN classifier was trained using Deep Learning on this data to produce a malignancy score per nodule. We defined a benign nodule rule-out test by calculating thresholds on the malignancy score that achieve 100% and 99.5% sensitivity on the NLST data. The study was set up so that a malignancy score for each nodule was generated. In total, performance was evaluated using Area-Under-the-ROC-Curve analysis (AUC) and rule-out performance measured the specificity at the two thresholds, i.e. the proportion of benign nodules correctly stratified at each threshold. There were 2201 nodules, measuring between 5-15mm from 1719 patients from three tertiary referral centres in the UK, Germany and Netherlands. The CT data included heterogeneous scan parameters, scanner manufacturers and clinical indications. Diagnostic ground-truth was established according to Fleischner or British Thoracic Society guidelines. The dataset contained 222 unique cancers from 215 patients. Result: AUC on all-site data was 0.92 (95%CI = 0.89-0.93) and broken down per-site the AUC was 0.97 (Netherlands, n=883, 26 cancers), 0.93 (UK, n= 698, 51 cancers), and 0.84 (Germany, 620, 145 cancers). The two thresholds used to reach sensitivity of 100% and 99.5% were the same and achieved an overall sensitivity on the data of 99.1% with a specificity of 25.0%. Per-site results were 25.6% (Netherlands), 27.8% (UK) and 20.6% (Germany) specificity with 100%, 100% and 98.6% sensitivity respectively. Overall performance on an independent European multicentre data was comparable to that achieved on the NLST training data, although there was some variability in the performance across the three centres, potentially providing an opportunity for further optimisation.

Background: Casitas B-lineage lymphoma (Cbl), an E3 ubiquitin ligase, selectively regulates receptor tyrosine kinase (RTKs), e.g. EGFR, MET. Cbl loss of function (LOF) mt can prevent ubiquitination of EGFR and potentiate EGFR signaling. Cbl mt have been described in cases of EGFR-TKI resistance but because EGFR signaling can activate signaling of fusion kinases and other ERBB family members, the implications of Cbl mt warrant broad characterization.

Method: Biopsies from NSCLC pts tested with Next-Generation Sequencing on a 592-gene panel (ILLUMINA NextSeq, ArcherDx) were analyzed retrospectively. Cbl domains of interest: LOF [tyrosine kinase binding (TKB), linker (L), ring finger (RF), ubiquitin- and ubiquitin-associated (UBA)] and unclear function [N-terminal (NT) and proline-rich (PR)]. Chi-square analysis was used to compare co-alteration rates. Result: Among 4,484 NSCLC pts’ tumors (50% M/50% F; age range: 20-90, median 71.5) 222 had Cbl mt (5%), of which 65 (28% of mt, 1.4% of cohort) were LOF: 13% TKB (29), 7% L (15), 5% RF (13), and 3.6% UBA (8). Cbl LOF mt were primarily observed in adenocarcinomas (48/65), metastatic sites (35/65) and equal between M/F. Cbl mt in other exclusions whether on type, attenuation margin, or otherwise. This resulted in 7551 benign and 314 malignant nodules from 5373 patients with mean age 62±5 years and 3180 males. An automatic segmentation method, based on Deep Learning, was used to segment the nodule volume using a single point placed within the nodule on the CT image as an initialization. The nodule volume, V, was calculated from the segmentation and then converted to an equivalent spherical diameter, \(D_s = \sqrt[3]{\frac{V}{\pi}} \). We evaluated four implementations: 1) the original Brock model using as input the manual nodule sizes provided in the NLST dataset (BaselineManual); 2) the original Brock model using as input automatically calculated equivalent spherical diameter, \(D_s \) (BaselineAuto); 3) a Brock model re-fitted to the NLST dataset, using the manual nodule sizes (OptimManual); 4) a Brock model re-fitted to the NLST dataset, using the automatic nodule sizes (OptimAuto).

Statistics were computed by bootstrapping across 1000 draws without replacement with 70%/30% training/testing per-patient splits. The performance of each combination was measured using Area-Under-the-Receiver-Operating-Curve (AUC-ROC) of predicting nodule malignancy. The relative weighting of size coefficients was also compared. Result: The AUC-ROC was 86.5% (95% confidence interval (CI): 83.2, 89.7) for BaselineManual, 87.4% for OptiManual (84.3, 90.5), 88.5% for BaselineAuto (85.7, 91.4), and 89.0% for OptimAuto (86.2, 91.8). The AUC-ROC was 86.5% (95% CI: 83.2, 89.7) increasing to 0.53 (0.49, 0.57) in OptimAuto, an increase of 0.07 (0.06, 0.09)

Conclusion: Regulation of RTK signaling through Cbl-mediated degradative pathways represents an important node for dysregulation in cancer. Presence of Cbl LOF mt in oncogene-driven tumors may provide a bypass signaling-enabled molecular landscape. Further analysis of the role of Cbl LOF mt in de novo- or acquired TKI resistance in pts is identified.

Background: The ubiquitin (Ub)-proteasome system (UPS) is the principal pathway for diverse intracellular proteins including EGFR, which the E2 ubiquitin-Conjugating enzymes play critical roles by transferring the Ub on their conserved cysteine residue to the α-amino group of lysine residues on substrates. Method: To systematically identify ubiquitin pathway genes that are critical to lung carcinogenesis, we used a hightrough-put silencing method to knockdown 696 genes in non-small cell lung cancer (NSCLC) cells, and investigated the significance of the candidates in patient samples, cellular and animal models. Result: We identified 31 candidates that were required for cell proliferation in two NSCLC lines, among which the E2 ubiquitin conjugase CDC34 represented the most significant one. CDC34 was elevated in tumor tissues in 67 of 102 (65.7%) NSCLCs, and smokers had higher CDC34 than nonsmokers. The expression of CDC34 was inversely associated with overall survival of the patients. Forced expression of CDC34 promoted, whereas knockdown of CDC34 inhibited lung cancer in vitro and in vivo. CDC34 bound EGFR and competed with E3 ligase c-Cbl to inhibit the polyubiquitination and subsequent degradation of EGFR. In EGFR-L858R and EGFR-T790M/del(19) driven lung cancer in mice, mock knockdown of CDC34 by lentivirus mediated transfection of short hairpin RNA significantly inhibited tumor formation. Conclusion: These results demonstrate that an E2 enzyme is capable of competing with E3 ligase to inhibit ubiquitination and subsequent degradation of oncprotein substrate, and CDC34 represents an attractive therapeutic target for NSCLCs with or without drug-resistant EGFR mutations.

**Conclusion:** An egfr (n = 1), and HER2 (D1125E).
Background: Pleomorphic Lung Carcinoma (PC) is a rare subtype of NSCLC poorly responsive to systemic therapy. Both epithelial and sarcomatoid phenotypes exist, suggesting an important role of epithelial-to-mesenchymal transition. We aimed to determine MET copy number (CN) within individual tumour components and establish its correlation with immunohistochemistry (IHC) expression. Method: Histopathological assessment and diagnosis was confirmed for 57 cases of resected PCs from the Royal Brompton Hospital Biobank. DNA was isolated from multiple regions and MET copy number determined by digital droplet PCR (ddPCR). IHC using c-MET (EP1454Y) and H-scores were assigned independently by two histopathologists. Result: Cases: median age 66 years, 36.2% T3, 41.4% T2 and 13.8% T1. In the epithelial areas, adenocarcinoma was the most common (45.6%) followed by undifferentiated NSCLC (22.8%) and squamous (17.5%); in pleomorphic areas, mixed giant/spindle cell (35%), spindle cell (31%) and giant cell (26%). MET-CN gain by ddPCR was seen in 25/58 (44%) of cases (CN>2.3). 3/58 (5%) had CN>5. There was a significantly higher MET-CN in pleomorphic compared to epithelial areas (2.7 versus 2.2 P = 0.046). While this did not correlate with c-MET IHC, an H-score of >223 had 75% sensitivity and 52.4% specificity for MET-CN >5.0 (Figure).

Conclusion: There is intra-tumoral heterogeneity in MET-CN between tumoural subsets. This may account for the development of pleomorphic phenotypes in PC. Consequently MET-directed therapies such as crizotinib may be highly effective only against the MET-amplified component in PC and may not impact on overall tumoural control due to minimal efficacy in the non-amplified epithelial component. MET expression using IHC does not correlate with MET-CN determined by ddPCR, although may provide a screening tool for MET amplification. MET aberrations are potentially druggable and therefore this has implications for sampling and MET testing.

MA21.05 COMPREHENSIVE GENOMIC CHARACTERIZATION AND PROGNOSTIC NOMOGRAM DEVELOPED BY 295-GENE PANEL TARGETED SEQUENCING
B. Zhang1, L. Zhang1, T. Zhang2, D. Yue1, C. Li1, Z. Zhang1, J. Ye2, H. Wang3, S. Chuai2, C. Wang1
1Department of Lung Cancer, Tianjin Medical University Cancer Institute and Hospital, Tianjin/CN, 2Burning Rock Biotech, Guangzhou, China, Guangzhou/CN

Background: The genomic landscape of lung cancer has been thoroughly studied in the western population. But comprehensive genetic profiling reports have been limited for the Chinese patients. Here we conducted deep targeted sequencing on a large cohort of Chinese treatment-naive lung cancer patients and identified novel molecular patterns. We developed nomogram models for prognosis prediction by integrating genetic and clinical characteristics and aim to explore more precise models for risk stratification beyond TNM staging. Method: This was a retrospective study, enrolling diagnosed lung cancer patients at Tianjin Medical University Cancer Institute & Hospital from 2009 to 2012. We developed genomic landscape by targeted sequencing using a panel consisting of exons and critical introns of 295 cancer-related genes. Nomogram models were established to provide risk stratification in lung adenocarcinoma (LUAD) and lung squamous cell carcinoma (LUSC) patients Result: 513 tumor tissue samples were collected at very beginning of treatment (stage I, n=193; stage II, n=140; stage IIIA, n=140; stage IIIB, n=5; stage IV, n=28; unknown, n=7). The most frequently mutated oncogenic genes in LUAD were EGFR (55%) and KRAS (11%), compared to 14% and 33% in TCGA. Heterogeneity existed in terms of mutual exclusive and co-occurrent mutated gene pairs between LUAD and LUSC. In LUAD, pairs with most significant exclusivity was EGFR/KRAS and co-occurred was NOTCH3/GRIN2A, whereas the most significant concurrent gene pair in LUSC was ZNF703/FGFR1. To predict survival, our nomograms identified that, in stage I-IIIA LUAD and LUSC, mutated TET2 contributed to more favorable DFS while mutations in EPHA3 and ETV5 indicated better OS. Stage and mutated KRAS were associated with inferior DFS and OS (DFS, n=222, c-index=0.714; OS, n=308, c-index=0.706). In the T3+2bNO&M0 subgroup, which is considered clinically low risk for relapse, older patients who carry BRCA2 mutations were found to strongly correlate with poor DFS (n=121, c-index=0.709), while age and mutated KRAS were distinct indicators of inferior OS (n=163, c-index=0.725). The calibration for survival probability displayed well agreement between nomogram prediction and actual outcomes. Stratification of different risk groups based on nomogram prediction displayed significant differences among Kaplan-Meier curves for survival outcomes (p<0.0001). Conclusion: This is the so far largest cohort of
Chinese lung cancer patients with comprehensive genomic profiling reported. We revealed unique molecular profiles than TCGA and distinct mutual exclusivity and co-occurrence patterns between LUAD and LUSC. In addition, the nomogram models show promise of more precise prognostic prediction of NSCLC patients when integrating genetic information with clinical characteristics.

**MA21.06 PROTEINS ASSOCIATED WITH SURVIVAL DIFFER DEPENDING ON MOLECULAR SUBTYPES, AND MUTATIONAL- AND SMOKING-STATUS IN NSCLC BIOPSIES**

A. Halvorsen¹, M. Haugen², Å. Øjlert¹, S. Solberg³, L. Jørgensen³, G. Mælandsmo¹, O. Brustugun¹, Å. Helland¹

¹Department of Cancer Genetics, Oslo University Hospital - the Norwegian Radium Hospital, Oslo/NO, ²Department of Tumor Biology, Institute for Cancer Research, Ous Radiumhospital, Oslo/NO, ³Department of Cardiothoracic Surgery, Ous-Rikshospitalet, Oslo/NO, ⁴Section of Oncology, Drammen Hospital, Vestre Viken Hospital Trust, Drammen/NO

**Background:** Purpose: Proteins are the functional players driving both normal and disease physiology. The proteomic changes observed in lung cancer may be a consequence of mutations in essential driver-genes.

The purpose of this study was to identify proteins in lung cancer biopsies associated with survival in groups stratified by smoking status, and EGFR-, TP53- and KRAS-mutations.

**Method:** We have performed a profiling of 295 cancer relevant proteins, of which 60 were in a phosphorylated state, using reverse phase protein arrays (RPPA). We analyzed biopsies from 80 lung cancer patients (adenocarcinoma) and correlated the protein expression pattern with progression free survival (PFS) based on mutational- and smoking-status.

**Result:** Spearman correlation analysis revealed a higher number of proteins with significant association to PFS (p<0.05) among the wild type samples compared to the mutated samples. High expression of protein kinase C (PKC) and the isoforms alpha, beta and delta, included the phosphorylated state, showed the strongest association with better PFS, especially in the wild type samples.

Ten proteins were associated with PFS in never-smokers, where eight of these were unique for this group. Unsupervised hierarchical clustering separated the samples into four subclusters, each enriched with one of the three molecular subtypes TRU, PI and PP (Comprehensive molecular profiling of lung adenocarcinoma, Nature, 2014). Subcluster 2 contained two smaller clusters (2a and 2b) enriched with samples of subtype PP, where subcluster 2a was associated with poor PFS (p=0.003, Figure 1).

**Conclusion:** As of today, we do not have any effective treatment targeting KRAS- and TP53- mutated cells. This study shows that expression of specific proteins and phospho-proteins associated with PFS differ depending on molecular subtype, and mutational- and smoking-status. Proteins associated with PFS may serve as therapeutic targets to circumvent treatment resistance.

**Background:** Smoking is by far the most important cause of lung cancer. However, lung cancer among never-smokers is common and increasing [1]. A smoking-independent subgroup of lung adenocarcinoma with certain molecular and clinical features exists [2-3]. Therefore, as a 1st project within the Swedish Molecular Initiative against Lung cancer (SMIL), we aim to characterize never-smoking lung cancer for etiological, diagnostic and therapeutic purposes. **Method:** Through the Swedish National Lung Cancer Registry [1], we identified all individuals who underwent surgery for lung cancer in Sweden 2005-2014 and who were reclassified as never-smokers (n=540). At each study site (n=6), clinical data were reviewed by a thoracic oncologist/pulmonologist through patients’ medical charts and archived tumor tissues were retrieved and reviewed by a thoracic pathologist. For subsequent studies, we extracted DNA and RNA (using the Qiagen AllPrep kit for FFPE tissue) and constructed tissue microarrays. As a first pre-planned analysis, we performed fusion gene mapping using an RNA-based NanoString nCounter Elements assay, as previously described [4]. **Result:** In the first 212 (out of 540) analyzed samples, we detected 17 fusions involving ALK, 8 involving RET, and 2 involving NTRK2. In addition, MET exon 14 skipping was found in 17 samples. In total, these findings involved 21% of analyzed cases. Additional results from further studies on the cohort will be presented. **Conclusion:** SMIL is an ongoing nationwide molecular research collaboration, and we currently collect one of the largest never-smoking lung tumor cohorts worldwide. From the first pre-planned analyses, we conclude that, in a population-based cohort of early stage lung cancer from never-smokers, druggable oncogenic fusions are frequent. **References:** 1. http://www.cancercentre.se/vast/cancerdiagnoster/lungo-och-lungskval/kvalitetsregister2. 2. **MA21.09 DIFFERENTIAL GENE EXPRESSION IN TUMOR AND NORMAL TISSUE REVEALS NEW INSIGHTS IN THE BIOLOGY OF NON-SMALL CELL LUNG CARCINOMA**

A. Spatz1, V. Lazari, E. Rubin2, K. Lach1, H. Wangi, A. Papadakis3, R. Moscona4, P. Jimenez4, G. Kasyjmanova5, V. Cohen6, J. Agulnik7, L. Kemp6

1Department of Integrative Oncology, British Columbia Cancer Research Centre, Vancouver/BC/CA, 2Worldwide Innovative Network, Villejuif/SR, 3Ben Gurion University of the Negev, Beer-Sheva/IL, 4Lady Davis Institute for Medical Research, Montreal/CA, 5National University of Asunciun, Asunciun/PY, 6Department of Oncology, Jewish General Hospital and McGill University, Montreal/CA, 7University Medical Center Groningen, Groningen/NL

**Background:** Effective use of targeted cancer therapies typically depends upon the identification of actionable genomics somatic alterations, benefiting only a minority of Non-Small Cell Lung Carcinoma (NSCLC) patients. To integrate transcriptomic assessment in cancer precision medicine, we have evaluated the mRNA expression levels in tumors and their matched normal lung tissues with the hypothesis that mRNA quantification in tumors relative to their matched normal tissue may better reveal small transcriptional differences that are associated with major biological effects. **Method:** The discovery set used 123 frozen macrodissected treatment-naive NSCLC tumors and matched normal tissues from surgical resections performed at the Multidisciplinary Thoracic Oncology Institute (Parkland Hospital, Dallas, TX), and the validation set used 143 FFPE macrodissected treatment-naive NSCLC tumors and matched normal tissues from surgical resections performed at the Jewish General Hospital (Montreal, QC, Canada). A pathology review was performed in all cases. In the discovery dataset, expression levels of 17,318 genes and miRNAs using an Agilent Technologies platform; in the validation set, the NanoString nCounter technology was used with a customized 148 probe set that was designed according to the results of the discovery phase. The primary objective of the study was post-surgery prognostics outcome. The secondary objectives were post-surgery overall survival (OS) and the identification of pathway-driven expression signatures. **Result:** A set of highly expressed genes correlated with post-surgery PFS. Details of the prognostic signature will be presented at the meeting. Importantly, mRNA levels of normal tissues were highly variable between individuals. Organ matche reference enabled to control for the noise signals related to individual background genetic variability. The cell cycle G2M checkpoint was the most significantly deregulated expression pathway in this cohort; nine genes in this pathway are upregulated in tumors, depending on their histology: CHEK1, TOP2A, AURKA, CDC2, PLK1, CDC2, CDC25A, CDC25B, and CDC25C. CHEK1 is a pivotal gene in regulating the G2/M cell cycle pathway that triggers the double-strand break excision repair in which the main effector is PARP1. CHEK1 was overexpressed in 86% of adenocarcinomas, versus 42% for PARP1. **Conclusion:** Conventional transcriptomic approaches using expression metrics obtained in tumor pools may miss important changes due to individual variability in non-tumoral tissue. The present work illustrated that paired matched tumor and normal tissues can identify new key genes involved in the biology and pathogenesis of NSCLC, and opens new avenues for integrating transcriptomic investigations in the precision medicine arena. **Keywords:** transcriptome, Prognosis, Pathology

**MA21.10 LARGE-SCALE DISCOVERY OF NOVEL HUMAN ONCOFETAL TRANSCRIPTS IN LUNG**

B. Minatel1, V. Martinez1, A. Sage1, E. Marshall2, T. Tokar3, D. Becker-Santos1, W. Robinson1, I. Jurisica1, W. Lam1

1Integrative Oncology, British Columbia Cancer Research Centre, Vancouver/BC/CA, 2Data Science Discovery Centre for Chronic Diseases, Krembil Research Institute, Toronto/CA, 3Children’s and Women’s Health Centre of British Columbia, BC Children’s Hospital Research Institute, Vancouver/CA

**Background:** Oncofetal genes are those expressed during both embryogenesis and tumorigenesis, but silenced in non-survival (PFS). Although most described oncofetal gene have been shown to play important roles in tumour development and display potential as diagnostic and prognostic markers, this area of research remains largely unexplored. The advent of high-throughput technologies has not only allowed for large-scale discovery of biomarkers, but has also highlighted the role of non-coding RNAs from tissue development to malignant transformation. Small non-coding RNAs (snRNAs, e.g., miRNA, snoRNA, piRNA, snRNA) are key players in gene-regulatory networks, and have shown promise as fluid-based biomarkers. In this study, we performed a comprehensive characterization of the snRNA transcriptome of fetal, non-malignant and tumor lung tissues to identify development-associated (oncofetal) snRNAs with roles in lung cancer, including previously unseen unannotated snRNAs. **Method:** Here, 209 paired non-malignant/tumour lung samples from two cohorts (BCCA, n=118 and TCGA, n=91) and 25 fetal lung samples were analyzed through the platform mirMaster. This platform aligns sequence reads to the hg38 genomic build, quantifies known snRNA species and predicts novel miRNA candidates using the mirDeep2 algorithm. The snRNA species that had no significant alterations in expression between fetal and tumours samples, but displayed significant differential expression between fetal/non-malignant and tumour/non-malignant tissues were classified as oncofetal snRNAs. The biological relevance of the
oncofetal snRNAs and the novel miRNA candidates was investigated by gene-target prediction and pathway enrichment analyses, using mirDIP, ITH and pathDIP databases. Result: Our study provides the first large-scale characterization of the lung snRNA transcriptome in fetal, non-malignant and tumour tissues. In particular, we discovered the expression of 464 novel miRNA candidates and identified a large subset of oncofetal snRNAs. Target prediction analysis showed that the novel miRNA candidates discovered in all lung tissues are involved in cellular processes associated with cell proliferation, migration and survival, including the Wnt, MAPK and Notch signaling pathways, which are known to be associated with the development and progression of lung cancer. Additionally, oncofetal snRNAs were found to be associated with cell cycle control and differentiation, highlighting the functional relevance of these molecules. Conclusion: We have not only expanded the lung snRNA transcriptome, but also revealed the expression of a large number of snRNAs relevant to lung tumorigenesis that are not expressed in normal adult tissues. Our results will aid in the development of more accurate fluid-based biomarkers for the early-detection of lung cancer.

MA21 MOLECULAR SUBTYPEING, CBLC, AND NON CODING RNA
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA21.11 EPIGENOMIC MAPPING OF CELL-FREE DNA IN PATIENTS WITH NON-SMALL CELL LUNG CANCER
C. Bestvina1, J. Karpus2, X. Cui2, C. Oosterbaan2, B. Won3, C. He3, J. Patel1
1Hematology/oncology Fellow, University of Chicago Medicine, Chicago/US, 2Section of Hematology/oncology, The University of Chicago Medicine, Chicago/IL/US

Background: Epigenetic modifications such as DNA methylation play an important role in human cancers, and have been implicated in tumor progression and drug resistance. Prior studies suggest 5-hydroxymethylcytosine (5hmC) has many important regulatory functions, given the colocalization of 5hmC within regulatory regions such as transcription factor binding sites, promoters and enhancers. Elevated 5hmC levels have been associated with increased gene expression. Genome-wide mapping of 5hmC has been performed in several different cells and tissues including brain and bone, though this has not previously been studied in lung cancer. It is possible the 5hmC profile can serve as a valuable biomarker for diagnosis, assessment for resistance, and surveillance for recurrence in non-small cell lung cancer (NSCLC). Method: This was an exploratory study with a primary objective to perform genome-wide 5-hydroxymethylcytosine profiling of circulating cell-free DNA (cfDNA) in patients with epidermal growth factor receptor (EGFR)-mutated lung cancer. Thirty-three different patient samples were collected from 32 different patients with advanced NSCLC, with a known EGFR mutation by prior tissue genotyping such as FoundationMedicine or cfDNA such as Guardant. Samples were classified as “controlled” if the disease burden was stable or decreasing, versus “uncontrolled” if disease burden was increasing. Patients ranged from previously untreated to heavily pretreated. Full profiling of 5hmC in cfDNA was performed. Result: A difference in modification between “controlled” and “uncontrolled” disease was found in 311 differentially modified regions (p<0.01), and in 189 differentially modified genes (p<0.01). Figure 1: Degree of methylation of a) 311 differentially modified regions b) 189 differentially modified genes.

Conclusion: In a retrospective analysis, a strong correlation exists between the methylation of specific regions and genes and the state of disease control. Future research should focus on if 5hmC profiling can be used to monitor disease status, to predict response to treatment, or alongside ctDNA for diagnostic accuracy.

MA22 NEW THERAPEUTICS, PATHOLOGY, AND BRAIN METASTASES FOR SMALL CELL AND NEUROENDOCRINE TUMOUR
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA22.01 PARP INHIBITOR RADIOSENSITIZATION OF SMALL CELL LUNG CANCER DIFFERS BY PARP TRAPPING POTENCY
B. Lok1, J. Laird2, J. Ma3, E. De Stanchina4, J. Poirier1, C. Rudin3
1Molecular Pharmacology Program, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2New York University School of Medicine, New York/NY/US, 3Albert Einstein College of Medicine, New York/NY/US, 4Antitumor Assessment Core Facility, Memorial Sloan Kettering Cancer Center, New York/NY/US, 5Thoracic Oncology Service, Memorial Sloan-Kettering Cancer Center, New York/NY/US

Background: Small cell lung cancer (SCLC) is an aggressive malignancy with a critical need for novel therapies. Our goal was to determine whether PARP inhibition could sensitize SCLC cells to ionizing radiation (IR) and if so, to determine the contribution of PARP trapping to radiosensitization. Method: Short-term viability assays and clonogenic survival assays (CSA) were used to assess radiosensitization in six SCLC cell lines. Doses of veliparib and talazoparib with equivalent enzymatic inhibitory activity but differing PARP trapping activity were identified and compared in CSAs. The dose modification factor (DMF), defined as the ratio of RT dose needed to achieve an equivalent level of survival with RT alone compared to that for RT plus drug, was calculated at 37% survival. Phosphorylated gH2AX sub-nuclear foci were assessed by immunofluorescence to quantify double-stranded DNA breaks (DSBs). Talazoparib, IR, and their combination were tested in three patient-derived xenograft (PDX) models. Result: Talazoparib radiosensitized 5 of 6 SCLC cell lines in short-term viability assays with a talazoparib dose of 20 nM demonstrating a DMF ranging from 1.61 – 2.88 in 4 cell lines with 0.2 nM demonstrating a DMF of 1.56 in 1 additional cell line. We confirmed radiosensitization in 3 of 3 cell lines with DMF ranging from 1.40 – 2.20. To determine effects of PARP trapping on radiosensitization, we identified that concentrations of 200 nM talazoparib and 1600 nM veliparib similarly inhibited PAR polymerization; however, talazoparib exhibited greater PARP trapping activity that was associated with superior radiosensitization (DMF 3.3 with talazoparib vs DMF 1.0 with veliparib). This observation further correlated with an increased number of DSBs induced by talazoparib as compared to veliparib, where we found that talazoparib produced more residual DSBs than veliparib and DMSO with IR (gH2AX foci mean per cell: talazoparib 53.5, veliparib 33.5, DMSO 25.5) and without IR (40.0, 19.6, 14.6). Finally, a dose of 0.2 mg/kg talazoparib in vivo caused tumor growth inhibition in combination with IR but not as a single agent in 3 SCLC PDX models. Conclusion: PARP inhibition effectively sensitizes SCLC cell lines and PDXs to RT, and PARP trapping activity enhances this effect. PARP inhibitors, especially those with high PARP trapping activity, may provide a powerful tool to improve the efficacy of RT in SCLC.

Keywords: small cell lung cancer, PARP INHIBITOR, radiosensitization

MA22.02 ACTIVATION OF MAPK SUPPRESSES NEUROENDOCRINE TRANSCRIPTION FACTORS AND CAUSES TRANSDIFFERENTIATION OF SMALL CELL LUNG CANCER
Y. Inoue, W. Lockwood
Department of Integrative Oncology, British Columbia Cancer Research Centre, Vancouver/CA

Background: Gene alterations involved in activating signaling through receptor tyrosine kinases/RAS/RAF/MEK/ERK pathway are extremely rare in small cell lung cancer (SCLC). In addition, EGFR expression is lost during the histological reprogramming of EGFR mutation-positive lung adenocarcinoma (LUAD) to SCLC, despite the cancer retaining the original EGFR mutation. These observations imply that signaling through mitogen-activated protein kinases (MAPKs) - critically important in non-small cell lung cancer - might be detrimental in SCLC biology. Here we investigated the impact of induction of two mutated oncoproteins, EGFR(G858R) and KRAS(G12V), the most common drivers of LUAD, on the phenotype and signaling profiles of SCLC. Method: EGFR(G858R) or KRAS(G12V)

Conclusion: In a retrospective analysis, a strong correlation exists between the methylation of specific regions and genes and the state of disease control. Future research should focus on if 5hmC profiling can be used to monitor disease status, to predict response to treatment, or alongside ctDNA for diagnostic accuracy.

Keywords: cell-free DNA, DNA methylation, Gene Expression Regulation
were aberrantly expressed in an inducible manner in three SCLC cell lines (H1217, H82, and HS24). The effects of induction of these oncogenes were determined through cell viability analysis and Western blotting analysis particularly focusing on the regulation of master neuroendocrine transcription factors such as insulinoma-associated protein 1 (INSM1), POU class 3 homeobox 2 (BRN2), achaete-scute homologue 1 (ASCL1), and neurogenin differentiation factor 1 (NEUROD1). Genome-wide expression profiles were assessed in a longitudinal manner after oncogene induction and specific gene sets driven by MAPK activation in each SCLC cell line were defined. Result: INSM1 and BRN2 were expressed in all the SCLC cell lines assessed. ASCL1 was expressed only in H2107 (classic type). Alternatively, NEUROD1 was expressed in the variant type SCLC cell lines, H82 and HS24. Induction of mutant-EGFR or -KRAS resulted in different cell viability according to cell lines; H82 cells showed higher proliferation rate and the others showed lower proliferative ability. Furthermore, induction of these oncogenes caused transition from suspension to adherent phenotype in all the three cell lines. Importantly, EGFR/KRAS induction downregulated neuroendocrine transcription factors and these effects were more strongly observed after KRAS induction than after EGFR induction, which was consistent with the difference in degrees of phospo-ERK1/2 upregulation after induction of these mutant-oncogenes. Notably, treatment with SCH772984, an ERK1/2 inhibitor, rescued the repression of neuroendocrine factors by KRAS induction. Gene expression profiling is currently underway to reveal specific factors mediating ERK induced suppression of neuroendocrine programs.

Conclusion: Activation of the RAS/RAF/MEK/ERK pathway causes phenotypic transition in SCLC growing in suspension to the adherent phenotype and suppresses neuroendocrine differentiation. Thus, ERK signaling has an fundamental role in repression of neuroendocrine differentiation programs and may be important in regulating histological transversion of SCLC to and from NSCLC with implications to drug resistance.

MA22 NEW THERAPEUTICS, PATHOLOGY, AND BRAIN METASTASES FOR SMALL CELL AND NEUROENDOCRINE TUMOUR
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA22.03 SCLC CIRCULATING TUMOUR CELL DERIVED EXPLANTS: THE CLINICAL CHARACTERISTICS OF PATIENTS WHOSE SAMPLES GENERATE CDX
A. Vickers1, L. Carter1, M. Galvin1, M. Carter1, L. Franklin2, K. Morris2, J. Pierce3, K. Fresé1, F. Blackhall1, C. Dive1
1The Christie NHS Foundation Trust, Withington, Greater Manchester/GB, 2Clinical and Experimental Pharmacology, Cancer Research UK Manchester Institute, Manchester/GB

Background: Small cell lung cancer (SCLC) prognostic is dismal, with minimal improvement in recent years. Work with SCLC cell lines and targeted therapies have been disappointing when translated into clinical practice. Circulating tumour cells (CTCs) represent a readily accessible liquid biopsy, which can be used to generate CTC derived explants (CDXs) for the study of SCLC biology and the investigation of biomarkers and therapeutics. These clinically relevant models appear to mirror patient response to therapeutics. Our aim was to assess if the patients whose samples generated a CDX represent the SCLC population, and determine if the clinical features of these patients offer insight into CTC biology.

Method: This was a single centre, retrospective analysis of 147 SCLC patients who had participated in The CHEMORES Study in which SCLC patients were asked to donate blood samples for the discovery and validation of novel biomarkers. Paired patient blood samples were taken for CTC enumeration using CellSearch Technology and for attempted CDX model generation. We obtained demographic and clinical information on these patients, and analysed the data for differences between patients whose samples generated a CDX and those whose did not.

Result: 231 paired blood samples were taken from 147 patients, with 45 CDXs successfully generated from 34 patients. CTC number was significantly higher in samples which generated a CDX than those which didn’t, p=0.001. Successful progression samples had significantly lower CTC number than successful baseline samples, p=0.026. There was no significant difference in age, gender, pack year history, performance status, stage, chemosensitivity or the presence of liver or brain metastases between patients whose samples did and did not generate a CDX. Metastatic burden was significantly higher in patients whose samples generated a CDX, p=0.001. Progression free (PFS) and overall survival were significantly shorter in patients whose samples generated a CDX, p<0.001.

Conclusion: CTC number correlates with CDX success, although a specific CTC phenotype may be more important. CTCs at progression may have a more aggressive phenotype than those at baseline. CDXs appeared to represent the SCLC population which is important when translating knowledge gained by studying CDXs into clinical practice. CTCs may play a role in the widespread metastatic dissemination of SCLC and thus survival of patients. Shortened PFS in the absence of difference in chemosensitivity may be due to outliers with particularly long PFS in the unsuccessful group. Further genomic and phenotypic analysis of subpopulations of CTCs may provide further insight.

MA22.05 IMPACT OF TUMOR SPREAD THROUGH AIR SPACES (STAS) IN LUNG NEOENDOCRINE TUMORS (NETS)
R. Aly1, T. Eguchi2, K. Kadota2, N. Rekhtman3, K.S. Tan4, P. Adusumilli5, W. Travis6
1Thoracic Service, Memorial Sloan Kettering Cancer Center, New York/NY/US, 2Kagawa University, Kagawa/JP, 3Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US, 4Epidemiology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US, 5Thoracic Service and Center for Cell Engineering, Memorial Sloan Kettering Cancer Center, New York/NY/US, 6Dept of Pathology, Memorial Sloan Kettering Cancer Center, New York/NY/US

Background: We have previously reported the prognostic significance of STAS in lung adenoacinaroma and squamous cell carcinoma. The aim of this study was to investigate the incidence and prognostic impact of STAS in lung NETs. Method: We evaluated all tumor slides (range 2-7, median 3) for presence of STAS from patients with p-Stage I-II primary lung NETs (n=628, typical carcinoid (TC, n=305), atypical carcinoid (AC, n=38), large cell neuroendocrine carcinoma (LCNEC, n=93) and small cell lung carcinoma (SCLC, n=57)). Patients with combined NETs were excluded from this analysis (n=19). Cumulative incidence of recurrence (CIR) and lung cancer-specific cumulative incidence of death (LC-CID) were analyzed by competing risks approach. Result: STAS was identified in 25% of NETs (15% in TC, 37% in AC, 43% in LCNEC, and 46% in SCLC). Prognostic analysis in TC cohort was not conducted due to the small number of events (<5 events). Patients with STAS positive tumors were associated with higher CIR than STAS negative tumors in the total (AC-LCNEC-SCLC) cohort as well as individual AC, LCNEC and SCLC cohorts (Figure 1, A-D). STAS was also associated with higher LC-CID in all cohorts except for AC (Figure 1, E-H). In multivariable analysis, STAS was a significant risk factor for recurrence and lung cancer specific-death, independent of stage and histologic subtype. Stratified by stage, STAS was an independent predictor of recurrence (subhazard ratio [SHR] 2.39, 95% CI 1.26-4.54, p= 0.007) and lung cancer-specific death (SHR 2.42, 95% CI 1.21- 4.84, p= 0.012) in LCNEC. In SCLC, STAS was also an independent risk factor of lung cancer-specific death (SHR 4.06, 95% CI 1.35-12.35, p= 0.014).

Background: Impact on survival in patients with surgically resected multifocal neuroendocrine lesions (MNET), such as diffuse idiopathic pulmonary neuroendocrine cell hyperplasia (DIPNECH) or tumorlets, along with primary typical lung carcinoid (TC) is unclear. Aim of this study is to analyze whether synchronous preinvasive multifocal neuroendocrine lesions of the lung with primary TC tumors (MNET+TC) may represent a negative prognostic factor. Method: A retrospective study, prospectively collected, for TC from two institutional databases was evaluated with a lifelong follow-up. Patients who did not receive surgery, underwent bronchial resection or lung transplant were excluded. Pathology specimens were all reclassified according to the 2015 WHO classification. Patients who underwent lobectomy or sleeve lobectomy were excluded. Lesions of the lung with primary TC tumors (MNET+TC) may represent a negative prognostic factor. Careful search of MNET should be always performed in clinical and pathological staging of a suspected primary TC. The increased risk of progression of MNET+TC warrants an accurate and lifelong follow-up.

Keywords: diffuse idiopathic pulmonary neuroendocrine cell hyperplasia, tumorlets, Typical pulmonary carcinoid tumor

Conclusion: Synchronous multifocal neuroendocrine preinvasive lesions (MNET) with primary typical carcinoid (TC) lung tumors can be a negative prognostic factor. Careful search of MNET should be always performed in clinical and pathological staging of a suspected primary TC. The increased risk of progression of MNET+TC warrants an accurate and lifelong follow-up.

MA22.07 PROGNOSTIC VALUE OF DISTANT ORGAN-SPECIFIC METASTASES IN NEWLY DIAGNOSED LUNG NEUROENDOCRINE TUMORS: A POPULATION-BASED STUDY

J. Wen1, M. Fan1, J. Chen1, D. Liu1, X. Xu1, J. Zhang2, Y. Gu1, L. Huang1

1Department of Radiation Oncology, Fudan University Shanghai Cancer Center, Shanghai/CN, 2Department of Radiation Oncology, Fudan Shanghai Cancer Center, Shanghai/CN

Background: Lung neuroendocrine tumors (Lung NETs) are rare neoplasms with inferior outcomes for patients with distant metastases. The AJCC cancer staging system for the classification of NETs was first introduced in 2010. However, the prognostic impact of metastatic sites for lung NETs are poorly explored. We aimed to fill this gap of our knowledge using the SEER database. Method: Clinical-pathological characteristics, specific metastatic sites and outcomes of stage IV lung NETs (according to AJCC 7th edition) were extracted from the SEER database from 2010-2014. Overall survival (OS) and Lung cancer-specific survival (LCSS) were estimated by the Kaplan-Meier method and comparisons conducted using log-rank tests and Cox regression models. Results: A total of 2337 stage IV lung NETs patients were identified. The 5-year OS and LCSS were 10.7% and 18.3%, respectively. Among them, 2159 patients had specific organ metastases (liver, lung, bone or brain) and 388 patients (16.9%) were identified. Overall KM progression free survival achieved at 5 and 10 years respectively MNET+TC 93.2% and 83.8% compare to TC 98.4% and 96.1% (p=0.00039). Thirty-six MNET+TC were matched pairs vs. TC alone. Univariate Cox proportional hazards model for matched patients MNET+TC compared to TC was 2.78 (95% CI:0.84-9.3, p=0.095). Difference in progression free rate between matched groups was p<0.001.

Conclusion: Synchronous multifocal neuroendocrine preinvasive lesions (MNET) with primary typical carcinoid (TC) lung tumors can be a negative prognostic factor. Careful search of MNET should be always performed in clinical and pathological staging of a suspected primary TC. The increased risk of progression of MNET+TC warrants an accurate and lifelong follow-up.

MA22 NEW THERAPEUTICS, PATHOLOGY, AND BRAIN METASTASES FOR SMALL CELL AND NEUROENDOCRINE TUMOUR
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA22.09 SHOULD STEREOTACTIC RADIOSURGERY BE CONSIDERED FOR SALVAGE OF INTRACRANIAL RECURRENCE IN SMALL CELL LUNG CANCER?

Background: Prophylactic cranial irradiation (PCI) remains a standard of care for small cell lung cancer (SCLC) to improve overall survival (OS) and prevent recurrence in limited (LS) and extensive stage (ES) disease. Intracranial recurrence (IC) after PCI affects 12-33%. Limited published data describe outcomes of salvage radiosurgery (SRS). Our purpose was to review outcomes after IC post-PCI or therapeutic whole brain radiotherapy (WBRT).

Method: Consecutive patients with pathologically-confirmed SCLC assessed (01/2013-12/2015) at a tertiary cancer centre (Catchment 1.5M) were retrospectively reviewed. Demographics, treatment and outcomes were abstracted and summary statistics calculated. Kaplan-Meier estimates and univariate and multivariate analysis (MVA) via the Cox proportional hazard model were performed.

Result: Median age was 66.3yrs, 53% female, and 80% ECOG 0-2 (N =372). Median survival (MS) was 24 months (95%CI 18.3-29.7 mos) for 103 LS, and 7 months (95%CI 6.1-7.9 mos) for 269 ES patients. 72/103 LS received PCI (69.8%), 84.7% of whom had radical thoracic radiotherapy (RT). 54/269 ES patients presented with brain metastases (BM); 98/215 of the remaining received PCI, and 72 of those thoracic RT (84.7% 25-30Gy/10). PCI dose was 25Gy/10 in 95.9%. PCI patients had better performance status (PS), and were more likely to receive chemotherapy (CT) and thoracic RT (all p<0.013). 18.8% (32/170) recurrent post-PCI (13 LS, 9 ES) at a median of 11.5 mos. 45/54 presenting with BMs received WBRT (83.3% 20Gy/5), 14 of whom recurred. MS after PCI was 28 mos vs 12 mos for LS and ES, respectively. For LS patients with IC post-PCI, MS was 20 mos vs 38 mos without IC (p<0.03). On MVA, interval between brain RT predicted OS after PCI (HR 0.9, p<0.001), while stage (HR 3.56, p=0.008) and cranial RT dose predicted IC (HR 0.65, p=0.047). At IC, 56.5% (26/46) had <5 BM, median 1.7cm (range 0.5-5cm), 39.1% had no extracranial disease, 6 were asymptomatic, and 50% had ECOG 0-2. 30/46 had ReRT; 27 WBRT and 3 stereotactic radiosurgery (SRS). In retrospect, 17/46 would have been candidates for salvage SRS; 5 LS post-PCI; 8 ES post-PCI; and 4 ES post-WBRT. Conclusion: This cohort seems to challenge the belief that in-brain progression is always: diffuse; associated with clinical deterioration; and synchronous with systemic failure. With potential for OS >6 months, repeat WBRT risks meaningful neurocognitive toxicity. Further data are required; however, approximately 1 in 3 SCLC patients who recur after PCI or WBRT appear clinically appropriate for salvage SRS.

TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45

MA22.10 PREVALENCE AND RISK FACTORS OF BRAIN METASTASES IN LIMITED STAGE SMALL CELL LUNG CANCER IMMEDIATELY BEFORE PROPHYLACTIC CRANIAL IRRADIATION
X. Chu¹, X. Yang², Z. Zhu³
1Radiation Oncology, Fudan University Shanghai Cancer Center, Shanghai/CN, 2Department of Oncology, Fudan University Shanghai Cancer Center, Shanghai/CN, 3Department of Radiation Oncology, Fudan University Shanghai Cancer Center, Shanghai/CN

Background: Prophylactic cranial irradiation (PCI) reduces the incidence of brain metastasis (BM) and improves overall survival (OS) in limited-stage Small Cell Lung Cancer (LS-SCLC) patients with complete or partial remission after receiving chemoradiotherapy. However, cranial magnetic resonance imaging (CMRI) before scheduled PCI is not mandatory, and its necessity remains controversial. Therefore, we conducted this study to evaluate LS-SCLC patients’ BM rate revealed by CMRI immediately before PCI.

Method: 283 consecutive LS-SCLC patients diagnosed at our center between 2014 and 2017 were evaluated, all had negative base-line CMRI. Patients received platinum-based chemotherapy plus concurrent or sequential thoracic radiation. 119 complete or partial responders were identified. All received another CMRI immediately before PCI and constituted the cohort of interest. Logistic regression was employed to assess the relationship between pre-PCI BM risk and the following variables: age, gender, smoking history, lymph node stage or time from treatment initiation to pre-PCI MRI (TPCI). Cox regression analysis on OS and LCSS revealed that age > 60 years (HR 2.1%, p<0.001; 1-, 5-year LCSS: 26.8%, 7.7%, p<0.001). Multivariate Cox regression analysis on OS and LCSS revealed that age > 60 years (p<0.001), male gender (p<0.001), poorer differentiation (p<0.001) and brain metastases (p<0.001) were independently poor prognostic factors for stage IV lung NETs patients.

Conclusion: Evaluation by CMRI immediately before PCI might be considered as a distinct category of dismal outcomes. Logistic regression employed was assessed to test the relationship between pre-PCI BM risk and the following variables: age, gender, smoking history, lymph node stage or time from treatment initiation to pre-PCI MRI (TPCI). Cox regression analysis on OS and LCSS revealed that age > 60 years (HR 2.1%, p<0.001; 1-, 5-year LCSS: 26.8%, 7.7%, p<0.001). Multivariate Cox regression analysis on OS and LCSS revealed that age > 60 years (p<0.001), male gender (p<0.001), poorer differentiation (p<0.001) and brain metastases (p<0.001) were independently poor prognostic factors for stage IV lung NETs patients.

MA22 NEW THERAPEUTICS, PATHOLOGY, AND BRAIN METASTASES FOR SMALL CELL AND NEUROENDOCRINE TUMOUR
TUESDAY, SEPTEMBER 25, 2018 - 15:15-16:45
with a total of 754 brain metastases were identified. In 67 (55.8%) patients BMs were detected at diagnosis of SCLC and in 53 (44.2%) patients BMs developed later without previous PCI. The median number of metastases was 3, and 27 (22.5%) patients had a single BM. There were 22 (18.3%) patients with hippocampal metastases. A total of 23 (3.1%) metastases involved the hippocampal avoidance area. On logistic regression analysis, the number of brain metastases was an independent risk factor for HMs. **Conclusion:** The overall incidence of hippocampal metastases in our cohort of SCLC patients is high. As HS-WBRT may increase the risk of treatment failure in the spared region, prospective randomised trials are encouraged.

**Keywords:** small cell lung cancer, Brain metastasis, Whole Brain Radiotherapy

The figure depicts the results of the diagnostic profiling in the upper panel (A-C), and prognostication in lower panel (D-F). Unsupervised heat map separated adenocarcinomas (grey) from granulomas, and among the gene set analysis, differences in interleukins, microglial function, antigen processing, cytokines and macrophage functions were the most significant for cohort discrimination. A 33 gene set signature was able to separate granuloma from cancer with mean AUCs of 0.982. Expression of BC immune related genes were remarkably different between the patients who recurred, and there were differences in profiles of locoregional recurrences compared to systemic recurrences (data not shown). Patients with elevated T-regs but decreased T-cells were characterized by distant progression, while decreased mast cells and increased CD-8 and total T-cells were associated with local recurrence. A three step prognostication index using 19 genes could stratify these patients by time to progression (E,F). **Conclusion:** These encouraging data offer the potential for immune transcriptional signatures to better select patients for diagnosis/management of early stage adenocarcinoma. Further validation studies are underway for possible presentation at WCLC18.

MA23.02 CIRCULATING TUMOR DNA ANALYSIS WITH A NOVEL VARIANT CLASSIFIER FOR RECURRENCE DETECTION IN RESECTED, EARLY-STAGE LUNG CANCER

1Department of Thoracic/head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US, 2Guardian Health, Redwood City/US, 3Thoracic and Cardiovascular Surgery, MD Anderson Cancer Center, Houston/TX/US, 4Radiation Oncology, MD Anderson Cancer Center, Houston/TX/US, 5Thoracic Head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US, 6Thoracic and Cardiovascular Surgery, MD Anderson, Houston/TX/US, 7Melanoma Medical Oncology, MD Anderson Cancer Center, Houston/TX/US, 8Thoracic/head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US, 9Thoracic/head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US

Background: ctDNA is a blood-based biomarker with promising potential in lung cancer for minimal residual disease (MRD) assessment and early detection of recurrence. However, data regarding feasibility are limited, especially for stage I-II disease. Method: We performed longitudinal plasma ctDNA analysis of early-stage lung cancer patients (pts) undergoing resection at MD Anderson Cancer Center from April 2016 to Jan 2017. Plasma ctDNA was analyzed from pre-operative and multiple post-operative time points until disease recurrence. ctDNA profiling was performed using the Guardant360 Digital Sequencing panel (Guardant Health). Key genes (165) covering SNVs in 21 genes and indels in 9 genes that are commonly present in lung cancer. ctDNA profiles from ~30,000 lung cancer pts were used to train a classifier to exclude non-tumor related mutations. Result: A total of 40 pts were included in this analysis, comprised of the first 17 pts with recurrence in the longitudinal study and 23 consecutive pts without recurrence. This cohort was primarily stage I and II (15 [38%), 16 [40%]). Histology included adenocarcinoma (29 [73%]), SCC (6 [15%]), and SCLC (2 [5%]). 58% had adjuvant therapy. Median follow-up was 17.7 (3 - 24.5) months and median time to recurrence was 7.1 (3.4 - 16.5) months in this selected cohort. At least one ctDNA alteration was detected in 55% [21/38] of pts with evaluable pre-operative samples and in 22% (8/37) of pts at 4 weeks post-op. Presence of ctDNA at 4 weeks post-op heralded eventual recurrence with 43% sensitivity and 91% specificity (75% PPV, 73% NPV) and was significantly associated with worse recurrence free survival (p=0.022, HR 6.52, 95% CI 1.3 - 32.6). While also accounting for stage. In the absence of the variant classifier, an additional 7/37 pts had non-tumor alterations detected at 4 weeks post-op with a recurrence sensitivity and specificity of 57.1% and 69.6%. ctDNA was identified in 76% [13/17] of pts prior to or at the time of recurrence. The median interval between ctDNA detection and radiographic recurrence was 91 days. Conclusion: Detection of post-op ctDNA, as early as 4 weeks after resection of early-stage lung cancer, is associated with significantly increased risk of recurrence. Accurate detection of ctDNA in this MRD setting is enabled by a highly sensitive sequencing platform that incorporates a novel variant classifier to enhance clinical specificity.

MA23.03 RISK ASSESSMENT FOR INDETERMINATE PULMONARY NODULES USING A NOVEL, PLASMA-PROTEIN BASED BIOMARKER ASSAY

A. Fish1, A. Vachani2, M. Beggs1, L. Carbonell1, Z. Haddad3, A. Jungil1, S. Kamer1, B. Patel1, H. Yu1, A. Wu4, P. Massion5, M. Arjomandi6, J. Brown7, N. Trivedi7, T. Rubenstein7

1Medical Affairs, Magarray, Milpitas/CA/US, 2Pulmonary, Allergy, and Critical Care Division, University of Pennsylvania, Philadelphia/PA/US, 3University of California San Francisco, San Francisco/CA/US, 4Division of Allergy, Pulmonary and Critical Care Medicine, Vanderbilt-Ingram Cancer Center, Nashville/TN/US, 5San Francisco Vamc, San Francisco/US

Background: To reduce overdiagnosis and overtreatment of non-cancerous pulmonary nodules found on CT scans, a noninvasive and easily administered test is needed to assess clinically significant disease risk. Such an assay should also accurately inform whether additional invasive evaluation, including lung biopsy or thoracic surgery, is warranted. Objective: To determine the performance of a novel, plasma-based multiplexed protein test model when compared to the Veterans Affairs Clinical Factors Model (VA model) for discriminating between a lung cancer diagnosis established pathologically and an Indeterminate Pulmonary Nodule (IPN) that could be clinically and radiographically stable for at least one year. Method: The protein biomarker-based risk model had been trained and tested with a cohort of 277 subjects at high risk of lung cancer, aged 25-85, who were current smokers with an indeterminate lung nodule 4-30mm in diameter (121 subject training set; 59 subject test set) from eight medical centers across the US. Using retrospective plasma samples, we compared the protein biomarker model results with the malignant or benign outcomes in an independent validation of 97 subjects from the Vanderbilt University medical center. Result: Among the 97 validation study subjects (average age 60.1 years, range 42-83; average nodule size 16.1mm), the protein biomarker model correctly identified as benign or malignant an additional 44 of the 68 (65%) indeterminate pulmonary nodules classified as having the intermediate risk by the VA model. Negative predictive value was 0.94. Only three patients with malignant disease were missed (94% sensitivity) while an additional 28 intermediate risk samples (41%) were properly classified as true positive, thus potentially avoiding aggressive interventions in those subjects with benign disease. Conclusion: This study evaluated a novel plasma protein biomarker assay model as a noninvasive risk assessment aid for characterizing indeterminate pulmonary nodules. When the model results are combined with the VA model, risk stratification for benign nodules is improved compared to current methods in clinical practice. We hypothesize patients with benign disease may benefit the most from this assay by avoiding unnecessary lung biopsy and subsequent overtreatment, while improving patient quality of care and reducing costs from these procedures. Providers and their patients in whom they suspect lung cancer may consider using this novel assay prior to proceeding with more aggressive interventions.

Background: The incidence and prognosis associated with patients undergoing sub-lobar resections and having positive lymph nodes (PLN) has been rarely studied. Our investigation will retrospectively review this topic. Method: The National Cancer Database(NCDB) was queried during the years 2004-2014 to assess patients undergoing sub-lobar resection (wedge, segmentectomy, and sub-lobar-NOS, N = 38,599) and specifically the patients with PLN (N = 5484). Patients were excluded who had any pre-op chemotherapy and/or radiation. had follow-up of less than 3 months, had stage IV disease or >1 tumor nodules. Multi-variable modeling(MVA) was used to determine the following factors for PLN: age, sex, stage, chemotherapy, and number of nodes positive). Propensity score matching(PSM) was used to determine pre-operative risk factors for PLN in patients having at least one node examined(N=22712) (matched by median number of nodes examined) and to assess the role of PSM in those patients with the matched model (matched by age, sex, stage, chemotherapy, and number of nodes positive). Result: The incidence of PLN decreased progressively during our study from 17.9% in 2004 to 9.4% in 2014 (N=8.3-5.0% and N2.9-6.4%). A lower risk of PLN was noted for squamous cell carcinomas, bronchoalveolar (minimally invasive adenocarcinoma) and right upper lobe tumor, but the risk increased with age, tumor size and clinical stage. In the node positive group, MVA demonstrated that OS was worse with males, older ages, non-Hispanic Whites (compared to Asian and Hispanic Whites), lowest

MA23.06 SMALL RESIDUAL SETUP ERRORS AFTER IMAGE-GUIDED RADIOTHERAPY AFFECT HEART DOSE AND ARE LINKED TO OVERALL SURVIVAL

C. Johnson¹, G. Price², A. McWilliam², C. Fairey-Finn², M. Van Herk²
¹The Christie NHS Foundation Trust, Manchester Cancer Research Centre, Manchester/GB, ²Division of Cancer Sciences, University of Manchester, Manchester/GB

Background: There is limited evidence of the effect of radiotherapy image guidance on survival. This work investigates the relationship between small residual set-up errors following IGRT and overall survival in lung cancer patients (mostly with significant comorbidities), and explores which anatomy may be responsible for observed differences.

Method: Residual setup errors of 546 NSCLC patients treated with an off-line 5mm action threshold correction protocol for bony anatomy were summarized per patient as the mean and standard deviation for each axis, as well as the vector magnitude in a direction from tumour towards the heart, and included in multivariate Cox regression. Delivered dose distributions including residual setup errors were estimated and the difference between the delivered and planned dose was compared for patients who did/did not survive longer than 1 year. Permutation testing (n=1000) assessed significance.

Result: Residual setup errors were not correlated with any pre-treatment clinical variable. Patients with a residual shift towards the heart (mean ~2 mm, max 5mm) have significantly worse overall survival (hazard ratio 1.310, p < 0.001). The average dose in the heart region changes linearly with the residual shift magnitude towards the heart (~0.8Gy/mm). A higher delivered dose than planned in a region at the heart base (Figure 1, arrow) is associated with poorer survival in multivariate analysis (hazard ratio 1.214/Gy, p < 0.001).

Conclusion: Small residual shifts after IGRT are strongly associated with overall survival in NSCLC patients, with shifts of the high dose region towards the heart leading to worse survival. The most likely cause of shorter survival is a corresponding increase in dose to the heart base. This analysis provides direct evidence of the importance of accurate patient positioning and highlights the significance of the heart base as a dose sensitive organ in thoracic radiotherapy patients with early effects on survival.

Keywords: Cardiac toxicity, Image Guided Radiotherapy, non small cell lung cancer

test.png

Figure 1: Data mining results (t-statistics map) of delivered - planned dose vs survival at one year. Axial, coronal and sagittal views of the reference patient CT, with the significance levels overlaid (defined at t-values of 3.9, 3.5, 3.0, 2.6 and 2.2). The most significant region is highlighted in the axial view by the arrow. Patients who did not survive one year had a significantly higher delivered than planned dose in this region. It indicates the base of the heart as responsible for poorer survival.

MA23.07 DEFINING THE ROLE OF ADJUVANT THERAPY FOR EARLY STAGE LARGE CELL NEUROENDOCRINE LUNG CANCER

E. Wakeam¹, S. Stokes², A. Adibfar², N. Leigh³, M. Giuliani², T. Varghese², G. Darling¹
¹Toronto General Hospital, Toronto/CA, ²University of Utah, Salt Lake City/US, ³University of Toronto, Toronto/CA, ⁴Medical Oncology, Princess Margaret Cancer Centre, Toronto/CA, ⁵University of Toronto and Princess Margaret Cancer Center, Toronto/AB/CA

Background: Large cell neuroendocrine lung cancer (LC-NEC) is a rare, high-grade neuroendocrine tumor. Patterns of adjuvant treatment after surgical resection have not been well defined. Method: Patients with a pathologic diagnosis of LC-NEC were identified in the National Cancer Database 2004-2014. Patient demographics, tumor and treatment characteristics were examined. Survival differences in patients receiving chemotherapy were evaluated using Kaplan-Meier curves, and multivariate hierarchical Cox models were constructed to evaluate the impact of patient, histologic, tumor, and hospital characteristics on overall survival (OS). A conditional landmark of 90-day postoperative survival was used to address immortal time bias and propensity-matching was used to address imbalance in covariates between groups.

Result: 1,793 patients were identified with pathologically stage I LC-NEC, of which 482 (26.9%) received adjuvant chemotherapy. Use of adjuvant chemotherapy remained similar across the study period. Patients receiving adjuvant chemo were younger, less comorbid and more likely to have T2 tumors. Significantly longer survival was observed with the receipt of adjuvant chemotherapy (5-year OS 59.2% vs. 45.3%), which persisted after adjustment in multivariable Cox models (HR 0.69, 95%CI 0.58 – 0.82, p<0.0001). Adjuvant chemotherapy was associated with longer survival in patients with tumors 2-3cm (60.4% vs. 41.8%; HR 0.64, 95%CI 0.46–0.89, p<0.0001), and T2 tumors (59.8% vs. 42.1%; HR 0.63, 95%CI 0.50–0.81, p<0.0001), but no differences were observed for LC-NEC patients with tumor size <2cm. Adjuvant chest radiotherapy was not associated with improved survival. T-stage specific propensity-matching confirmed these findings, however the association between survival and adjuvant chemotherapy for patients with tumors 2-3cm was no longer significant.

Figure 1. Kaplan-Meier curves for patients with pt1 tumors <2cm, pt1 tumors 2-3cm and pt2 LC-NEC tumors treated with surgery, with their associated hazard ratios (HR) for death in the derived from adjusted multivariable Cox models, reflecting the hazard for death for patients receiving adjuvant chemotherapy.

pT1 tumors <2cm

5-yr OS 51.0% vs. 57.2%
HR 0.85 95% CI 0.61 – 1.20, p=0.37

(See next page)
those who were done by thoracotomy (Open) in an intent-to-treat analysis. Associations between potential covariates and treatment were analyzed using the Pearson Chi-square test for categorical variables and Wilcoxon Rank Sum test for continuous variables. Univariable and multivariable logistic models and proportional hazards model were used to assess the effect of surgical approach on 30 day and 90 day mortality and overall survival. Relative prognosis was summarized using odds ratios (OR) and hazards ratios (HR) estimates and 95% confidence limits. **Result:** A total of 4,938 patients underwent pneumonectomy during the study period, of which 755 (15.3%) were completed by minimally invasive approaches (MIS). No difference was noted in 30 and 90-day mortality rates for MIS compared to Open approaches (6.8% and 12.3% vs 6.7% and 11.9% respectively, p = 0.9 and 0.86). Tumor histology and stage characteristics were similar between the two groups. Mean lymph nodes examined was higher in the MIS group compared to Open (21 ± 16 vs 16 ± 0.2, p=0.034). Surgical approach was not associated with any difference in perioperative mortality with univariable or multivariable analysis. MIS was associated with improved overall survival on univariable analysis, but this was not evident with multivariable analysis. **Conclusion:** Pneumonectomy performed by minimally invasive approaches does not compromise perioperative mortality or long term outcomes. Further investigation into the impact of minimally invasive approaches on perioperative outcomes for whole lung resection is warranted.

Background: Systematic nodal dissection (SND) is an international standard of lymph node dissection for non-small cell lung cancer (NSCLC). Recently, lobe-specific patterns of mediastinal lymph node metastases have been recognized, and lobe-specific nodal dissection (LSD) has been proposed for early-stage NSCLC. The purpose of this study was to assess the surgical outcomes according to the extent of mediastinal lymph node dissection for patients with NSCLC by using a nationwide registry database. Method: From among 11,663 patients in a Japanese lung cancer registry study for 2004, 5392 patients with clinical stage (c-stage) I or II NSCLC that was completely resected by lobectomy and either SND or LSD were enrolled. Patients who received preoperative therapy or had middle lobe tumor were excluded. In the LSD group, inferior mediastinal (subcarinal) nodes were not dissected for upper lobe tumors, and superior mediastinal nodes were not dissected for lower lobe tumors. To reduce the selection bias, an inverse probability of treatment weighting (IPTW) method using a propensity score was implemented. Result: LSD and SND were performed in 1,258 (23.5%) and 4,124 (76.5%) patients, respectively. LSD group included more c-IA and upper lobe tumors relative to SND group, although there was no significant difference in age and preoperative comorbidity. There was no significant difference in postoperative morbidity and mortality between 2 groups. Extended pathological N2 disease outside LSD area was found in 3.2% of the SND group, but recurrences were not different between 2 groups (all recurrences: 22.0% in LSD, 26.9% in SND; local recurrence: 6.1% in LSD, 7.7% in SND; p=0.788). The 5-year overall survival (OS) was 81.5% in LSD and SND in 75.9%. An IPTW–adjusted Cox model showed that LSD did not have a negative prognostic impact and instead was associated with favorable survival (hazard ratio: 0.68, 95% confidence interval: 0.60–0.77). Conclusion: This retrospective registry study suggested that LSD is an alternative to SND for selected patients with c-stage I or II NSCLC. Future prospective studies are warranted to determine whether LSD is applicable and provides clinical benefit for the general population of patients with c-stage I or II NSCLC.

Background: Accumulation of molecular abnormalities may depict evolution trajectories of tumor initiation and development. However, the genomic profile of early stage adenocarcinoma and molecular mechanism of invasiveness acquisition from pre-invasive to invasive adenocarcinoma remains barely explored. Method: We simultaneously collected 20 patients with adenocarcinoma in situ (AIS) (n=5), minimally invasive adenocarcinoma (MIA) (n=5) and stage IA adenocarcinoma (lepidic/acinar predominant) (n=10). Whole exon sequencing (WES) was performed in pre-invasive adenocarcinoma with multi-region specimens and stage IA adenocarcinoma. Analysis of genomic alteration among different pathological status was performed and tumor mutation burden (TMB) was calculated as well as six mutation types individually. Enriched pathways of each pathology were measured through KEGG analysis. Result: Baseline characteristics was generated through heatmap with smokers (2/20, 10%) and EGFR mutation (13/20, 65%) among whole population. AIS/MIA indicated much lower number of mutations than invasive adenocarcinoma (IAC) while TMB revealed the same trend without statistical significance. Multi-region sequencing showed high heterogeneity of single nucleotide variation (SNV) in AIS and MIA. Unique SNV presented dominant proportion in initial status. Cluster analysis showed higher copy number variation in AIS/MIA than IAC with cell adhesion molecules (CAMs) enriched in AIS/MIA while variety pathway enrichment in IAC through KEGG analysis. C>A transversions held major proportion in early stage adenocarcinoma and a significant increase in the proportion of C>T and C>G mutation was exhibited when evolving into IAC.
Conclusion: Intratumor heterogeneity may occur in the very beginning of adenocarcinoma. High copy number variation was dominant event for AIS/MIA while higher tumor mutation burden was seen in IAC. Tobacco signature encompassing C>A transversions dominates the early development of adenocarcinoma and APOBEC signature may play a potential role in acquisition of cancer invasiveness.

MA24.02 GENOMIC ALTERATIONS IN LUNG ADENOCARCINOMA PRECURSOR LESIONS
M. Asiedu1, N. Reed1, M. Aubry1, A. Roden1, D. Wigle1

Background: Adenocarcinoma in situ (AIS) and minimally invasive adenocarcinoma (MIA) are thought to be precursor lesions of invasive disease. Genomic alterations in these lesions have not been described.

Method: Genomic analysis including whole genome and exome sequencing, and SNP array analysis were performed on 9 AIS and 18 MIA pathologically confirmed samples to identify single nucleotide variants (SNVs), structural variations and copy number variations. Mutation significance and signature analysis were determined by MutSig and NMF analyses. Pathway analysis was performed using ingenuity IPA. Result: The range of mutation burden for AIS and MIA was 0.7 to 12/Mb with a median of 1.7/Mb. This compared to a mean of 7.2/Mb for invasive lung adenocarcinoma. Significantly mutated genes identified in AIS and MIA were ELAVL4, LIN37, XCL1, ELK3, RPS9, FBXO2, HLA-B and MYOG, which affected pathways regulating ERK1, ELAV1 and TP53. Genes with recurrent mutations included MTPN, CDC27, GGT2, CTBP2, EGFR, NCOA1 and TGF1 and implicated EGFR, MYC and MAPK1 pathways. Somatic mutations were characterized by C>T and T>C transition signature, whereas CNV analysis found high concentrations of copy number amplifications at 6p21.3 to 6p22.1, 8q24.12 to 8q24.3 and at 21q22.3. There were comparable structural variations in the AIS cases compared to MIA. Conclusion: In contrast to hypothesized models of tumor progression, AIS and MIA can harbor significant genomic alterations and tumor mutation burden. These observations challenge the notion of accumulating mutation burden during the progression to invasive disease.

The finding of high mutation burden in some of these precursor lesions also suggests the intriguing concept of immunotherapeutic options for either treatment or chemoprevention.

Background: Despite refinement of treatment strategy for non-small cell lung cancer (NSCLC), pathological Stage I NSCLC still develops recurrent disease in approximately 20% of patients even after complete resection. Recently, tumor microenvironment which promotes distant metastasis, or ‘pre-metastatic niche’, has been indicated to play pertinent roles in postoperative recurrence of cancer. Our aim is to investigate biologic profiles of pre-metastatic niche in pathological Stage I NSCLC.

Method: Eighteen (12.7%) of 141 patients with pathological Stage IA or IB NSCLC were analyzed. Tumor biopsies were obtained both at the primary lesion and the pulmonary metastasis. Result: Tumor microenvironment was characterized by elevated expression of matrix metalloproteinase-7 (MMP-7), matrix metalloproteinase-2 (MMP-2), matrix metalloproteinase-9 (MMP-9), matrix metalloproteinase-12 (MMP-12), matrix metalloproteinase-14 (MMP-14), and matrix metalloproteinase-15 (MMP-15) in the primary tumor compared to the metastasis. Conclusion: Tumor microenvironment is characterized by elevated expression of matrix metalloproteinase in pathological Stage I NSCLC, which may play a role in the development of pre-metastatic niche and thus promote the recurrence of lung cancer.
who underwent R0 lobectomy between Jan. 2008 and Dec. 2013 developed distant metastasis postoperatively. From archived formalin-fixed paraffin-embedded specimens, these 18 cases of postoperative distant metastasis and matched cases were selected for total RNA extraction. To overcome inherent bias in selecting control patients, one-to-one matched pairs were created using propensity score matching. The number of grids ranged from 16 to 32 per case, based on tumor size (0.8 cm to 6.5 cm). Digital droplet polymerase chain reaction was used to genotype the sensitizing EGFR-mutation and T790M mutations at each region. Allelic frequencies (AF) of the mutations were measured. Recurrence free interval, defined as surgical resection date to date of recurrence detection, and total duration of therapy were extracted from medical records. From eight cases of TKI-naive mutant lung adenocarcinomas were positive for T790M at baseline. T790M tumor burden, defined as the mean allele frequency of T790M, ranged from 0.17% to 40.15% across the tumors. Three main patterns of distribution were observed. In two cases, T790M was present at low level (<1% AF) prevalence throughout the entire tumor. Five cases were characterized by the presence of distinct sub-clonal region, defined as T790M AF high in one or adjacent regions surrounded by regions with low or zero T790M AF. In one case, T790M was the predominant clone with T790M AF closely matching sensitizing EGFR-mutation AF. T790M tumor burden was not associated with either tumor size or recurrence free interval. Conclusion: T790M tumor cells exist prior to TKI-therapy in a majority, if not all, EGFR-mutated lung adenocarcinoma that developed T790M mutation as the resistance mechanism to EGFR TKI therapy, rather than by de novo acquisition during TKI-therapy exposure. However, pre-treatment T790M tumor burden did not appear to be associated with recurrence free survival, although this requires more cases for confirmation. 

Keywords: Heterogeneity, Resistance, T790M
tumour purity when examining non-coding RNA expression in order to avoid conclusions confounded by immune cells in bulk tumour data. Thus, we provide a resource for further elucidation of genomic links between immune and malignant cells, which may aid the development of future prognostic and therapeutic strategies.

MA24 GENOMIC EVOLUTION, KEAP 3 AND MORE NON-CODING RNA WEDNESDAY, SEPTEMBER 26, 2018 - 10:30-12:00

MA24.07 A NOVEL CIS-ACTING LncRNA CONTROLS HMGAl EXPRESSION IN LUNG ADENOCARCINOMA

Background: High mobility group A1 (HMGA1) chromatin remodeling protein is enriched in several aggressive cancer types, including NSCLC, where mRNA and protein expression are markedly increased. Additionally, high HMGA1 expression has been associated with poor overall survival and chemotherapy resistance. While HMGA1 is deregulated in lung cancer, the mechanisms that mediate its expression are only beginning to emerge. Long non-coding RNAs (lncRNAs), are a class of transcripts that have been implicated in the onset of cancer-associated phenotypes in tumourigenesis and metastasis. Recently, an emerging class of lncRNAs - cis-acting - has been shown to regulate the expression of neighbouring protein-coding genes, including oncogenes and tumour suppressor genes. Thus, lncRNAs may represent novel actionable therapeutic intervention points in known cancer driving pathways. Here we investigate the role of a cis-acting lncRNA, RP11.513I15.6, its deregulation in NSCLC, and its relationship with HMGA1. Method: LncRNA transcriptomes were deduced from RNA-sequences of 36 microdissected tumour and matched non-malignant tissues. Normalized sequence read counts were used to identify transcripts with significantly deregulated expression (Wilcoxon Signed-Rank Test, BH-p<0.05). Sequencing data obtained from The Cancer Genome Atlas were analyzed to validate these results. SIRNA-mediated knockdown of lncRNA candidates identified in these analyses were performed in a non-malignant cell line (epithelial cell line A375). Quantitative PCR quantified the effects of lncRNA knockdown on the expression of neighbouring cancer-associated protein-coding genes. Result: Our analyses identified RP11.513I15.6, an undescribed lncRNA neighbouring HMGA1, to be significantly downregulated in adenocarcinoma (2-fold downregulation in 81.5% of cases). This observation was confirmed in our validation cohort. HMGA1 expression was found to be anticorrelated with RP11.513I15.6, as tumours with downregulated RP11.513I15.6 displayed significant overexpression of HMGA1. This suggested that this lncRNA may be a key negative regulator of HMGA1. In vitro experiments demonstrated siRNA-mediated inhibition of RP11.513I15.6 in immortalized lung epithelial cells resulted in a significant increase in the expression of HMGA1 mRNA and protein. Taken together, our results suggest that RP11.513I15.6 is a novel cis-acting lncRNA that negatively regulates HMGA1, and may contribute mechanistically to the maintenance of cancer phenotypes. Conclusion: We have discovered a novel, 18-fold downregulated transcript that is anti-correlated with expression of HMGA1, a well-established oncogene. In vitro studies support the hypothesis that this transcript, RP11.513I15.6, is a cis-acting lncRNA as siRNA-mediated inhibition led to upregulation of neighbouring HMGA1. Characterizing this oncogene regulatory mechanism will not only further our understanding of cancer biology, but could uncover a novel therapeutic intervention point.

MA24.10 INTERROGATING THE METABOLIC EFFECTS OF KEAP1 INACTIVATION IN ADENOCARCINOMA

S. Best1, S. Ding1, A. Kersbergen1, B. Reljic2, K. Sutherland1

1Acrf Stem Cells and Cancer Division, The Walter and Eliza Hall Institute of Medical Research, Melbourne/VIC/AU, 2Cell Signaling and Cell Death Division, The Walter and Eliza Hall Institute of Medical Research, Melbourne/VIC/AU

Background: The lung is a highly oxidative environment, tolerated through the engagement of tightly controlled stress response pathways. A critical stress response mediator is the transcription factor Nuclear Factor Erythroid-2-Related Factor 2 (NFE2L2/NRF2), which is negatively regulated by Kelch-like ECH-Associated Protein 1 (KEAP1). Alterations in the KEAP1/NRF2 pathway have been identified in 23% of lung adenocarcinomas, suggesting that deregulation of the pathway is a major driver in lung cancer. Method: We generated a novel genetically engineered mouse model (GEMM) whereby Keap1 (Keap1fl/fl and Pten (Ptenf/f)) were conditionally deleted in the lung, utilising intranasal inhalation of Adenovirus-Cre. The effects on lung pathology were investigated using histopathology, metabolomics and flow cytometry. Result: We found that, while loss of Keap1 alone displayed no abnormalities in the lung, loss of Keap1 combined with loss of the tumour suppressor Pten, promoted malignant transformation. We further monitored tumour progression and immune infiltration in the lung, and metabolite profile changes in the serum of the Keap1fl/flPtenf/f mouse model. Notably, a tumour-specific metabolite signature was identified in the plasma of Keap1fl/flPtenf/f tumour-bearing mice, which indicated that tumourigenesis is associated with metabolic dysregulation. Furthermore, the immune milieu was dramatically changed by Keap1 and Pten deletion, and tumour regression was achieved utilising immune checkpoint inhibition. Conclusion: Our study highlights the ability to exploit both metabolic and immune characteristics in the detection and treatment of lung adenocarcinomas harboring KEAP1/NRF2 pathway alterations.

Background: Synchronous oligometastatic disease (sOMD) has been described as a separate disease entity; however there is no consensus on what specific criteria constitutes sOMD in NSCLC. A consensus group (CG) was formed aiming to agree on a common sOMD definition (sOMD-d) that could be used in future clinical trials. A European survey was circulated to inform the discussion on sOMD-d. Method: An EORTC Lung Cancer Group (LCG) / EORTC-d CG survey containing 31 questions on sOMD-d was distributed between 14/12/17 and 19/02/18 to EORTC LCG, sOMD-d participants, and several European thoracic oncology societies’ members. Result: 444 responses were analyzed (radiation oncologist: 55% [n=242], pulmonologist: 15% [n=66], medical oncologist: 14% [n=64], 78% with >5 years’ experience in treating NSCLC). Belgium (14%, n=62), Italy (12%, n=55), Germany (11%, n=47), and Netherlands (10%, n=44) contributed most. 39 (36%) physicians were interested in research to cure sOMD NSCLC patients and 82% (n=361) included the possibility to treat the patient with radical intent in their sOMD-d. The maximum number of metastases considered in sOMD-d varied: 19%, 42%, 4%, and 17% replied <2, 3, 4, and ≥5 metastases, respectively, 79% (n=353) stated that the number of organs involved was important for sOMD-d, and most (80%, n=355) considered that ≤3 involved organs (excluding primary) should be included in the definition. 317 (71.7%) allowed mediastinal lymph node involvement (MLN) in the sOMD-d, and 22.1% of them counted MLN as a metastatic site. For 195/327 (60%), when N2/N3 disease is included in the sOMD-d, there is no specific issue regarding the MLN volume/ location as long as radical treatment is possible. 384 (86%) considered pulmonary metastasis (outside primary tumour; M1a) as metastatic site. Most physicians considered sOMD patients with brain MRI (91%, n=403) and PET-CT (98%, n=437) for mediastium staging, most (64%, n=285) respondents stated that histology/cytology should be obtained when PET-CT shows suspected lymph nodes or in case of a central primary tumour. Pathological proof of NSCLC metastatic disease that was necessary in sOMD-d for 315 (71%) physicians, and 37% (n=163) acknowledged that histology should be obtained from at least from one metastatic site. Preferred primary outcome parameter in clinical trials of sOMD was overall survival (OS; 50%, n=325). Conclusion: Despite certain consensus criteria being obtained (81% aimed to cure and >90% mandated baseline imaging with PET-CT and brain MRI), a number of issues remain unresolved and will require further discussion by a panel of experts to agree on a sOMD-d.

Background: Synchronous oligometastatic NSCLC definition varies between: 1) metastasis in 1 organ (TNMB), 1-3 metastases (ESMO), ≤3 metastases after systemic treatment with mediastinal nodes (MLN) counting as 1 site (Gomez, Lancet Oncol 2016) to 3-5 metastases in ongoing trials. A single definition is however needed to design and compare trials. To assess synchronous oligometastatic NSCLC definitions used by clinical experts in daily practice and its evolution, we redistributed a 2012-case based survey (Dooms et al, presented at WCLC 2013). Method: In December 2017, 10 real-life multidisciplinary treatment (MDT) discussed patients (all good condition, no significant comorbidities, 18FDG-PET and brain MRI staged, all ≤5 metastases, 9/10 ≤3 metastases, oncogene-addicted or wildtype NSCLC) were distributed to 33 international NSCLC experts involved in the EORTC oligometastatic NSCLC consensus group, questioning: 1) can you discuss these cases in your MDT?, 2) do these patients have oligometastatic disease? and 3) what is your treatment proposal for the oligometastatic disease patients? Current answers were compared to the previous ones, and the real-life treatment and survival of the patients was added. Result: 26/33 experts (24 centers) replied: 8 medical oncologists, 7 pulmonologists, 7 radiation oncologists, 4 thoracic surgeons. 62% discussed the cases in their MDT. 1 case had 100% oligometastatic disease consensus, 3 cases had >90% consensus, the number of treatment proposals varied between 3 to 8 (Table). Conclusion: Synchronous oligometastatic NSCLC definition was more conservative than in 2012 and linked to radical intent of treatment. Number of organs, MLN status and possibility for radical treatment seem to be components of daily practice synchronous oligometastatic definition.

MA25.05 CHARACTERISTICS & SURVIVAL OF RESECTED STAGE IV NON-SMALL CELL LUNG CANCER (NSCLC) IN THE MID-SOUTH QUALITY OF SURGICAL RESECTION COHORT
N. Faris1, Y. Lee2, M. Smeltzer2, M. Ray2, C. Fehnel1, C. Houston-Harris1, N. Akinbobola1, P. Ojeabulu1, E. Owen1, R. Eubanks1, H. Dox1, T. Talton1, G. Valaulikar1, H. Wiggins1, B. Wolf1, P. Levy1, E. Robbins1, R. Osarogiagbon1

Background: Surgical resection is potentially curative in subsets of oligometastatic NSCLC. We evaluated the characteristics and survival of resected stage IV NSCLC in a population-based cohort. Method: Patients were included who had curative-intent resections from 11 hospitals in 4 contiguous Dartmouth Hospital Referral Regions in the mid-Southern USA from 2009-2018. Statistical analyses were performed using univariate and multiple Cox regression models. Result: Of 3092 resections, 96 (3.1%) were stage IV: 38 M1a, 54 M1b, and 4 M1c. Of the M1a patients, 1 had a pleural effusion, 37 had a contralateral lung nodule. The most common sites of extrathoracic metastasis were bone (13 (13.5%)), and brain (25 (26%)). Other extrathoracic sites were distant lymph nodes, liver, adrenals, thyroid, pancreas, colon, soft tissue, and esophagus. Stage IV patients had a younger median age (63 vs 67 (p<0.0001)), less Medicare coverage but more Medicaid or Commercial insurance (p=0.0248), fewer comorbid conditions (p=0.0096), higher Cf (p=0.0001), and higher-grade tumors (p=0.0002). 58% (22) of M1a patients did not receive treatment to the site of metastatic disease, compared to 72% (39) and 75% (3) of M1b and M1c, respectively (p=0.0086). For patients with bone metastases, median/5 year survival was 1.28 years/0%, compared to 5.16 years/51% for other metastatic sites and 6.39 years/56% for non-stage IV NSCLC (p=0.0058) (Figure 1). In fully adjusted models, survival for Stage IV patients without bone metastasis did not differ significantly from Stage I-III patients (HR: 1.3, p=0.15). However, Stage IV patients with bone metastasis had significantly worse survival (HR:3.2, p=0.0006).

MA25.06 RPA ANALYSIS FOR OLIGOMETASTATIC NON-SMALL CELL LUNG CANCER: SMOKING COMBINE T3/4 PATIENTS MAY NOT BE BENEFIT FROM LOCAL CONSOLIDATIVE TREATMENT

J. Zhang, Y. Tang, S. Liu, S. Dong, X. Yang, Y. Wu, W. Zhong
Guangdong Lung Cancer Institute, Guangdong General Hospital and Guangdong Academy of Medical Sciences; Southern Medical University., Guangzhou/CN

Background: In the literature on oligometastasis, the relative importance of local consolidative treatment (LCT) has been gradually accepted. This study set out to investigate the prognosis heterogeneity and the effect of LCT for oligometastatic non-small cell lung cancer patients.

Method: We identified 436 patients in Guangdong General Hospital (GGH) from 2009 to 2016 with oligometastatic disease, and the factors predictive of overall survival (OS) were evaluated using Cox regression. Risk stratifications were defined using recursive partitioning analysis (RPA) on training set (2009–2014), which were further confirmed on validation set (2015–2016). And the effect of LCT for different risk groups was further examined by Kaplan-Meier method.

Result: Factors predictive of OS were: T stage (p=0.001), N stage (p=0.008), metastatic sites (p=0.031) and EGFR status (p=0.043). Prognostic risk RPA model was established, 4 risk groups were identified: Group I, never smokers and N0 disease (3-year OS: 55.6%, median survival time (MST)=42.8m); Group II, never smokers and N+ disease (3-year OS: 32.8%, MST=26.5m); Group III, smokers and T1/T2 disease (3-year OS: 23.3%, MST=19.4m); and Group IV, smokers and T3/T4 disease (3-year OS: 12.5%, MST=11.1m). Among four groups, OS significant differences were observed according to LCT except group IV (p=0.45).

Conclusion: This retrospective study identified the poor prognostic population (smoking combine T3/4 disease) of oligometastatic non-small cell lung cancer patients, and this population may not be benefit from local consolidative therapy.

**MA25.07 EFFECTIVENESS OF SYSTEMIC THERAPY COMBINED WITH THORACIC RADIOTHERAPY FOR PATIENTS WITH OLIGOMETASTATIC NSCLC: A POOLED ANALYSIS**

J. Wang, X. Lu, L. Wang
Radiation Oncology, Cancer Hospital, Chinese Academy of Medical Sciences, Beijing/CN

**Background:** Local therapy combined with systemic therapy for oligometastases or oligo-recurrence (≤ 5 lesions) in NSCLC has become one of the hottest spots in recent years. At present, there is lack of results from randomised phase III trial in this regard. Therefore, we performed a pooled analysis, aiming to evaluate the effectiveness of the combination of systemic therapy and local thoracic radiotherapy for patients with oligometastatic NSCLC. **Method:** Computerized search of the Pubmed database was performed using the following key words: non-small cell lung cancer, metastasis, stage IV, thoracic radiation. Abstracts were ruled out. In addition, we also reviewed the references listed in the identified articles and included eligible studies for integrity of the literature search. Combination therapeutic modality should include systemic therapy (chemotherapy or targeted therapy) and thoracic radiotherapy. Authors with more than 1 publication involving the same study population were included only once, and the one with most relevant and complete data were included. Literature retrieval was terminated by April 2018. All the analysis was performed in the Stata/SE 12.0. **Result:** A total of 32 articles with full text were retrieved in our initial literature search. After reviewing these articles and corresponding references, 16 studies (9 retrospective studies vs. 7 prospective phase II studies) with a total of 791 oligometastatic NSCLC patients were finally identified as eligible for this analysis. The median progression free survival (PFS) ranged from 6.6 to 16.0 months and median overall survival OS ranged from 10.0 to 27.1 months. Four studies involving 256 patients reported the post-radiotherapy response, resulting in a pooled objective response (CR + PR) rate of 58% (95% CI: 0.41, 0.76). A total of 3 studies involving 168 patients provided comparison data on PFS between systemic therapy alone and systemic therapy plus thoracic radiotherapy, leading to a pooled hazard ratio (HR) of 0.42 (95% CI: 0.28, 0.64) for the combined modality group. **Conclusion:** Consolidation thoracic radiotherapy as an addition to systemic therapy may offer significant outcome benefits for oligometastatic NSCLC, leading to a numerically comparable response and survival to locally advanced NSCLC. Results from phase III randomized controlled trials are awaited. **Keywords:** oligometastatic non-small cell lung cancer, pooled analysis, thoracic radiotherapy

**MA25.09 M1B DISEASE IN THE 8TH EDITION OF IASLC STAGING OF LUNG CANCER: PATTERN OF SINGLE EXTRATHORACIC METASTASIS AND CLINICAL OUTCOM**

**Background:** The 8th edition of IASLC staging of lung cancer has revised M classification and defined M1b disease for single extrathoracic metastasis, which is distinguished from M1c with multiple extrathoracic metastases. We investigated the prevalence of M1b disease in stage IV NSCLC patients (pts), and studied the pattern of single extrathoracic metastasis and its relationship with overall survival (OS). **Method:** 567 pts with stage IV NSCLC (236 males, 331 females, median age: 63) diagnosed in 2008-2012 were reviewed to determine M stage according to the 8th edition of IASLC staging of lung cancer (M1a: separate tumor nodules in a contralateral lobe, pleural/pericardial nodule or effusion; M1b: single extrathoracic metastasis; M1c: multiple extrathoracic metastasis in one or more organs). Clinical characteristics and OS were compared according to M stage. **Result:** Among 567 pts, 57 pts (10%; 95%CI: 7.6-13%) had M1b disease with single extrathoracic metastasis, while 119 pts (21%) had M1a and 391 pts (69%) had M1c disease. Squamous histology was more common in M1b (9/57; 16%) than in M1a (7/119; 6%) and M1c pts (22/391; 6%) (Fisher P=0.03). The median OS of M1b pts was 14.8 months (95%CI: 12.7-16.9 months), compared to 22.7 months (95%CI: 18.5-31.6 months) for M1a and 13.4 months (95%CI: 11.8-15.3 months) for M1c pts (log-rank P < 0.0001). Among 57 M1b pts, brain was the most common site of single metastasis (n=28; 49%), followed by bone (n=16; 23%), lymph node (n=11; 16%), liver (n=3; 5%), muscle (n=2; 4%), and aortic node (n=1; 2%). M1b pts with liver metastasis had shorter OS than others (median OS: 8.1 vs. 16.1 months, log-rank P=0.046). Single metastasis in M1b pts were locally treated in 31 pts (54.5%). Brain metastasis was more frequently treated with local treatment than others (26/28, 92.9%vs. 5/29, 17%; p<0.0001). **Conclusion:** M1b disease was noted in 10% of stage IV NSCLC pts. Squamous histology was more common in M1b than in M1a and M1c groups. Brain was the most common site of single metastasis and was often treated locally. Single liver metastasis in M1b disease was associated with shorter OS. The study characterized the unique clinical features of the new category of M1b disease among stage IV NSCLC.

**Background:** Evidence is rapidly accumulating for the use of radical treatment approaches for patients with oligometastatic Non-small cell lung cancer (NSCLC). Several limitations remain, however, to further strengthen the use of radical therapy as opposed to standard maintenance therapy, including a lack of robust markers to predict patient response. In this study, we assessed the utility of reaching a complete response (CR) by PET-CT in patients with oligometastatic disease after radical treatment. **Method:** From 2012 to 2017, 56 patients who underwent radical treatment (surgery, radiotherapy, chemotherapy plus radiotherapy, radiofrequency and SBRT alone or in any combination) were included. Response to radical treatment was evaluated by PET-CT, Maintenance treatment was permitted. **Result:** 37 patients were included in the analysis. Mean age was 52.7. At diagnosis 43.2% of patients presented with CNS metastases. After 4 cycles of first-line therapy, 100% of patients received treatment to the primary site, while 83.8% also received therapy to metastases. Following radical treatment, 19 (51.4%) patients achieved a CR by PET-CT, while 18 (48.6%) had a partial response (NON-CR). Median PFS was 26.2 months (95%CI 12.2-40.1), and was positively affected by CR by PET-CT (NR vs. 14.3 [95%CI 11.9-16.7]; p<0.001). Median overall survival (OS) was NR. OS was also positively affected by CR by PET-CT (42-month survival: 82.5%±18 for CR vs. 34.4%±28 for NON-CR by PET-CT; p=0.01). **Conclusion:** Patients with oligometastatic NSCLC who undergo radical treatment and reach a CR by PET-CT show a significant improvement in survival outcomes. Our results suggest that CR by PET-CT could serve as a surrogate marker for prolonged survival in this patient subgroup.

Background: Brain metastases (BM) develop in ~45% of patients with EGFR mutant (EGFRm) non-small cell lung cancers (NSCLC). There are limited reports on clinical/molecular factors associated with BM outcomes after radiotherapy in EGFRm NSCLC patients. Method: We identified patients with EGFRm NSCLC who presented with or developed BM and had their tumor resected. Clinical, demographic and TP53 status were collected from medical/pathology records. Whole-Exome Sequencing of the primary tumor was performed. Overall survival (OS) and intracranial progression (IP) were defined from start of BM treatment and correlated with clinical/molecular features. IP was defined from the date of BM treatment until any brain failure, either local (previously untreated) or intracranial. Results: Of 41 eligible patients with BM, 9 were excluded due to sequencing problems. Of the 32 remaining patients, 20 (62%) had their BM treated with WBI (15 WBI alone and 5 TKIàWBI), 12 (38%) with TKI±SRS (9 TKIàSRS; 3 SRS alone). Median age at BM was 59.5 years (median 2.5y). Most patients (72%) were female (81%), non-smoker (78%), non-Asian (62%) and 50% presented as stage III or higher at diagnosis. An EGFR exon 19 mutation was present in 72% of patients, 25% had 2 or more EGFRm, 15% with additional driver mutations and 53% with TP53 co-mutation. At a median follow-up of 1.21y, no clinical/molecular factors (treatment, age, gender, ethnicity, smoking status, stage at presentation, EGFR exon 19 versus 21, number of EGFRm, additional driver mutations, TP53 co-mutation) correlated with survival. There was a trend for longer survival for patients treated with TKI±SRS (median 3.4y) compared to WBT±TKI (median 1.4y): p = 0.08 and for age at BM ≤59.5y (median 2.5y) compared to >59.5y (median 1.4y): p = 0.2. Higher risk of IP was observed in younger patients (age as continuous variable) with HR of 0.94(95%CI 0.88–1.0), p = 0.04; favoring older patients and remained significant after accounting for treatment modality on multivariate analysis p = 0.03. No additional clinical/molecular factors correlated with IP. Conclusion: In our study, younger age at BM treatment was associated with higher risk. We also observed a trend for longer OS for younger patients (<59.5y) and for patients treated with TKI±SRS. Our data suggest that younger patients with EGFR BM should undergo close intracranial follow up and that future studies to define the benefit of brain-directed multimodality treatment are warranted.

Keywords: lung adenocarcinoma, brain metastases, Genomics
Background: Anaplastic lymphoma kinase (ALK) rearrangement confers sensitivity to ALK inhibitors (ALKis) in non-small-cell lung cancer (NSCLC). Although several drugs provided an impressive outcome benefit, the most effective sequential strategy is still unknown. Method: We retrospectively collected 242 ALK-positive advanced NSCLC diagnosed between 2010 and 2018 in 23 Italian institutions (expanded data collection from Gobbini et al. Lung Cancer 2017). 138 patients received exclusively crizotinib as ALKis (not considered for this analysis). 78 patients received crizotinib and a new (second or third) generation ALKis as further treatments (group A); 26 patients performed a new generation ALKi as upfront agent (group B). These groups are larger than those considered in a previous analysis (15 and 8 patients, respectively). Result: Study population clinical features and treatments received are summarized in Table 1 (next page).

Group A Crizotinib followed by new generation ALKis N=78

With a median follow-up of 22.6 months (CI 95% 20.09-25.10), 33 patients had died (32%). In group B, the median progression free survival (PFS) for new generation ALKis administered as first (14.0 months, CI 95% 9.52-18.47), second (12.7 months, CI 95% 7.22-18.17) or third-line (12.8 months, CI 95% 6.24-19.35) was not statistically different (p= 0.522). The median time from the start of crizotinib to the disease progression after the new generation ALKI sequentially performed (group A) was longer than that one detected in group B for the upfront new generation ALKIs (29 vs 14 months, HR 2.47 [CI95% 1.35-4.50], p=0.003). This result was confirmed even considering the time lost between the two treatments in group A. The median overall survival (OS) was not reached. The 12-months OS rate was 97% in group A and 84% in group B. Conclusion: New generation ALKIs maintain their efficacy regardless of the treatment setting considered. The sequential strategy seems to provide a substantial benefit, but a longer follow-up and larger samples are needed to clarify the survival impact.

Ma26.03 Activity of Osimertinib and the Selective RET Inhibitor BLU-667 in an EGFR-Mutant Patient with Acquired RET Rearrangement

Z. Piotrowska1, H. Isozaki1, J. Lennerz1, S. Digumarthy1, J. Gainor1, N. Marcoux1, M. Banwait1, D. Dias-Santagata1, A. J. Iafrate1, M. Mino-Kenudson1, R. Nagy2, R. Lanman2, E. Evans3, C. Clifford4, B. Wolf4, A. Hata5, L. Sequist6

1Massachusetts General Hospital, Boston/MA/US; 2Guardant Health, Redwood City/CA/US; 3Blueprint Medicines Corporation, Cambridge/US

Background: The spectrum of acquired resistance (AR) to osimertinib is not yet fully characterized. We present a single-center cohort of osimertinib AR biopsies and results of a patient with RET-mediated AR treated with the investigational RET-specific TKI BLU-667 and osimertinib.

Method: We assayed tissue via SNaPshot or Foundation One next-generation sequencing (NGS) and plasma via Guardant360 NGS under an IRB-approved protocol. In vitro studies assessed implications of RET fusions in EGFR-mutant cancers. We treated one patient with osimertinib/BLU-667 using an IRB and FDA-approved compassionate use protocol.

Result: 41 EGFR-mutant patients with AR to osimertinib were assessed histologically and queried by tissue NGS (n=22), plasma NGS (n=9) or both (n=10). Key AR findings: SLC7A12 rearrangement (2/32 tissue); EGFR C797S (5/32 tissue, 5/19 plasma, all cis with T790M); MET amplification (7/32 tissue, 3/19 plasma); BRAF rearrangement (2/32 tissue) and CCDC6-RET rearrangement (1/32 tissue, 1/19 plasma [distinct case]).

CCDC6-RET was expressed in PC9 (EGFR del19) and MGH134 (EGFR L858R/T790M) cells, which maintained MAPK signaling and conferred resistance to osimertinib and astatin. Inhibition of RET by BLU-667 or cabozantinib resensitized cells expressing CCDC6-RET to EGFR inhibition.
A 60-year-old woman with EGFR del19 progressed on afatinib (T790M+), then osimertinib. Tissue biopsy at osimertinib AR showed acquired CCECG-RET (T790-wt). She began osimertinib 80mg/BLU-667 200mg daily x 2 weeks, then BLU-667 was increased to 300mg daily. Her dyspnea improved within days of initiation. Scans after 8 weeks revealed a marked response with RECIST tumor shrinkage of 78% (Figure). She experienced only grade 1 toxicities of fatigue, leukopenia, hypertension, dry mouth, and elevated transaminases.

**Conclusion:** RET rearrangements are rare but recurrent in EGFR-mutant patients with AR to osimertinib. In vivo models suggest they mediate AR and this patient provides proof-of-concept that combination EGFR+RET inhibition with osimertinib/BLU-667 is a well-tolerated and effective regimen for RET-mediated AR. Further study is ongoing.

**MA26.05 COMPREHENSIVE ANALYSIS OF TREATMENT RESPONSE AND PROGRESSION PATTERN IN CHINESE PATIENTS WITH DIFFERENT ALK FUSION-VARIANTS**

M. Qiao¹, C. Zhao¹, X. Li¹, T. Jiang¹, F. Wu¹, X. Chen¹, C. Su¹, C. Zhou²
¹Department of Medical Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN

**Background:** ALK inhibitors and chemotherapy are two major strategies in the treatment of patients with ALK-rearrangements in China. However, the respective treatment response varies and heterogeneous. This study aimed to comprehensively analyze the impact of ALK variants on different treatment response and explore progression pattern respectively.

**Method:** We retrospectively analyzed a cohort of 135 patients with determined ALK variants and medical record from January 2013 to July 2017 in Shanghai Pulmonary Hospital. **Result:**

The most frequent ALK variant was variant 1 in 62 patients (46%), followed by variant 3a/b in 52 patients (38%) and variant 2 (12%). 69 (51.1%) of patients received chemotherapy, whereas 64 (47.4%) were treated with crizotinib and 2 (1.5%) with alectinib. The similar PFS was observed in patients ALK variant 1 and non-variant 1 regardless of first-line treatment strategy (crizotinib: 15.7 vs. 12.8 months, p=0.53; chemotherapy: 5.7 vs. 8.1 months, p=0.098). However, in the subgroup analysis, patients with ALK variant 1 and baseline brain metastasis had significantly shorter PFS in the first-line setting versus non-variant 1 (4.9 vs. 11.3 months, HR=2.96, p<0.01). Additionally, ORR was 21.6% and 50% in variant 1 and non-variant 1 patients with brain metastases, respectively. Moreover, in the analysis of progression pattern, 55 patients with ALK variant 1 and 57 patients with ALK non-variant 1 exhibited PD.

As to ALK variant 1, the incidence of CNS relapse in patients treated with crizotinib was significantly higher than patients treated with chemotherapy (39.3% vs. 7.4%, p=0.005). In terms of ALK non-variant 1, the patients treated with chemotherapy had higher incidence of bone progression than patients treated with crizotinib (25% vs. 0%, p=0.021).

**Conclusion:** Our results firstly indicate the treatment-naïve patients with ALK variant 1 and baseline brain metastasis have inferior response to initial cancer treatment. Different ALK variants have distinct landscape of progression pattern when treated with crizotinib or chemotherapy.

Conclusion:

but not according to local testing (HR=1.7; 95% CI=0.45-6.2; p=0.44).

survival was significantly better for concordant cases than discordant cases. There was no significant association with sex, stage or smoking status.

not differ for concordant nor discordant cases, and neither for local nor central validation. In particular, our findings suggest that staining intensity in 2+ intensity level was high in interpreting ROS1 (SP384) in NSCLC samples.

Background:

Metastasized NSCLC with an ALK fusion are sensitive to a range of tyrosine kinase inhibitors. ALK-positive NSCLC has been identified in the pivotal phase III trial with fluorescence in situ hybridization (ALK FISH+). These tumors are also expressing the fusion product (ALK IHC+), which can be confirmed by ALK IHC+ and ALK FISH+. These tumors are also expressing the fusion product (ALK IHC+), which can be confirmed by ALK IHC+ and ALK FISH+.

Case: Fifteen centers participated. Registration of 3523 ALK IHC tests revealed 26 Department of Pathology, Antwerp University Hospital, Antwerp/BE, 27 Dept. of Pathology, Gazi University, Ankara/TR, 22 Center for Integrated Oncology (CIO), Universitätsklinikum Köln, Köln/DE, 23 Institute of Pathology, University Hospital Basel, Basel/CH, 24 Pfizer, Berlin/DE, 25 Department of Pathology and Medical Biology, Gria Research Institute, University of Groningen, University Medical Center Groningen, Groningen/NL, 26 Department of Pathology, Antwerp University Hospital, Antwerp/BE, 27 Dept. of Thoracic Oncology, Netherlands Cancer Institute, Amsterdam/NL

MA26.07 ROS1 (SP384) IMMUNOHISTOCHEMISTRY INTER-READER PRECISION BETWEEN 12 PATHOLOGISTS

1Ventana Medical Systems, Tucson/US, 2INSITITUTE OF PATHOLOGY, University Hospital Basel/CH, 3Département d'Histopathologie, Cliniques Universitaires de Bruxelles, Brussels/B, 4Histogenex, Antwerp/BE, 5Department of Pathology, VU University Medical Center, Amsterdam/NL, 6VU University Medical Center, Amsterdam/NL, 7Hospital Sanchinarro, Madrid/ES, 8Department of Pathology, University Hospital Cologne, Cologne/DE, 9Department of Pathology, University of Aberdeen, School of Medicine and Dentistry, Aberdeen/GB, 10Histogenex, Antwerp/BE, 11Centre Jean Perrin, Claremont-Ferrand/FR, 12Hospital Sanchinarro, Madrid/ES, 13Pathology Unit, Azienda Della Ricerca - Hospital S. Maria delle Croci, Ravenna/IT, 14Pfizer, Berlin/DE, 15Department of Histopathology, Royal Brompton and Harefield NHS Foundation Trust, Brentford/GB, 16Pathology, Istanbul University, Cerrahpasa Medical Faculty, Istanbul/TR, 17Department of Pathology, Antwerp University Hospital, Antwerp/BE, 18Department of Pathology, VU University Medical Center, CiNL, 19Ventana Medical Systems, Tucson/AZ/US, 20Roche Diagnostics France, Meylan/FR

Background:

ROS1 positivity is often clinically detected by fluorescence in situ hybridization (FISH), however ROS1 IHC can be used to screen samples prior to FISH confirmation of ROS1 status. The ROS1 (SP384) antibody detects ROS1 (SP384) protein with sensitivity, specificity, and consistency. Consistent interpretation of a ROS1 IHC assay between pathologists is important patient evaluation. Here we present inter-reader precision of 12 pathologists across 60 FFPE cases stained with ROS1 (SP384).

Method:

A retrospective cohort of 60 FFPE NSCLC cases stained with Human Monoclonal IHC 3969SP (Ventana Medical Systems, Tucson/US) was included. ALK-positive cases were selected to represent positive, negative, and borderline ROS1 IHC status. Twelve practicing lung pathologists independently scored the cases as positive or negative around a cutoff of cytoplasm staining in > 30% tumor cells at a ≥ 2+ intensity level using Pathotrainer software (Pathomation bvba). Scoring was blinded to other readers and ROS1 status of the cases. Overall percent agreement (OPA), negative percent agreement (NPA), and positive percent agreement (PPA) were calculated in comparison to the group result. Average overall percent agreement (AOPA), average positive agreement (APA), and average negative agreement (ANA) were calculated pairwise for each reader pair. Following independent assessment, participating pathologists conducted a discordant case review establishing consensus reads for all 60 cases and compared 44 cases to available FISH results. Cases selected to represent positive or negative around a cutoff of cytoplasm staining in > 30% tumor cells at a ≥ 2+ intensity level using Pathotrainer software (Pathomation bvba). Scoring was blinded to other readers and ROS1 status of the cases. Overall percent agreement (OPA), negative percent agreement (NPA), and positive percent agreement (PPA) were calculated in comparison to the group result.

Case: Fifteen centers participated. Registration of 3523 ALK IHC tests revealed 44 concordant (ALK IHC+/FISH+) and 18 discordant (ALK IHC+/FISH-) cases. Central validation revealed 37 concordant and 6 discordant cases and staining patterns to be considered when interpreting ROS1 (SP384) IHC.

Patients with advanced and metastatic NSCLC who had progressed after treatment with EGFR-TKIs with/without asymptomatic brain metastases (BM) were enrolled in an open-label, multicenter, phase I/II study with dose-escalation and expansion cohorts. Lazzertinib was administered once daily at doses between 20 to 320 mg in a 21-day cycle. Patients were assessed for safety, tolerability, pharmacokinetics and efficacy. T790M status was confirmed in the dose-expansion cohorts. Result: A total of 115 patients (median age 62 years, female 62%) were enrolled. The dose-escalation cohort included 38 patients administered with 20 to 320 mg across 5 dose levels. No dose-limiting toxicities were observed in the dose-escalation cohort. Systemic exposure increased dose-dependently. Of the evaluable patients (n=110) at data cut-off, the objective response rate (ORR) was 65% (95% confidence interval [CI], 54.9 to 73.4). The ORR for 93 of the T790M+ patients was 65% (95% CI, 54.9 to 73.4). In patients with BM (n=12), the intracranial ORR was 50% (95% CI, 21.1 to 78.9). The most common treatment-emergent adverse events (AEs) were pruritus (19%), decreased appetite (17%), rash (14%), and constipation (12%). The most frequently reported TEAEs of grade ≥ 3 were hyponatraemia (2%), nausea (2%) and pneumonia (2%).

**ORR in T790M+ patients**

* Patients were deemed evaluable for response if they underwent a post-baseline radiological assessment (RECIST 1.1) or were discontinued prior to the post-baseline assessment.

**Conclusion:** Lazzertinib was safe, well-tolerated and exhibited promising systemic and intracranial antitumor activity in EGFR T790M+ NSCLC patients. The dose-escalation cohort as the first and second-line setting has been initiated from April 2018.

**Keywords:** Lazzertinib, T790M, 3rd generation EGFR TKI

---

**MA26 NEW THERAPIES AND EMERGING DATA IN ALK, EGFR AND ROS1 WEDNESDAY, SEPTEMBER 26, 2018 - 13:30-15:00**

**MA26.10 CNS ACTIVITY OF RAMUCIRUMAB IN COMBINATION WITH OSIMERTINIB IN PATIENTS WITH ADVANCED T790M-POSITIVE EGFR-MUTANT NSCLC**

1Hospital Universitario 12 de Octubre, Madrid/ES; 2Medical Oncology, Gustave Roussy, Villejuif/FR; 3National Taiwan University, Taipei City/TW; 4Chungbuk National University Hospital, Cheongju/KR; 5Hospital Universitario Ramon y Cajal, Madrid/ES; 6Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul/KR; 7Yonsei Cancer Center, Yonsei University Health System, Seoul/KR; 8Department of Oncology, University of Ulsan College of Medicine, Asan Medical Center, Seoul/KR; 9Eli Lilly and Company, Indianapolis/US; 10Eli Lilly and Company, New York/US; 11Memorial Sloan Kettering Cancer Center, New York/NY/US

**Background:** Many patients with NSCLC develop central nervous system (CNS) metastasis. Osimertinib, a novel third-generation EGFR tyrosine kinase inhibitor (TKI), has previously demonstrated CNS and systemic efficacy in patients with EGFR-mutant NSCLC. Combination of an EGFR TKI with a VEGF/VEGFR2-directed monoclonal antibodies (mAb) have shown promising results in EGFR-mutant NSCLC. Ramucirumab, human IgG1 VEGF/VEGFR2-directed monoclonal antibodies (mAb), has been shown in phase 1/2 studies to improve CNS outcomes. The current study evaluated the eficacy of ramucirumab+osimertinib in patients with CNS metastasis.

**Method:** In this ongoing, open-label, multicenter Phase 1 study (NCT02789345), patients with T790M-positive EGFR-mutant (Ex19del or L858R) NSCLC who had relapsed after first-line EGFR TKI therapy were enrolled. Patients with asymptomatic and stable CNS metastasis (with/no prior radiotherapy) were eligible. Primary objective of the study was to assess safety and tolerability of ramucirumab+osimertinib. Secondary endpoints include objective response rate (ORR) and disease control rate (DCR). Exploratory endpoints relevant to CNS include CNS ORR and CNS DCR.

**Result:** Patients (N=25) were enrolled. Five patients (n=3) or 1 (n=2) and 10 patients had CNS metastasis at enrollment while 15 never had CNS metastasis. Patients with CNS metastasis could have had prior radiotherapy (n=7) or no radiotherapy (n=3) to the CNS. Median follow-up time was 7.23 months. Fifteen patients remained on study treatment (five with CNS metastasis, ten without). TEAEs of interest (CNS metastasis, no CNS metastasis), such as headache (4/10, 5/19), vomiting (3/10, 4/15), and nausea (2/10, 4/15), were observed with comparable rates in patients with or without CNS metastasis. One patient developed TEAE of cerebral hemorrhage (Grade 1), related to CNS metastasis, but unrelated to study treatment, according to the investigator. Another patient with CNS metastasis developed Grade 1 TRAE of subdural hemorrhage, unrelated to CNS metastasis, 7 weeks after the last dose of ramucirumab. Only one patient with CNS metastasis had measurable CNS lesions (tumor shrinkage of 24% [SD] as best response). The other nine patients with CNS metastasis had non-measurable CNS lesions, one of whom had a CNS Complete response; thus his systemic best response was SD. The rest of patients had CNS non-CR/non-PD. To date, one patient (1/25) developed CNS progression (due to new CNS lesion); her CNS best response was SD.

**Conclusion:** Ramucirumab+osimertinib showed potential antitumor activity in the CNS. Patients with CNS metastasis, with/without prior radiotherapy, appeared to tolerate this combination similarly to patients without CNS metastasis.

**Keywords:** CNS (brain) metastasis, ramucirumab, Osimertinib
Conclusion: Efficacy was similar in the dose-reduced patients and the overall study population. Incidence/severity of dacotinib-related AE decreased with dose reduction, thereby allowing patients to continue treatment. 

Keywords: dose reduction, non-small cell lung cancer, Dacotinib

MA27.01 ESTABLISHMENT OF PDX FROM TUMORS CHARACTERIZED BY EGFR MUTATIONS OR ALK FUSION GENES FROM RESECTIONS, BIOPSY AND PLEURAL FLUIDS

LMP, University of Toronto, Toronto/CA

Background: Patient-derived xenograft (PDX) models allow for cancer tissue expansion, providing an effective method to evaluate tumor biology and mechanisms of response or resistance. Our study aims to establish models in patients enriched for lung adenocarcinoma (LUAD) with EGFR mutations or ALK fusion genes which respond initially to oral therapeutics. We prospectively developed resistant disease and disease endpoints within 2 years. The PDXs will be evaluated for their potential to model novel therapy outcomes, to determine resistance mechanisms and to evaluate novel therapy strategies to overcome resistance. 

Method: From August 2015 to January 2018, we collected 109 samples from patients with EGFR- or ALK-driven LUAD and from never-smoker LUAD patients with unknown mutation status. Five samples with low tissue viability (i.e., necrotic) or very low tumor content (<100 malignant cells) were excluded. Adequate samples were implanted into the subcutaneous tissue of NOD-SCID mice. At this time, 16 samples have reached the study endpoint (tumor growth ≥1.5 cm³) and 60 showed no tumor-growth following implantation (median follow-up: 8m). Results are currently pending for 18 models. Result: Samples were collected from surgical resections (31, 36%), CT-guided biopsies (12, 14%), EBUS (19, 22%) and pleural fluid effusions (24, 28%). Most patients were female (51/86, 59%), never smokers (62/85, 73%), and had stage III or IV cancer (55/79, 70%). Mutations in EGFR and ALK were found in 55/81 (68%) and 12/84 (14%) primary cancers, respectively. Early-passage xenograft engraftment (XG) was observed in only 16 (19%) PDXs, including 9/55 (16%) EGFR- and 1/12 (8%) ALK-mutant cancers. The phenotype and molecular changes (EGFR and ALK) were consistent within the PDX model and its corresponding patient sample. Samples collected from surgical-resection specimens showed a trend towards higher engraftment rates (p=0.084). Conversely, the presence of EGFR or ALK mutations showed a trend towards non- engraftment (noXG, p=0.075). Patient smoking status and tumor stage did not influence engraftment rate. To identify reasons for no tumor-growth, we conducted histological analysis in the subcutaneous fat-pads (nodes in the implant sites) of 28 noXG mice. Interestingly, we identified small non-palpable foci of carcinoma in 8 animals (4 EGFR+ and 2 ALK+). 

Conclusion: Environmental or molecular factors may impair engraftment of EGFR+ and ALK+ LUAD samples in PDX models. Nevertheless, these models recapitulate the primary disease and could be useful for population-based drug-screening studies.

Keywords: lung adenocarcinoma; patient-derived xenograft; TKI

MA27.02 HYPOFRACTIONATED RADIOTHERAPY NORMALIZES TUMOR VASCULARITY IN NON-SMALL CELL LUNG CANCER XENOGRAFTS THROUGH P-STAT3/HIF-1 ALPHA PATHWAY

X. Jin, F. Tong, X. Dong, C. Wei, H. Lu

Cancer Center, Union Hospital, Huazhong University of Science and Technology, Wuhan/China

Background: Our study aimed to investigate specific biological effect of hypofractionated radiotherapy (HFRT) on tumor angiogenesis, when compared with conventional radiotherapy (CRT). 

Method: Firstly, models of nude mice as well as dorsal skinfold window chamber (DSWC) bearing H460 and HCC827 (NSCLC cell lines) were established. Tumors suffered irradiation with doses of 0 Gy (control group), 22 Gy delivered into 11 fractions (CRT group) or 12 Gy delivered into 1 fraction (HFRT group). After irradiation, xenograft volumes were recorded every other day. At different time points after irradiation, the vasculature of DSMC was visualized by FITC-Dextran, α-SMA and CD34 immune-histochemical staining was employed to detect the micro-vessel density (MVD) and coverage rates of pericyte on tumor vessels; pimonidozole hydrochloride was used to detect hypoxia; western blotting and RT-PCR were used to detect the expression levels of p-STAT3, HIF-1α, SDF-1 and VEGFA. Then, S3I-201, the STAT3 inhibitor, was used to further verify the mechanism of the effect of HFRT on vascular normalization. Result: Compared to CRT groups, the growth suppression effect of HFRT on tumor tissue was enhanced, accompanied by stronger effect on decrease in MVD, vascular normalization and improvement of tumor hypoxia. RT-PCR and western blotting exhibited that HFRT promoted the vascular normalization by activating STAT3/HIF-1α signaling pathway. 

Conclusion: Compared to CRT, the pathway of p-STAT3/HIF-1α and its downstream angiogenic factors (VEGFA and SDF-1) might play important roles in forming a window-period of vascular normalization in NSCLC, which contributed to the specific biological effect of HFRT on tumor vasculature.

Keywords: HFRT, angiogenesis, NSCLC

MA27.03 MULTI-OMIC CHARACTERIZATION OF TKI-TREATED DRUG-TOLERANT CELL POPULATION IN AN EGFR-MUTATED NSCLC PRIMARY-DERIVED XENOGRAFT

E. Stewart, M. Cabanero, V. Raghavan, J. Bruce, P. Guilhamon, R. Singhania, N. Pham, S.Y. Shen, T. Li, M. Li, N. Leighl, F. Shepherd, T. Pugh, D. De Carvalho, M. Lupien, G. Liu, M. Tsao

Princess Margaret Cancer Centre, University Health Network and University of Toronto, Toronto/ON/CA

Background: Sixty to eighty percent of advanced stage lung adenocarcinoma patients with epidermal growth factor receptor (EGFR) activating mutations have tumors respond initially to EGFR tyrosine kinase inhibitors (TKIs). However, cure is not yet achievable with any EGFR TKI monotherapy, as patients eventually progress due to acquired resistance. In vitro evidence suggests that minor populations of epigenetically modified drug tolerant cells (DTCs) may be important for tumor cells surviving TKI. We hypothesize that molecularly characterizing DTCs in vivo and comparing them to the untreated tumor in a patient-derived xenograft (PDX) model may delineate mechanisms of tolerance that closely mimic those occurring in patients. 

Method: DTCs were produced via chronic exposure to erlotinib in a lung adenocarcinoma PDX harbouring an exon 19 deletion. Histological, genomic, transcriptomic (including single-cell RNA-seq), and epigenetic characterizations were performed on DTCs and compared to untreated baseline (BL) tumors. Result: Compared to BL, DTCs exhibit decreased levels of proliferation (Ki67 by immunohistochemistry (IHC) and increased expression of senescence/quiescence (p21) and anti-apoptosis (BCL-XL) immunohistochemistry (IHC) markers, while maintaining EGFR pathway signaling(pEGFR, pAKT, pERK, pS6). Whole exome–sequencing provides evidence that DTCs likely do not represent mutationaly distinct subclones from the bulk tumor. Instead, DTCs exhibit a number of differentially expressed genes compared to BL tumors that are involved in cell cycle arrest, senescence/quiescence, differentiation, vesicles, and inflammation. Genes with epigenetic differences (chromatin openness and/or promoter methylation) are involved in similar cellular processes. A minor (<2%) subpopulation of transcriptomically-defined DTC-like cells in the BL tumors are very similar to the DTCs, supporting the hypothesis that DTCs may exist prior to treatment. A number of transcription regulators are found to have differential gene expression and epigenetic regulation as well as DNA-binding motifs found in regions of chromatin uniquely open in DTCs or baseline tumors. These transcription regulators are involved in cell maintenance, proliferation, and differentiation, and may play key roles in promoting DTC phenotype. Conclusion: In this specific EGFR mutant PDX model sensitive to first generation TKIs, DTC-like cells are found in the BL untreated tumors, and its resultant phenotype after exposure to TKI appears to be involved in cell cycle, differentiation, senescence/quiescence, proliferation and maintenance. PDX models may provide insights into therapeutic strategies to target DTCs, and further improve the survival of EGFR-mutated NSCLC patients.

MA27.06 THERAPEUTIC SILENCING OF Oncogenic KRAS WITH A MUTANT-SPECIFIC SHORT INTERFERING RNA
C. Pecot1, A. Van Sweereingen2, B. Papke2
1Umeå University, Umeå, Sweden
2University of North Carolina, Chapel Hill, USA

Background: Oncogenic mutations in RAS genes are well-established drivers of cancer. In particular, lung, pancreatic and colorectal cancers carry high rates of oncogenic mutations in KRAS. Promising preclinical strategies with RNA interference (RNAi) have been developed to target oncogenic RAS function, yet a clinically effective anti-RAS therapy remains to be achieved. While genetic knock-down of mutant KRAS with RNAi is one promising approach, current methods are not selective and also decrease normal RAS, raising concerns about potential normal tissue toxicity. Method: We took a novel in silico approach to develop a library of siRNAs that are theoretically capable of silencing mutant KRAS sequences but sparing wild-type sequence. We utilized a model system to test our library of siRNAs against various human KRAS G12D and G13 mutations compared with the wild-type sequence. Dose titrations were performed to assess the unique affinity of our lead candidate for mutant v. WT. Using a KRAS mutant orthotopic lung model, we assessed in vivo silencing and therapeutic effects following delivery of our lead candidate when packaged into a nanoliposome. Result: Here we describe a custom designed short interfering RNA (siRNA) oligonucleotide (KRAS-m) that displays a higher affinity for the most frequent subsets of oncogenic KRAS (KRAS-m) than for wild-type KRAS mRNA. Using 3T3 cells stably expressing wild-type or various KRAS mutations, we observed that KRAS-m preferentially suppressed expression of G12C, G12D, G12V and G13D missense mutations compared with wild-type KRAS. Additionally, KRAS-m impaired proliferation of lung cancer cell lines in 2D as well as 3D spheroids embedded in extracellular matrix. In order to optimize in vivo stability and minimize toxicity, a 2’O-methylation strategy was utilized and several equipotent modifications were found. To overcome future clinical limitations of delivering siRNA to tumors, we evaluated a lipid nanoparticle platform (LNP) clinically-proven to be safe and highly efficient at delivering systemic RNAi. Biodistribution studies in a syngeneic, orthotopic metastasis model of KRAS (G12D) lung adenocarcinoma revealed substantial uptake of LNP-siRNAs in lung tumors and metastases. Time-kinetic studies in this model revealed a single delivery of LNP-KRAS-m siRNA significantly silenced KRAS protein expression in tumors for at least 3 days. Compared with LNP-control siRNAs, following two deliveries of LNP-KRAS-m siRNAs model led to significant reductions in disease burden. Conclusion: Taken together, our data indicate a novel strategy to target oncogenic KRAS-driven lung tumor progression using a mutant-specific siRNA capable of targeting many of the most common KRAS mutations.

Keywords: KRAS, siRNA, Therapeutic

MA27.07 LUNG ADENOCARCINOMA HARBORING BRAF G469V MUTATION IS UNIQUELY SENSITIVE TO EGF TYROSINE KINASE INHIBITORS
H. Notsuda1, N. Pham1, M. Li1, N. Liu2, V. Raghavan2, Z. Fang1, C. Marshall2, N. Moghal1, M. Ikura1, M. Tao3
1Princess Margaret Cancer Centre, University Health Network, Toronto/ON, Canada; 2Department of Medical Biochemistry and Biophysics, University of Toronto, Toronto/CA, Canada; 3Laboratories of Medical Genetics and Pathobiology, University Health Network, Toronto/CA, Canada

Background: BRAF mutations occur in 2-5% of non-small cell lung cancers with ~50% being non-V600E. Previous studies reported that two BRAF G469 mutations, G469V and G469A increase kinase activity and MAPK activation, thus are likely oncogenic. Patients with non-V600E mutations are most often not sensitive to approved BRAF inhibitors vemurafenib or dabrafenib. We established a lung adenocarcinoma (LUAD) patient derived xenograft (PDX) that is epidermal growth factor receptor (EGFR) wild type and non-amplified, but harbors BRAF G469V mutation, yet is sensitive to gefitinib. We performed functional studies to characterize the oncogenicity and sensitivity of BRAF G469 mutations to EGFR tyrosine kinase inhibitors (TKIs). Method: Primary cell lines were established from PDX12. NCI-H1395 and -H1755 LUAD cell lines with BRAF G469A mutation were obtained from ATCC. BRAF mutant driver activity was characterized by shRNA knockdown of BRAF in LUAD cell lines and the ability of the mutants to promote IL3-independent growth when expressed in Ba/F3 cells. PDX12 responsiveness to TKIs was evaluated by tumor volume shrinkage while cell line sensitivity was quantified using the MTS assay. Drug effects on signaling were assessed by phospho-immunoblotting. Computational modeling was used to predict how the mutations promote BRAF activation and sensitivity to EGFR-TKIs, while purified BRAF proteins were used to validate predictions. Result: Knockdown of BRAF by shRNA inhibited growth of all BRAF mutant cell lines, while ectopic BRAF G469V and G469A expression in Ba/F3 cells promoted IL3-independent MAPK activation and growth, supporting both mutations being oncogenic drivers. The XDC12 cell line was sensitive to EGFR-TKIs (gefitinib, erlotinib, afatinib, and osimertinib), but resistant to the BRAF inhibitor dabrafenib, which correlated with inhibition of MAPK phosphorylation. By contrast, H1395 and H1755 cell lines with BRAF G469A mutations were resistant to both the EGFR-TKIs and the BRAF inhibitor. Similarly, only Ba/F3 cells expressing BRAF G469V, but not G469A, were sensitive to EGFR-TKIs. Consistent with the in vitro data and our initial PDX findings with gefitinib, multiple EGFR-TKIs induced tumor shrinkage in PDX12 in vivo. Conclusion: BRAF G469WA mutations are oncogenic drivers but are insensitive to BRAF inhibitors. However, only BRAF G469V, but not G469A mutation, is sensitive to EGFR-TKIs. Thus, two different driver alterations affecting the same BRAF codon can lead to distinct drug sensitivities.

Keywords: BRAF G469V mutation, EGFR-TKIs, patient-derived xenograft model
MA27.09 DUAL INHIBITION OF BCL-XL AND MCL-1 IS REQUIRED TO INDUCE TUMOUR REGRESSION IN LUNG SQAMOUS CELL CARCINOMAS SENSITIVE TO FGFR INHIBITION

Background: Fibroblast growth factor receptor 1 (FGFR1) gene amplification has been described in 20% of lung squamous cell carcinoma (SqCC), suggesting that FGFR tyrosine kinase inhibitors may constitute a new therapeutic approach for patients carrying this genetic alteration. However, a recently completed clinical trial reported low response rates to FGFR therapy, indicating the need for refined biomarkers. We have recently described that high levels of FGFR1 RNA expression better predicts response to FGFR inhibitors, yet the treatment results in tumour cell status as opposed to cell death. BH3-mimetics are a class of anticancer agents that block the BCL-2 family of pro-survival proteins to induce cell death and were recently approved for clinical use in breast cancers. We therefore hypothesized that combining BH3-mimetics with FGFR-targeted therapy may enhance the killing of SqCC cells. Method: We developed patient-derived xenograft models of lung squamous cell carcinoma and evaluated the activity of specific inhibitors of BCL-XL (A1331852), BCL-2 (ABT-199), MCL-1 (S63845) or FGFR (BGJ398) as single agents or in combination in vitro and in vivo. Genetic knockout of BCL-XL was also performed using CRISPR/Cas9. We evaluated compounds synergy in vitro using Bliss assay and in vivo efficacy using mRECIST. Result: Here we demonstrate that FGFR therapy primes SqCC for cell death by increasing the expression of the pro-apoptotic protein BAX. We identified a greater reliance of lung SqCC cells on BCL-XL compared to BCL-2 for survival. However, neither BCL-XL nor MCL-1 inhibitor alone gives a survival benefit in combination FGFR therapy in vivo. In contrast, triple BCL-XL, MCL-1 and FGFR inhibition resulted in tumour volume regression and prolonged survival in vivo, demonstrating the ability of BCL-XL and MCL-1 proteins to compensate for each other in lung SqCC. Conclusion: Our work therefore provides a rationale for the simultaneous inhibition of MCL-1, BCL-XL and FGFR1 to maximize therapeutic response in FGFR2-expressing lung SqCC. Keywords: FGFR, Patient-derived xenograft, BH3 mimetic

MA27.10 EGFR-TARGETED THERAPY ALTERS THE TUMOR MICROENVIRONMENT IN EGFR-DRIVEN LUNG TUMORS: RATIONALE FOR COMBINATION THERAPIES

Y. Jia, T. Jiang, X. Li, C. Zhao, C. Zhou, S. Zhao

Department of Medical Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN

Background: Non-small cell lung cancer patients harboring EGFR mutations have significant clinical benefit from EGFR-targeted tyrosine kinase inhibitors (TKIs). However, these patients develop resistance eventually. With the promising implementation of immune checkpoint inhibitors targeting the programmed cell death receptor/ligand 1 (PD-1/PD-L1) pathway for the treatment of lung cancer, there is a growing interest in developing combinatorial therapies that could utilize this immunooapproach in the context of targeted therapies. Although many clinical trials have attempted to study combining EGFRTKIs with PD-1/PD-L1 inhibitors in NSCLC cases, the clinical benefit is still undefined. Therefore, we carry out this study to investigate the immune response of EGFR-TKIs in EGFR-driven lung tumors, aiming to explore factors influencing the efficacy of this combination strategy. Method: We investigated the early and long-term antitumor effects of first-generation TKI gefitinib and third-generation TKI osimertinib respectively in mice with EGFR19DEL and EGFRERL858L-driven lung tumors. The changes of immune tumor in tumors were dynamically tested in different treatment groups by flow cytometry and immunohistochemistry. Result: Upon treatment of gefitinib and osimertinib, we saw significant tumor regression in mice with TKI-sensitive EGFR19DEL lung adenocarcinoma. However, mice with EGFRERL858L-driven tumors did not respond to gefitinib, but did show a significant tumor response to third-generation TKI osimertinib treatment. Accompanied with obvious tumor shrinkage, we saw a significant increase of infiltrating CD11b+ myeloid cells and CD3+ lymphocytes throughout treatment. We further analyzed the proportion of CD11b+ myeloid cells and CD3+ lymphocytes. Results showed that EGFR-TKIs may demonstrated anti-tumor activity by raising cytotoxic CD8+ T cells, activating dendritic cells, eradicating Foxp3+ Tregs and inhibiting M2-like polarization at early stage. However, these immune benefits occurred temporarily and gradually disappeared with treatment went on. On the other hands, the laboratory of myeloid-derived suppressor cells(MDSCs), particular mononuclear-MDSCs were consistently elevated responding to sensitive EGFRTKIs treatment. Conclusion: Together, results of our study provide novel insights into the immune response to EGFR-TKIs in vivo and provides rationale for potential combinations of EGFR-TKIs and immunotherapies for the treatment of lung carcinomas in the early setting, before the establishment of tumor relapse with long-term EGFR inhibition. Additional therapies aiming to eliminate certain immunosuppressive components should be considered when applying this combination strategy. Keywords: lung cancer, EGFR-TKI, tumor microenvironment

MA27.11 GENOMIC SEQUENCING AND EDITING REVEALED THE GRM8 SIGNALING PATHWAY AS POTENTIAL THERAPEUTIC TARGETS OF SQAMOUS CELL LUNG CANCER

P. Zhang1, S. Li2, Y. Yang3

1Department of Thoracic Surgery II, Peking University Cancer Hospital & Institute, Beijing/CN; 2Beijing Cancer Hospital, Beijing/CN; 3Department of Thoracic Surgery II, Peking University Cancer Hospital, Beijing/CN

Background: Lung cancer is the leading cause of cancer death worldwide. Squamous cell carcinoma (LUSC) is one subtype of non-small-cell lung cancer (NSCLC), and ranks at the second of lung cancer incidence. Although targeting receptor tyrosine kinases (RTKs) had already brought better clinical outcomes to NSCLC patients carrying corresponding mutations, very few mutated targets had been identified in LUSC subtype, probably because of the lack of mutation hotspot and functional validation of mutated candidate. Method: The whole exome (WES) and whole genome (WGS) sequencing and CRISPR-Cas9 genome editing techniques were integrated to explore and validate novel targeting candidates from 11 groups of LUSC primary tumors and corresponding patient-derived xenografts (PDxS). Result: The WES data revealed high homologies on the mutation types and signatures among primary tumor and different passages of PDX tumor samples. Nine significant genes carrying single nucleotide variations (SNVs) and three carrying copy number variations (CNVs) were identified as targeting candidates from WES and WGS data based on the mutation frequency and driver gene analysis. The oncogenic or tumor suppressor functions of those 12 candidates were validated through CRISPR-Cas9 loss-of-function system in tumor cells derived from PDX tissues carrying corresponding mutations and in normal bronchial epithelial cell-line. Furthermore, using CRISPRa transcriptionally activating system, one novel candidate, Metastatopic glutamate receptor 8 (GRM8) was elucidated to promote the survival of LUSC tumor cell through inhibiting cAMP pathway and activating MAPK pathway. Conclusion: The components of GRM8 signaling pathway could serve as potential targets of squamous cell lung cancer. Keywords: genome editing, GRM8, lung cancer
P1.01 ADVANCED NSCLC

P1.01-01 ROS1-POSITIVE NON-SMALL CELL LUNG CANCER: REAL-WORLD DATA IN KOREA
B.C. Ahn1, S. Park2, S.W. Lim3, H.R. Kim4, M.H. Hong5, B.C. Cho6, A. Mahn2
1Division of Medical Oncology, Department of Internal Medicine, Yonsei University College of Medicine, Yonsei Cancer Center, Seoul/KR; 2Division of Hematology-Oncology, Department of Medicine, Samsung Medical Center, Seoul/KR

Background: ROS1 rearranged non-small cell lung cancer (NSCLC) is classified as a distinct molecular subset with a therapeutically druggable target. ROS1 rearrangement is most often identified in never-smoker with adenocarcinoma and EGFFR and ALK wild type patients. Treatment with tyrosine kinase inhibitors (TKIs) which target the ROS1 kinase domain is considered standard of care for the ROS1-positive NSCLC, by showing a robust and durable response. However, information regarding the clinical characteristics and the outcomes of TKI treatment in the real world remains limited. Method: We have identified 103 consecutive cases of ROS1-positive NSCLC from January 2001 to February 2018 by break arrest fluorescence in situ hybridization (FISH) (n=84), next-generation sequencing (n=23) or both (n=3). Information on fusion breakpoints was available for 8 patients. Clinical data including patient characteristics, incidence of brain metastasis, and response to chemotherapy or TKI were retrospectively analyzed. Result: The median age was 56 years, 58.8% of patients were female, and 75.7% were never smokers. Adenocarcinoma was predominant (98.1%), and 2 cases with pleomorphic carcinoma were identified. Sixty percent of patients had an extra-thoracic metastatic lesion, and 22% had intracranial lesion at the initial presentation or at the time of recurrence. Median time to brain metastases was 12.0 months (range 2.1 to 84.1). Majority of the patients received palliative chemotherapy (93.2%), and 7.8% of patients received definite concurrent chemotherapy. The most common fusion partner was CD74 followed by SDC4, EZR, TPM3, TFG, ZCCHC8, SLMAP, and MYOIC, all of which had preserved tyrosine kinase domain of ROS1. There were no clinical correlations between different fusion partners and TKI treatment outcomes. The median overall survival for the study population was 52.1 months (95% confidential interval [CI] 23.6 – not reached). For 90 patients treated with pemetrexed-based chemotherapy, the overall response rate (ORR) and progression-free survival (PFS) was 53.3% and 8.0 months (95% CI 6.4 – 11.7), respectively. The ORR and PFS was 70.7% and 12.7 months (95% CI 8.1 – 21.8) for 50 patients treated with TKI. Brain metastasis was more commonly observed during the TKI treatment and 12.7 months (95% CI 8.1 – 21.8) for 50 patients treated with TKI. The ORR and PFS was 53.3% and 9.0 months (95% CI 6.4 – 11.7), respectively. The ORR and PFS was 53.3% and 12.7 months (95% CI 8.1 – 21.8) for 50 patients treated with TKI. Conclusion: ROS1-positive NSCLC has distinct clinical characteristics with high and durable response rate with TKI and pemetrexed-based chemotherapy. Given its novel characteristics and distinct clinical responses to ROS1-positive NSCLC has distinct clinical characteristics with high and durable responses. Responses were durable (median duration of response, not reached; range, 1.4 to 27.9 months). The 2-year PFS rate was 29%. At the time of database lock, 32 of 34 patients (94%) with OS ≥2 years were alive, with four (12%) remaining on treatment and progression-free: 14 (41%) were off treatment and progression-free without subsequent therapy. Three-year follow-up results to be presented include OS, PFS, and laboratory data on CSF, efficacy by TMB status, and clinicivo-pathological data on long-term survivors. Conclusion: With long-term follow-up, nivolumab plus ipilimumab continued to demonstrate durable clinical benefit and a consistent safety profile as first-line treatment for patients with advanced NSCLC.

P1.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-02 LONG-TERM OUTCOMES WITH FIRST-LINE NIVOLUMAB PLUS IPILIMUMAB IN ADVANCED NSCLC: 3-YEAR FOLLOW-UP FROM CHECKMATE 012
S. Anthony1, J. S. Ginsberg2, H. Borghaei3, J.W. Goldman, T. K. Brahmer4, N. Ready5, D. Gerber6, L. Chow7, R. Juergens5, S. Laurie8, F. Shepherd1, X. Li1, A. Li1, W. Geese1, M. Hellmann9
2Yale Cancer Center, New Haven/CT/US; 3Memorial Sloan Kettering Cancer Center and Research Institute, New York/NY/US

Background: CheckMate 012 (NCT01454102) is a phase 1 study evaluating several nivolumab monotherapy/combination regimens as first-line treatment for advanced non-small cell lung cancer (NSCLC). CheckMate 012 was the first study to suggest the benefit of nivolumab plus ipilimumab in NSCLC. In the phase 3 study CheckMate 227, nivolumab plus ipilimumab demonstrated significantly improved progression-free survival (PFS) as well as more frequent, deeper, and more durable responses versus chemotherapy in patients with chemotherapy-naive advanced NSCLC and high tumor mutational burden (TMB). Here, we provide 2-year follow-up results for nivolumab plus ipilimumab from CheckMate 012. Three-year results, the longest follow-up to date for an immuno-oncology combination in NSCLC, will be presented. Method: Eligible patients had recurrent stage IIIb or stage IV chemotherapy-naive NSCLC and Eastern Cooperative Oncology Group performance status 0–1. Patients received nivolumab 3 mg/kg every 2 weeks plus ipilimumab 1 mg/kg every 12 weeks (n=38) or every 6 weeks (n=39) until disease progression, unacceptable toxicity, or consent withdrawal; pooled results of these two cohorts are presented. Endpoints included safety/tolerability (primary); objective response rate and PFS (secondary); and overall survival (OS), chemotherapy-free survival (CFS), and efficacy by TMB status (exploratory). Result: With 2 years of follow-up, no new safety signals were observed. Thirty-three of 77 patients (43%) achieved objective responses, including six investigator-assessed complete responses (8%), three of which were complete pathological responses. Responses were durable (median duration of response, not reached; range, 1.4 to 27.9 months). The 2-year PFS rate was 29%. At the time of database lock, 32 of 34 patients (94%) with OS ≥2 years were alive, with four (12%) remaining on treatment and progression-free: 14 (41%) were off treatment and progression-free without subsequent therapy. Three-year follow-up results to be presented include OS, PFS, and laboratory data on CSF, efficacy by TMB status, and clinicivo-pathological data on long-term survivors. Conclusion: With long-term follow-up, nivolumab plus ipilimumab continued to demonstrate durable clinical benefit and a consistent safety profile as first-line treatment for patients with advanced NSCLC.

Background: Up to 50% of NSCLC patients develop brain metastases (BM). Prophylactic Cranial Irradiation (PCI) is a potentially useful strategy to prevent this event, although its use remains controversial due to inherent risks. Therefore, actions such as dosing adjustment for Whole Brain Radiotherapy (WBRT), or hippocampal-sparing techniques have been explored. We evaluated the impact of PCI on cognitive function and Quality of Life (Qol). Method: Within the clinical trial NCT01603849 we evaluated a total of 84 histologically-confirmed NSCLC patients with high risk of developing BM (adenocarcinomas harboring oncodrivers (EGFR or ALK) and/or carcinomembrinocyte antigen (CAE) level at diagnosis ≥ 20 pg/mL). Patients were randomized 1:1, 41 to receive PCI and 43 without PCI (p=0.031). MMSE scores and median score values for global deterioration were evaluated at baseline and follow-up. There were also no differences in percentual change at 1-yr (Table).

**Conclusion:** PCI was not associated with significant differences in MMSE and QoL scores, furthermore there were no differences when assessing specific subscales (e.g. fatigue and cognitive functioning). These results along with the clinical benefit in OS highlight the benefit of this approach particularly among patients at high risk of developing BM.

Hoffmann-La Roche Ltd., Basel/CH. 4Genentech, Inc., South San Francisco, Ca/US. 5Tufts Medical Center, Cambridge, Ma/US. 6Foundation Medicine, Inc., Cambridge, Ma/US. 7University Hospital Basel, Basel/CH  

**Background:** Foundation Medicine (FMI) comprehensive genomic profiling and other next-generation sequencing (NGS) tests are gaining importance in routine clinical management of non-small cell lung cancer (NSCLC). They assess multiple genetic alterations that drive sensitivity or resistance to treatment, enabling optimal therapeutic decisions. We evaluated the effect of biomarker testing on treatment patterns and overall survival (OS) in real-world advanced NSCLC (aNSCLC) patients receiving different test types, and in non-tested patients. **Method:** The Flatiron Health (FH) Database comprises patient-level electronic health records from a large network of US cancer clinics. Patients had aNSCLC diagnoses between 01/2013 and 05/2017, ≥2 clinic visits in the FH network, first treatment starting ≤90 days after aNSCLC diagnosis, and biomarker tests before first treatment. Testing data were abstracted for five biomarkers (EGFR, ALK, KRAS, ROS1, and PD-L1). Patients were hierarchically categorized into three testing groups: FMI, other NGS, and single-biomarker non-NGS. Biomarker status and patterns in first treatment were described. Cox proportional hazards models were used to compare OS among testing groups and non-tested patients. **Result:** As of 11/30/2017, 355 patients had ≥1 FMI test, 780 had ≥1 other NGS test, and 6,363 had ≥1 non-NGS test prior to first treatment; 5,148 patients were never tested. Table 1 summarizes biomarker status, treatment patterns, and results of multivariate survival models adjusted for baseline demographic and clinical differences among testing groups. Patients with FMI tests were more likely to receive NCCN-recommended targeted treatments. Better OS was observed for FMI, other NGS, and non-NGS compared with non-tested patients.

**Conclusion:** The FH database represents an important real-world source of information on biomarker testing and its impact on clinical management of NSCLC patients. The results highlight the importance of biomarker testing in the routine clinical management of NSCLC.
**TREATMENT OF EML4-ALK+ LUNG CANCER.**

**P1.01-05 METFORMIN IN COMBINATION WITH CRIZOTINIB FOR THE TREATMENT OF EML4-ALK+ LUNG CANCER.**

A. Bland, M. Nimick, J. Ashton

Department of Pharmacology and Toxicology, University of Otago, Dunedin/NZ

**Background:** Lung cancer accounts for the highest incidence of cancer mortality worldwide, equating to around 2 million deaths each year. Oncogenic receptor tyrosine kinases (RTK) have been discovered to play a role in cancer progression, and can be the target of novel therapeutics. The anaplastic lymphoma kinase receptor (ALK) is an RTK, and as a result of a chromosomal 2 rearrangement, fuses with echinoderm microtubule associated protein like-4 (EML4) forming the oncogenic EML4-ALK of a chromosomal 2 rearrangement, fusing with echinoderm microtubule associated protein like-4 (EML4) forming the oncogenic EML4-ALK.

**Conclusion:** Complexity of real-world anNSCLC biomarker testing and associated treatments creates challenges when comparing OS among different testing groups. In the future, as more treatments targeting a wider array of genomic alterations become available and accessible, the utility of NGS-based assays to guide NCCN-recommended treatments with actionable targets and differences in OS may become more apparent.

1 Denotes biomarker status overall prior to starting first treatment and represents overall status of all test types. In case of multiple tests, the following hierarchy is used: positive-negative/pending/unnecessary/indeterminate/unknown.

2 Based on the NSCLC NCCN Guidelines, Version 3, 2018; 02/21/2018. NCCN-recommended targeted therapy implies treatment regimens containing at least one of the following: erlotinib, afatinib, gefitinib, osimertinib, crizotinib, ceritinib, alectinib,brigatinib, dabrafenib+trametinib, cabozantinib, vandetanib, ado-trastuzumab emtansine. Non NCCN-recommended targeted therapy implies treatment regimens containing at least one of the following: pembrolizumab, nivolumab, atezolizumab. Adjusted for age, sex, race, clinic type, payer type, smoking history, stage at initial diagnosis, ECOG performance status, histology, and year of advanced diagnosis. ECOG performance status overall prior to starting first treatment and represents overall status from all test-types. In case of multiple tests, the following hierarchy is used: pembrolizumab, nivolumab, atezolizumab. Adjusted for age, sex, race, clinic type, payer type, smoking history, stage at initial diagnosis, ECOG performance status, histology, and year of advanced diagnosis. Adjusted for age, sex, race, clinic type, payer type, smoking history, stage at initial diagnosis, ECOG performance status, histology, and year of advanced diagnosis. Adjusted for age, sex, race, clinic type, payer type, smoking history, stage at initial diagnosis, ECOG performance status, histology, and year of advanced diagnosis. Adjusted for age, sex, race, clinic type, payer type, smoking history, stage at initial diagnosis, ECOG performance status, histology, and year of advanced diagnosis.

Keywords: Oncology electronic health record (EHR), advanced non-small cell lung cancer (aNSCLC), next-generation sequencing.
and flow cytometry examined changes in the cell cycle in H3122 cells. **Result:** Crizotinib exhibits greater potency in H3122 cells compared to the ALK: A549 (IC50 of 0.16 μM vs. 1.3 μM). Interestingly, the addition of metformin (5 mM) to both cell lines did not change the IC50, however, reduced cell viability by ~30% at lower doses of crizotinib. The MTT assay found the same effect. The IC50 of metformin in H3122 cells was 22 mM, whereas this potency was lost in CR-H3122 cells (only a 50% reduction in cell viability with 50 mM). Mechanistically it was discovered that metformin decreases mTOR phosphorylation, a downstream protein of ALK, but has no effect on p-ALK. Both crizotinib and metformin produced a G1 phase arrest, with the effect being enhanced with the combination. **Conclusion:** Metformin enhances the effect of low dose crizotinib. It appears that metformin acts by targeting the downstream protein, mTOR, and produces a G1 phase arrest, instead of directly inhibiting ALK. The addition of metformin to chemotherapy provides a potential treatment for EML4-ALK+ and other lung cancers.

**Keywords:** crizotinib, metformin, EML4-ALK

**P1.01-06 PLINABULIN, A NOVEL IMMUNO-ONCOLOGY AGENT MITIGATES DOCETAXEL CHEMOTHERAPY-INDUCED-NEUTROPENIA AND -THROMBOCYTOPENIA IN NSCLC PATIENTS.**

D. Blayney1, S. Ogenstad2, Y. Shi1, Q. Zhang1, L. Du1, L. Huang4, R. Mohanlal3

1Stanford Cancer Institute, Stanford/CA/US, 2Statogen Consulting, Llc, Zebulon/US, 3Department of Medical Oncology, Cancer Institute and Hospital, Chinese Academy of Medical Sciences and Peking Union Medical College, Beijing Key Laboratory of Clinical Study on Anticancer Molecular Targeted Drugs, Beijing/CN, 4Harbin Medical University Cancer Hospital, Harbin/CN, 5Vanchun Bulin Pharmaceuticals Limited, Dalian/CN, 6Beyondspring Pharmaceuticals, New York/NY/US

**Background:** Plinabulin (Plin) is a novel non-GCSF small molecule with anti-cancer activity, in development for prevention of Chemotherapy (Chemo)-Induced-Neutropenia (CIN) and under evaluation with induced Docetaxel (Doc). Doc, Adriamycin, Cyclophosphamide, Irinotecan, Gemcitabine, Carboplatin, Abraxane). Plin is administered as a single (Chemo)-Induced-Neutropenia (CIN) and under evaluation with induced Docetaxel 75 mg/m² D1, and either Peg 6 mg D2 (n=14), or Plin at 5 μg/m² ~247 days (14% for Plin or Peg) and Duration of Grade 4/Severe Neutropenia (DSN; 14% for Plin or Peg). Plin at 5 μg/m² (40 μg/m²) was determined as an effective dose for clinical activity due to dendritic cell activation and related T-cell proliferation, Gemcitabine, Carboplatin, Abraxane). Plin is administered as a single (Chemo)-Induced-Neutropenia (CIN) and under evaluation with induced Docetaxel 75 mg/m² D1, and either Peg 6 mg D2 (n=14), or Plin at 5 μg/m². Plin established the baseline for Grade 4 neutropenia without Plin. We recently completed the Ph2 portion of the Ph2/3 Study 105, comparing Plin with Pegfilgrastim (Peg) for Doc CIN prevention in NSCLC. The 20 mg/m² Plin dose was equally effective as Peg for CIN, and this dose will be taken into Ph3. The CIN nadir was earlier in the Peg group, but the overall incidence of Grade 4 neutropenia was not statistically significant between the two groups. **Conclusion:** Plinabulin appears to be equally effective as Peg against Doc CIN, and this dose will be taken into Ph3. The CIN nadir was earlier in the Peg group, but the overall incidence of Grade 4 neutropenia was not statistically significant between the two groups.

**Keywords:** plnabulin, pegfilgrastim, docetaxel, neutropenia
metastases was started on first-line pembrolizumab. PD-L1 expression was 100%. Two weeks later, he had severe pelvic pain where a bone metastases had been previously diagnosed, not treated with radiation therapy. He required a 3-weeks hospitalization, with palliative care for pain control. Imaging showed three weeks later a major regression. He was rechallenged with pembrolizumab without recurrent symptoms, currently receiving his 5th cycle. A 74-year-old man with squamous cell lung cancer with bone and liver metastases was started on first-line pembrolizumab. PD-L1 expression was 95%. Three weeks later, he had severe nausea and vomiting lasting two weeks, not relieved by outpatient antiemetic medications. He was hospitalized for IV medications during 8 days. While hospitalized, imaging showed a major regression of the lung and liver lesions. He even needed corticosteroid medication to decrease his symptoms for 2 weeks. He was rechallenged without recurrent symptoms. No other etiologies were identified for the symptoms of these 3 patients, including immune–related adverse event (especially endocrine and liver tests), radiation therapy, infection, disease progression or medications. We diagnosed hyperresponsive disease on the basis of the severe symptoms, impression response on the CT scan and rechallenge with the same medication without recurrent symptoms. Conclusion: A major response to immune checkpoint inhibitors may mimic a progressive disease. Severe symptoms related to the tumor locations should not systematically be attributed to local progression. Clinicians should suspect the possibility of a hyperresponsive pattern and prescribe imaging to confirm or refute this hypothesis.

P1.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-09 PEIBROLIZUMAB PLUS IPLIMUMAB OR PLACEBO IN 1L METASTATIC NSCLC WITH PD-L1 TUMOR PROPORTION SCORE (TPS) ≥50%: KEYNOTE-598

M. Boyer1, J. Mclean2, L. Xu2, A. Samkari2, D. Carbone3
1Department of Medical Oncology, Chris O'Brien Lifehouse, Camperdown/NSW/AU, 2Merck & Co., Inc., Kenilworth/NJ/US, 3Ohio State University Comprehensive Cancer Center, Columbus/OH/US

Background: Pembrolizumab monotherapy significantly prolonged survival vs chemotherapy in previously untreated, advanced NSCLC with PD-L1 expression on ≥50% of tumor cells (TPS≥50%) in KEYNOTE-024. Pembrolizumab with chemotherapy led to higher objective response rates (ORRs) vs chemotherapy alone in a similar population in KEYNOTE-021. KEYNOTE-598 (NCT03302234) will evaluate the effects of combination immunotherapy with pembrolizumab and ipilimumab. Method: Eligibility for this randomized, double-blind phase 3 study requires patients be ≥18 years of age and have histologically/cytologically confirmed stage IV metastatic NSCLC, PD-L1 TPS ≥50% per IHC analysis on archival/newly obtained tumor sample, measurable disease per RECIST v1.1, ECOG PS 0/1, absence of EGRF/ALK aberration, and no prior systemic therapy. Patients will be randomized 1:1 to up to 35 administrations of pembrolizumab 200 mg Q3W with 18 cycles of either ipilimumab 1 mg/kg or placebo Q6W. Patients may be eligible for 17 and 9 additional administrations of pembrolizumab and ipilimumab/placebo, respectively. Treatment may be discontinued due to disease progression, intolerable toxicity, or consent withdrawal. Randomization is stratified by ECOG PS (0 vs 1), geography (East Asia vs non-East Asia), and histology (squamous vs nonsquamous). Response is assessed every 9 weeks through week 54, then every 12 weeks per RECIST v1.1 by BICR. Treatment-based decisions may utilize modified RECIST v1.1 for immune-based therapy (iRECIST). Site-assessed progression is verified by BICR before treatment discontinuation. AEs are graded per CTCAE v4.0. Primary endpoints are overall survival and progression-free survival. Secondary endpoints are ORR and duration of response by BICR: time to true deterioration in the composite endpoint of cough, pain in chest, and shortness of breath assessed by EORTC QLQ-C30 and EORC-13; and safety. Approximately 548 patients will be enrolled. Enrollment began on December 18, 2017, as of April 13, 2018, 33 patients have been enrolled. Result: “Section not applicable” Conclusion: “Section not applicable”

P1.01-10 STAGE III NON-SMALL CELL LUNG CANCER CLINICAL OUTCOMES WITH SURGICAL RESECTION AFTER DEFINITIVE NEOADJUVANT CHEMORADIOThERAPY

I. Caturegli1, M. Vyfhuis1, W. Burrows2, M. Suntharalingam1, S. Badiyan2, K. Scilla2, S. Carr1, J. Friedberg2, G. Henry2, S. Stewart2, C. Simone3, P. Mohindra1
1Radiation Oncology, University of Maryland School of Medicine, Baltimore/MD/US, 2Surgey, University of Maryland School of Medicine, Baltimore/MD/US, 3Medicine, University of Maryland School of Medicine, Baltimore/MD/US, 4Thoracic Surgery, University of Maryland School of Medicine, Baltimore/MD/US

Background: The role of neoadjuvant CRT followed by surgery (trimodality therapy) continues to evolve in patients with stage III non-small cell lung cancer (NSCLC). To date, limited prospective data exist assessing definitive preoperative radiotherapy doses. We report our clinical experience of high-dose (definitive) radiation-based trimodality therapy. Method: Between January 2000 and December 2016, 107 consecutive patients with stage III NSCLC treated with curative intent at our institution with definitive doses of neoadjuvant chemoradiotherapy (CRT) were analyzed. The primary endpoint was overall survival (OS) and secondary endpoint was freedom from recurrence (FFR), analyzed using the Kaplan–Meier method with log-rank testing. Cox regression with forward-model selection was used for the multivariate analyses (MVA).

Result: The patients had a median age of 58.5 years (range: 38-82) and were predominantly Caucasian (76%) with baseline performance status of 0 (69%). Stage grouping, according to the 7th edition of American Joint Committee on Cancer (AJCC) Lung Cancer Staging criteria, was IIIA: 78.5%, T3/4: 43.9%, N2: 74.8%, N3: 8.4%. CRT was delivered concurrently in 98% of the patients. Median radiation dose was 61.2Gy (range 39.6-69.6Gy); 89% receiving ≥60Gy. Radiation technique was (3D) conformal (71.0%) or intensity-modulated radiotherapy (IMRT) (27.1%). The 30-day and 90-day surgical mortality rates were 4.7% and 7.5%, respectively. At a median follow-up of 30 months (range: 3-186 months), estimated OS and FFR (median/5-year) were 61 months/ 49% and 29 months/ 35%, respectively. On univariate analysis (UVA), age ≥60 (HR, 1.776; 95% CI, 1.084–2.909; P = 0.023) and having no health insurance (HR, 3.071; 95% CI, 1.060–8.902; P = 0.039) as compared to those with private insurance predicted for an increased risk of death, while receiving consolidation chemotherapy was associated with improved survival (HR, 0.472; 95% CI, 0.258–0.864; P = 0.015). On MVA, age ≥60 was the only characteristic with a continued association with OS (HR, 1.779; 95% CI, 1.056–2.988; P = 0.039). On UVA, lack of health insurance was the only predictor of disease recurrence (HR, 6.059; 95% CI, 2.244–16.360; P =0.001). Conclusion: In a carefully selected population, full dose neoadjuvant CRT followed by surgery can achieve high OS and FFR even for stage III NSCLC patients, much higher than recent reports of bimodality therapy (RT/T1G 0617: median OS of 28.7 months and PACIFIC study: median PFS of 16.8 months). Prospective evaluation of high-dose radiation trimodality therapy versus induction chemotherapy alone is warranted.

Kg, Ingelheim Am Rhein/DE, 17Boehringer Ingelheim Rcv GmbH & Co. Kg, Vienna/AT, 18Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul/KR
Background: A global named patient use (NPU) program for afatinib in patients with advanced/metastatic NSCLC who had progressed during prior therapy was conducted between May 2010 and January 2016 (Cappuzzo F et al, Future Oncol 2018). Here we describe treatment outcomes for patients at Asian centers. Method: Eligible patients had progressed after clinical benefit on prior erlotinib/gefitinib and/or had an activating EGFR/HER2 mutation, had exhausted all other treatments, and were ineligible for afatinib trials. Patients received afatinib (starting dose: 30-50 mg/day). Dose modifications were allowed as tolerated. Time to treatment failure (TTF) was calculated from treatment initiation to discontinuation. Adverse event (AE) reporting was mandatory. Results: Data were collected from 2242 NSCLC patients across 10 Asian countries. Patients were heavily pretreated, 62% received ≥ 2 prior chemotherapy lines, and for most, afatinib was 4th-line therapy; almost all had received erlotinib/gefitinib (Table 1). 97% of patients with known tumor status were EGFR mutation-positive (m+). Median TTF was 7.6 months overall, and 7.2 months in patients with EGFR m+ tumors (Table 1). TTF was >12 months in patients with EGFR exon20 insertions and Her2 mutations. ORR was numerically higher in patients with exon20 insertions and G719X/L861Q/T790M mutations than in those with common HER2 mutations. TTF was >12 months in patients with exon20 insertions (TTF >12 months) and ≥6 months overall. The most frequently reported AEs were rash and diarrhea; no new/unexpected safety signals were identified.

Table 1. Named patient use (NPU) program for afatinib in advanced/metastatic NSCLC: results from Asian centers

| Total number of patients | 2242 |
| Age; years; median | 61 |
| Female/male; % | 60/40 |
| Any prior treatment; n (%) | 2442/2242 (99.2) |
| Prior erlotinib and/or gefitinib; n (%) | 2202/2223 (99.1) |
| Prior gefitinib only; n (%) | 866/2202 (39) |
| Prior TKI only; n (%) | 927/2202 (42) |
| Prior lines of chemotherapy | ≥3, 32%; ≥2, 62%; 1, 23%; 0, 15% |
| Prior lines of systemic therapy | ≥4, 37%; ≥3, 65%; 2, 21%; 1, 14%; 0, 0% |
| EGFR m+; n (%) | 1240/1281 (97) |

**Table 1.** Named patient use (NPU) program for afatinib in advanced/metastatic NSCLC: results from Asian centers.

| Specified EGFR mutation; n (%) | 1101/1240 (89) |
| TTF; months; n | ORR; %; n |
| All patients with data available | 7.6 | 1550 | 24.4 | 431 |
| EGFR m+ | 7.2 | 834 | 27.7 | 267 |
| EGFR mutation specified | 6.5 | 740 | - | - |
| Common mutations (DelE19 or L858R) | 6.4 | 692 | 27.4 | 230 |
| Uncommon mutations (all) | 8.0 | 84 | 30.3 | 33 |
| T790M | 6.0 | 34 | 21.1 | 19 |
| G719X, L861Q, or S768I | 7.8 | 28 | 42.9 | 7 |
| Exon 20 insertion | 18.0 | 25 | 42.9 | 7 |
| Her2 m+ | 12.2 | 12 | 14.2 | 7 |
| p.A775/G776insYVMA | 12.4 | 7 | 25.0 | 4 |

*median m+ve, mutation-positive; ORR, objective response rate; TTF, time to treatment failure Conclusion: This analysis from Asian countries in the afatinib NPU program revealed clinically meaningful TTF/ORR in this heavily pre-treated and refractory advanced NSCLC patient population, including activity in common and uncommon EGFR mutations. TTF was numerically longer in patients with uncommon mutations (particularly EGFR exon20 insertions) and HER2 mutations than in those with common EGFR mutations. The safety profile of afatinib was consistent with non-Asian centers.

Keywords: afatinib, NSCLC

**SWITCH MAINTENANCE PEMBROLIZUMAB IN PATIENTS WITH METASTATIC NON SMALL CELL LUNG CANCER (SWIPE)**

H. Charlambous1, F. Kyriacou1, I. Stylianou1, P. Vogazianos2, M. Allyajott1, D. Vomvas1, N. Katodritis1, G. Orphanos3

1Medical Oncology, Bank of Cyprus Oncology Centre, Nicosia/CY; 2Bank of Cyprus Oncology Centre, Nicosia/CY; 3Radiology, Bank of Cyprus Oncology Centre, Nicosia/CY

**Background:** Pembrolizumab is currently indicated for first line use for patients with ≥50% PD-L1 overexpression and for pretreated patients with >1% PD-L1 expression with metastatic Non Small Cell Lung Cancer (NSCLC). There are currently no data for its use as maintenance treatment. SWIPE is a prospective single arm, one stage Phase II study offering Pembrolizumab as maintenance therapy to non-progressors after first line palliative chemotherapy with NSCLC. (NCT 02705820) Method: Standard inclusion and exclusion criteria for checkpoint inhibitors studies apply, however also patients with WHO Performance Status (PS) 2 were allowed and there was no restriction on PD-L1 expression. Treatment consisted of Pembrolizumab 200 mg fixed dose every 3 weeks. Radiological assessment with CT scans every 9 weeks in the first year. The study employs a one stage phase II Fleming’s design using Immune Related (IR) Progression Free Survival (PFS) at 1 year as primary endpoint. Using response hypotheses of HO < 12 % and Ha > 25%, with a significance level α=0.05 and power 0.8, 48 patients are required to be entered into this study. Result: Thirty-six (36) patients have been enrolled so far. 29 patients have more than 6 months follow up data, and are the subjects of this analysis. 23 males and 6 female patients. Median age 65 years (range 40-82). PS WHO 0 for 12 patients, WHO 1 for 15 patients and WHO 2 for 2 patients. Histology: adenocarcinoma in 22 patients and squamous in 7 patients. In terms of best radiological response 2 patients had a partial response and 13 patients stable disease. Median IR PFS is 6.8 months (CI 4.0-17.2). The 6 month and 1 year IR PFS rate is 60.7% and 45.8%. Median OS is 11.3 months (CI 7.4-15.2). The 6 month and 1 year OS rate is 65.5% and 48.0% (SPSS version 23). Toxicity was mainly grade 1-2; commonest being fatique 18 patients (62%), anorexia, arthralgia and cough 10 patients (34%). One patient developed diabetes mellitus (grade 3) as auto-immune toxicity. Three (3) patients developed grade 3 neutropenia, none of which were related to Pembrolizumab. There was one death during treatment due to sepsis, unlikely to be related to Pembrolizumab. Conclusion: Maintenance Pembrolizumab is associated with a clinically meaningful disease control rate of almost 46% at 1 year with manageable toxicity.

**A STUDY OF S-1 PLUS CISPLATIN IN PATIENTS WITH ADVANCED NON-SMALL-CELL LUNG CANCER**

C. Lai1, Y. Wei2, T. Hisa3, G. Chang4, Y. Chen5

1Department of Internal Medicine, Buddhist Dafin Tzu Chi General Hospital, Chiayi/TW; 2Department of Internal Medicine, E-Da Hospital/-I-Shou University, Kaohsiung/TW; 3Department of Respiratory Therapy, China Medical University Hospital, Taichung/TW; 4Department of Internal Medicine, Division of Chest Medicine at Taichung Veterans General Hospital, Taichung/TW; 5Department of Chest Medicine, Taipei Veterans General Hospital, Taipei/TW

**Background:** Oral administration of S-1 (Tegafur/Gimeracil/Oteracil potassium fixed combination tablets, 1:0:4:1:0 in molar ratio) in combination with cisplatin has been proven non-inferior to the standard-of-care doublet regimen containing docetaxel plus cisplatin in a randomized phase III trial in Japanese patients with advanced non-small-cell lung cancer (NSCLC). The aim of the study was to evaluate the efficacy and safety profiles of oral S-1 plus cisplatin in Taiwanese patients with NSCLC. Method: Patients with previously untreated stage IIIB or IV NSCLC were treated with 40 to 60 mg (based on body surface area) of oral S-1 twice daily on days 1–21 plus cisplatin 60 mg/m^2^ on day 8 in a 5-week cycle for up to six cycles. Result: A total of 55 patients from 5 sites in Taiwan were enrolled and received the study medication. Among the 46 patients who completed at least 2 cycles of treatment and had tumor assessments, disease control rate was achieved at 69.6% (partial response: 19.6%, stable disease: 50.0%), with median overall survival (OS) and progression free survival (PFS) of 15.1 months (95%CI: 11.5, 25.6) and 5.7 months (95%CI: 3.3, 8.4), respectively. Grade 3 adverse events (AEs) related to study treatment occurred in 11 patients (20.0%). The most commonly observed treatment-related AEs were nausea (41.8%), followed by decreased appetite, anemia and diarrhea. No febrile

P1.01 ADVANCED NSCLC

**P1.01-14 IMMUNOTHERAPY (I) FOR ADVANCED, PRE-TREATED, NON-SQUAMOUS NSCLC (APNS-NSCLC). PRELIMINARY DATA OF A POOLED ANALYSIS**

D. Tassinari1, C. Cherubini1, M. Pilati1, M. Papi1, S.V.L. Nicoletti1, L.A. Lazzari Agli1, L. Landi1

1A. U.S. L. Della Romagna, Rimini/IT, 2Department of Oncology, City Hospital, Ausl Romagna, Ravenna/IT

**Background:** To assess the role of I for second line treatment of APNS-NSCLC. **Method:** A pooled analysis of the final data of the CA29057, the KEYNOTE-010 and the OAK trial was performed. Overall Survival (OS) was the primary end point of the trial. The outcomes of patients with PD-L1 expression of 1%-19% (PD-L1 1%-19%), PD-L1 expression 1% (PD-L1 <1%) or mutated-EGFR (EGFR+) were analyzed comparing any checkpoint inhibitor with standard chemotherapy. An indirect comparison with network meta-analysis was performed between the different checkpoint inhibitors whenever a significant difference was observed in the pooled analysis. Direct and indirect comparisons were performed using a random effect model. **Result:** The outcome of 1720 patients was analyzed. 313 patients had been treated with Atezolizumab (A), 292 with Nivolumab (N), 270 with Pembrolizumab (P), and 845 with Docetaxel (D). The preliminary results were detailed in the table. **Conclusion:** C195%: 95% Confidence Interval; **P:** Pooled Analysis; **:** Network Meta-Analysis.

**Conclusion:** Our data seem to confirm the role of I for APNS-NSCLC with PD-L1 1%-19%. On the contrary, not-significant benefits in terms of OS seem to emerge for patients with PD-L1 >PD-L1 1%-19% expression. Likewise, no significant differences seem to emerge from the indirect comparisons between A, N and P for patients with a PD-L1 1%-19% expression. Although all these data need to be analyzed with caution, as expression of indirect comparisons are waiting further confirmations from clinical trials they can support clinicians for daily clinical practice.

P1.01-15 ROSI-REARRANGED NON-SMALL CELL LUNG CANCER IS ASSOCIATED WITH HIGH RATE OF VENOUS THROMBOEMBOLISM: ANALYSIS OF THE METROS TRIAL

R. Chiari1, B. Bicciuti1, L. Landi2, A.M. Morelli3, A. Delmonte4, G. Sipatelli5, D. Cortimovi6, F. Facchinetti7, S. Pilotto8, C. Verusio9, A. Chella10, L. Bonanoti11, D. Galetta12, F. Cappuzzo13

1Medical Oncology, Santa Maria Della Misericordia Hospital, Azienda Ospedaliera Di Perugia, Perugia/IT, 2Oncology-Hematology, Ausl Della Romagna, Ravenna/IT, 3Medical Oncology, Istituto Scientifico Romagnolo Per Lo Studio E La Cura Dei Tumori – IRCCS, Meldola/IT, 4Thoracic Oncology, IEO, Milan/IT, 5Oncology Unit, Asst San Gerardo Hospital, Monza/IT, 6Medical Oncology, University of Parma, Parma/IT, 7Department of Medicine, Medical Oncology, University Hospital of Verona, Verona/IT, 8Medical Oncology, Ospedale Di Sarzano, Sarzano/IT, 9Pneumologia Universitaria, Ospedale Di Pisa, Pisa/IT, 10Medical Oncology, Istituto Oncologico Veneto, Padova/IT, 11National Cancer Research Centre, Istituto Tumori “Giovanni Paolo ii” Bari, Italy, 12Barz/IT, 13Ausl Romagna, Ravenna/IT

**Background:** Patients with lung cancer are at increased risk for venous thromboembolism (VTE) and 8% to 15% of patients with advanced non-small-cell lung cancer (NSCLC) experience a VTE event during the course of their disease. The incidence of VTE in molecularly defined NSCLC is still unknown. However, emerging data suggests that patients harbouring ALKrearrangements are at increased risk of VTE at light of the high amino-acid sequence and structural homology with ALK. The role of ALK in NSCLC is still unknown. However, emerging data suggests that patients harbouring ALKrearrangements are at increased risk of VTE at light of the high amino-acid sequence and structural homology with ALK. We undertook this study to determine the incidence of VTE in patients with ROS1-rearranged NSCLC. **Method:** The METROS trial is a multicentre prospective phase II study designed to assess efficacy, safety, and tolerability of Crizotinib in pre-treated metastatic NSCLC with METatalyplication or METeXon 14 mutation or ROS1 rearrangement. ROS1-rearranged patients enrolled within cohort A and expansion cohort of the trial were evaluated in this analysis. **Result:** Among 48 patients with ROSI-rearranged advanced NSCLC (median age 50 [28-82]); 17 males [35.4%] and 21 females [64.5%]; PS 0-1 [95.8%], 2 [4.2%]; 20 current/former smokers [43.75], 27 never smokers [56.25]). 20 (41.6%) had at least one VTE event. VTE events consisted in pulmonary embolism (PE) in 11 patients (55%), deep vein thrombosis (DVT) in 11 patients (55%), renal vein thrombosis in 2 patients (10%). Seven patients (35%) had ≥1 VTE event. Patients with VTE were more likely to be older than 65 years (P = 0.029). No other associations between clinical characteristics and development of VTE were observed. The occurrence of VTE was not associated with overall survival. **Conclusion:** The incidence of VET is 3- to 5-fold higher in patients harbouring ROS1-rearrangement than previously observed for the general NSCLC population. Whether molecular profile of NSCLC should be incorporated into a risk-stratification tool and decision-making algorithm for VTE diagnosis, prophylaxis and treatment remains to be determined prospectively.

P1.01 ADVANCED NSCLC

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-16 FIRST-LINE PEMBROLIZUMAB WITH OR WITHOUT CHEMOTHERAPY IN PD-L1 POSITIVE NSCLC: A NETWORK META-ANALYSIS OF RANDOMIZED TRIALS

M. Doherty1, S. Delos Santos2, A. Putri Rahmadian2, K. Chan1

1Medical Oncology, Sunnybrook Odette Cancer Centre, Toronto/ON/CA, 2Sunnybrook Research Institute, Toronto/CA

**Background:** Pembrolizumab has replaced platinum-doublet chemotherapy as first-line treatment for advanced non-small cell lung cancer (NSCLC) with tumor PD-L1 expression ≥50%. Among PD-L1 unselected patients, pembrolizumab + chemotherapy is superior to chemotherapy alone. This network meta-analysis compared pembrolizumab alone with pembrolizumab + chemotherapy in patients with ≥50% PD-L1 positive NSCLC. **Method:** Using the Keynote 024 and 042 (PD-L1 ≥50% subgroup) trials, an indirect network was constructed to compare pembrolizumab and pembrolizumab + chemotherapy through the chemotherapy control arms of each trial. Baseline characteristics and chemotherapy outcomes in both trials were examined for heterogeneity. Overall survival (OS), progression-free survival (PFS), objective response rate (ORR) and adverse events (AEs) including immune-related adverse events (irAEs) were extracted from trial results. AE results were unavailable for the PD-L1 ≥50% subgroup of KN189, so overall AE results were used. Comparisons were expressed as hazard ratios (HRs), relative risks (RRs) of outcomes, and as risk difference (RD) for ORR and toxicity. **Result:** 507 patients were included: 154 on pembrolizumab, 357 on chemotherapy and 410 on combination. Baseline characteristics of patients in both...
trials were similar in age, sex, performance status and smoking history. Both trials also had similar chemotherapy outcomes (PFS 6 vs 5 mos) suggesting similar patient prognosis. Network meta-analysis showed no difference between pembrolizumab + chemotherapy and pembrolizumab alone in OS (HR 0.70, 95%CI 0.38-1.30, p=0.26) or PFS (HR 0.72, 95%CI 0.45-1.16, p=0.18), but combination therapy was associated with higher ORR (+21.5%, 95%CI 4.83-38.2%, p=0.011). Overall and grade 3-5 AE rates were higher with combination treatment compared with pembrolizumab alone, but irAE appeared less common with combination treatment (table). Conclusion: Among patients with >/=50% PD-L1 positive NSCLC, pembrolizumab + chemotherapy did not improve OS or PFS compared with pembrolizumab alone, but was associated with higher ORR. Lower rates of irAE with combination therapy are interesting and warrant further study.

### P1.01-17 IMMUNE-RELATED ADVERSE EVENTS IN PATIENTS WITH METASTATIC NON-SMALL CELL LUNG CANCER: SEX DIFFERENCES AND RESPONSE TO THERAPY.

N. Duma1, A. Azzouqa2, S. Yadav1, K. Hoversten1, C. Reed1, A. Sitek1, E. Enninga1, J. Paludo3, V. Agerailler1, Y. Lou1, J. Molina2, K. Leventakos1, L. Knottschade1, H. Dong1, A. Mansfield1, R. Manochakian1, R. Doncha2, A. Adjei1

1Medical Oncology, Mayo Clinic, Rochester/MN/US, 2Medical Oncology, Mayo Clinic, Jacksonville/FL/US, 3Internal Medicine, Mayo Clinic, Rochester/MN/US, 4Hematology and Oncology, Mayo Clinic, Jacksonville/FL/US

**Background:** Sex differences in non-small cell lung cancer (NSCLC) outcomes have been described. Immune-related adverse events (IRAEs) have emerged as a serious clinical problem in the use of immune checkpoint inhibitors (ICI). Risk factors for IRAEs and their association with response to therapy remain controversial. Therefore, we studied sex differences in IRAEs and their association with response to therapy.

**Method:** All patients with metastatic NSCLC treated with anti-PD1 and anti-PDL1 therapy at Mayo Clinic Rochester and Florida from 2015 to 2018 were reviewed. Patients receiving treatment at an outside facility or with history autoimmune disorders were excluded. Kaplan-Meier method was used for time-to-event analysis.

**Result:** 231 patients were identified, 120 (52%) were women and 111 (48%) were men. Baseline characteristics and ICI distribution were similar among groups (Table 1). Women were more likely to experience IRAEs compared to men (48% vs. 31%, p<0.008). Among patients with IRAEs, women were more likely to be prescribed systemic steroids (63% vs. 41%, p<0.02). Women were more likely to develop pneumonitis (23% vs. 12%, p<0.03) and arthralgia (17% vs. 3%, p>0.04). However, dermatologic toxicities (35% vs. 9%, p<0.002) were more commonly seen in men. In 17% of women the ICI was discontinued due to toxicity (men 7%). Besides sex, no other clinical characteristic was associated with increased IRAEs. Women with IRAEs were more likely to have a radiographic response compared with women without IRAEs (37% vs. 26%, p>0.22). Better PFS was observed in women with IRAEs (10 months vs. 3.3 months, p<0.002) compared to women without IRAEs.

**Conclusion:** Women with metastatic NSCLC are more likely to experience IRAEs compared to men. In women, an association between IRAEs and response to therapy was observed. Larger studies are needed to investigate the mechanisms underlying these associations.

**Keywords:** Immunotherapy, metastatic lung cancer, immune-related adverse events

### P1.01-18 IMMUNOSENESCENCE CORRELATES WITH PROGRESSION UPON PD-(L)1 BLOCKADE (IO) IN ADVANCED NON-SMALL CELL LUNG CANCER (NSCLC) PATIENTS.

R. Ferrara1, M. Naigeon1, E. Auclins1, B. Duchemann1, L. Cassard2, J. Michi2, C. Boselli1, J. Grivel1, A. Desnoyer2, L. Mezzou2, F. Aboubakar Nana1, L. Hendriks1, D. Planche1, C. Caramella1, J. Remon1, M. Ngocamus1, C. Nicotra1, B. Besse1, N. Chaput1

1Medical Oncology Department, Gustave Roussy, Villejuif/FR, 2Laboratory of Immuno-Oncology, Gustave Roussy, Villejuif/FR, 3Gastrointestinal and Medical Oncology Department, Hôpital Européen Georges Pompidou, Paris/FR, 4Gustave Roussy, Villejuif/FR, 5Amastricht University Medical Center, Maastricht/NL, 6Radiology, Gustave Roussy, Villejuif/FR, 7Drug Development Department, Gustave Roussy, Villejuif/FR

**Background:** Immunosenescence is a progressive remodeling of immune functions with a multifactorial etiology (i.e. aging, chronic inflammation, cancer). Although a CD28 CD57 KLRG1 phenotype on peripheral T-lymphocytes is a potential hallmark of immunosenescence, the characterization of such phenotype in IO-treated NSCLC patients and the correlation with clinical characteristics and benefit from immunotherapy are unknown. **Method:** A senescent immune phenotype (SIP) defined as a percentage of circulating CD8+ CD28- CD57+ KLRG1+ T-lymphocytes was assessed by flow cytometry (FC) on fresh blood samples from IO-treated aNSCLC patients (03/2017-04/2018). A log-rank maximization method was used to identify a SIP cut-off level and dichotomize patients accordingly. The objective was to correlate SIP with clinical characteristics and RECIST response by univariate logistic regression analysis.

**Result:** 39 aNSCLC patients were evaluable for SIP before IO: 38% ≥ 65 years, 87% non-squamous, 38% KRAS mutated, 54% with PD-L1 expression ≥ 1%. Among 30 patients evaluable for IO response, only 1 (10%) of 10 SIP+ experienced disease control (PR/SD), compared to 13 (65%) of 20 SIP- patients; similarly, PD rate was significantly higher in SIP+ compared to SIP- patients (90% vs 35%, p=0.007) (Figure).

**Conclusion:** Women with metastatic NSCLC are more likely to experience IRAEs compared to men. In women, an association between IRAEs and response to therapy was observed. Larger studies are needed to investigate the mechanisms underlying these associations.

**Keywords:** Immunotherapy, metastatic lung cancer, immune-related adverse events

Background: Although EGFR-TKI alone has been a standard first-line treatment for patients with advanced NSCLC with EGFR mutations, our phase II study (NEJ009) showed promising efficacy of GCP. NEJ009, an open-label, randomized phase III study, was conducted to evaluate the superiority of GCP vs G in progression-free survival (PFS), PFS2, and overall survival (OS).

Method: Patients with newly diagnosed stage III/IV recurrent NSCLC harboring EGFR activating mutations (exon 19 deletion or exon 21 L858R) were randomized 1:1 to G 250 mg PO QD or GCP (G 250 mg PO QD combined with carboplatin AUC 5 + pemetrexed 500mg/m², every 3 weeks). The primary endpoints consisting of PFS, PFS2, and OS were sequentially analyzed according to a preplanned gate-keeping method. Secondary endpoints included objective response rate, safety, and quality of life.

Result: In Sep 2017, a preplanned required number of events of PFS2 was observed. The ITT population included 344 patients with baseline characteristics fairly well balanced between the arms. Although GCP demonstrated significantly better PFS compared to G, there was no difference in PFS2 between the arms as below. Additional OS analysis (G:101 events vs GCP:83 events) revealed that median survival time of GCP was much longer than that of G (52.2 months vs 38.8 months, HR: 0.695, p=0.013). Conclusion: NEJ009 was the first phase III study which evaluated the efficacy of a combination of EGFR-TKI and platinum doublet chemotherapy in untreated advanced NSCLC patients with EGFR mutations. Although GCP regimen failed to demonstrate its superiority in PFS2, it may increase long survivors.

Keywords: EGFR, gefitinib, phase III
was used to compare curves. Multivariate analysis was performed with according to lymphocyte (Lp) count at the first IO administration. BL was treated with IO at Istituto Nazionale dei Tumori, Milan, Italy, between cohort of mNSCLC pts.

We investigated this topic in a retrospective medical oncology, Istituto Nazionale Dei Tumori, Milan/IT

IMMUNOTHERAPY

P1.01-22 EFFECT OF BASAL LYMPHOPENIA ON OUTCOME OF NON SMALL CELL LUNG CANCER PATIENTS TREATED WITH IMMUNOTHERAPY

Medical Oncology, Istituto Nazionale Dei Tumori, Milan/IT

Background: The advent of immunotherapy (IO) induced profound change in treatment paradigm of metastatic non small cell lung cancer (mNSCLC). Different agents proved efficacy against the disease, leading to an improvement in patients’ (pts) survival. Nonetheless, only a minority of treated pts actually derives a benefit from IO. Several predictive factors, such as PD-L1 and tumor mutation burden, have been identified. Contradictory evidences have shown a potential negative predictive role of basal lymphopenia (BL). We investigated this topic in a retrospective cohort of mNSCLC pts. Method: Data about all consecutive mNSCLC pts treated with IO at Istituto Nazionale dei Tumori, Milan, Italy, between 04/2013 and 01/2018 were retrospectively collected. Pts were stratified according to lymphocyte (Lp) count at the first IO administration. BL was considered as a categorical variable, using the Institutional cutoff of 900 Lps/mL. Survival was estimated with Kaplan-Meier method. Log-rank test was used to compare curves. Multivariate analysis was performed with Cox proportional model. Result: One hundred fifty pts were analyzed, for a median follow-up of 28.6 mos. IO consisted in an anti-PD1 agent in 64.0% of cases, in an anti-PD-L1 agent in 31.3% of cases, in a combination anti-PD-L1+anti-CTLA4 in 4.7% of cases. First-line IO was administered in 23 cases, second-line IO in 66 cases, third- or more advanced-line IO in 61 cases. Median progression free survival (PFS) and overall survival (OS) of the global population were 3.2 and 11.2 months (mos), respectively.

Background: Immune checkpoint inhibitors improved outcomes of patients with advanced non-small cell carcinoma (NSCLC). In clinical trials 30% of patients had programmed death receptor ligand-1 (PD-L1) expression above 50% and this frequency may vary through different regions of the world. We aim to describe the real world data on prevalence of PD-L1 expression, EGFR mutation and ALK translocation in Brazil. Method: Immunohistochemistry (IHC) for PD-L1, antibody 22C3 PharmDx Dako, was performed in 5 laboratories in Brazil in August/2017 through Apr/2018 in cases of advanced NSCLC approved for treatment with immunotherapy. Mutations in EGFR (exons 18 to 21) by Cobas®(Roche), NGS, or other non-specified tests and ALK by IHC (antibodies 5A4 or DS53) or FISH (Vysis System) were performed in non-squamous cases. All analyses were with SAS (version 9.4). P-values <0.05 were deemed to be statistically significant. Result: PD-L1 expression was assessed in 1382 samples of advanced NSCLC. The median age was 67 years, and 55.6% were male. 56.6% had adenocarcinoma, 18.0%, squamous, 20.7%, non-specified NSCLC. 2.5%, other histologies, 1.9%, missing. Of the 1380 cases, 17.4% presented PD-L1 expression ≥50%, 26.4%, 49%, and 57.1% <1%. The histological subtype showed association with the expression of PD-L1 (p=0.0431). In adenocarcinoma, 60.7% had no PD-L1 expression, 23.1%, had 1-49%, and 16.1%, ≥50%.

Monday, September 24, 2018 - 09:45-18:00

P1.01 ADVANCED NSCLC

P1.01-24 CLINICAL EFFICACY OF IMMUNOTHERAPY IN METASTATIC NON-SMALL CELL LUNG CANCER PATIENTS TREATED WITH PRIOR RADIOTHERAPY

D. Glick1, E. Wai1, M. Lesperance1, N. Croteau2, E. Brooks1, D. Fenton1, L. Florino1, G. Geller2, Z. Poonja1, D. Ksieniski1
1Radiation Oncology, BC Cancer- Victoria, Victoria/BC/CA, 2University of Victoria, Victoria/BC/CA, 3Medical Oncology, BC Cancer Victoria, Victoria/BC/CA

Background: Pivotal clinical trials (KEYNOTE-001) have demonstrated improved survival in non-small cell lung cancer (NSCLC) patients treated with both radiotherapy (RT) and immunotherapy (IO). The purpose of this study was to document response rates and survival in patients receiving both RT and IO in routine clinical practice.

Method: All metastatic NSCLC patients treated with Nivolumab or Pembrolizumab between 11/2015 and 10/2017 in one Canadian province were identified. Demographic, tumor, treatment, toxicity, and response data were collected. Fisher’s Exact Test and Chi Squared Test were used to assess the relationship between treatment characteristics and outcome. Log Rank Test and Cox Regression were used to assess overall survival (OS) and progression free survival (PFS).

Result: 271 patients treated with IO were identified of which 202 were treated with previous RT (75%) including 153 treated with chest radiotherapy. Median follow up from initiation of IO was 30.3 (0.3-139.9) weeks. At time of last follow up, 56% of patients had died. There were no statistically significant differences in physician assessed response rate or progression free survival between patients treated with prior radiotherapy (52% vs 58%, p=0.41) or prior chest radiotherapy (52% vs 55%, p=0.71). Median PFS was 11 weeks in patients who received RT and 13.9 weeks in patients who did not (p=0.73). Median OS was 41.3 weeks in the radiotherapy cohort versus 42.9 weeks (p=0.50). On univariate analysis, ECOG (p<0.002) and CCI (p=0.057) were strongly associated with OS. Prior chest radiotherapy, prior curative radiotherapy, brain metastases, type of IO, squamous histology, smoking status and age did not.

Conclusion: There were no statistically significant differences in response rates, PFS or OS in patients receiving IO for mNSCLC treated with or without prior RT.

Log Rank Test and Cox Regression were used to assess overall survival (OS) and progression free survival (PFS).

Result: 271 patients treated with IO were identified of which 202 were treated with previous RT (75%) including 153 treated with chest radiotherapy. Median follow up from initiation of IO was 30.3 (0.3-139.9) weeks. At time of last follow up, 56% of patients had died. There were no statistically significant differences in physician assessed response rate or progression free survival between patients treated with prior radiotherapy (52% vs 58%, p=0.41) or prior chest radiotherapy (52% vs 55%, p=0.71). Median PFS was 11 weeks in patients who received RT and 13.9 weeks in patients who did not (p=0.73). Median OS was 41.3 weeks in the radiotherapy cohort versus 42.9 weeks (p=0.50). On univariate analysis, ECOG (p<0.002) and CCI (p=0.057) were strongly associated with OS. Prior chest radiotherapy, prior curative radiotherapy, brain metastases, type of IO, squamous histology, smoking status and age did not.

Conclusion: There were no statistically significant differences in response rates, PFS or OS in patients receiving IO for mNSCLC treated with or without prior RT.

P1.01-26 SINGLE-CENTRE EXPERIENCE OF CLINICAL OUTCOMES FOR ADVANCED NSCLC PATIENTS IN PHASE I CLINICAL TRIALS

D. Graham1, T. Jordan2, N. Tinsley3, S. Aukety1, A. Vickers1, C. Kelly1, R. Kurup1, A. White1, A. Smith1, A. Walsh1, C. Thomson1, S. O’Reilly1, M. Norfolk1, D. Chang1, F. Blackhall1, Y. Summers2, R. Califano4, P. Taylor3, F. Thistlethwaite2, N. Cook2, L. Carter2, M. Krebs4
1Experimental Cancer Medicine Team, The Christie NHS Foundation Trust, Manchester/GB, 2Faculty of Biology Medicine & Health, University of Manchester, Manchester/GB, 3Manchester University and the Christie NHS Foundation Trust, Manchester/GB, 4Wythenshawe Hospital, Manchester University NHS Foundation Trust, Manchester/GB, 5Experimental Cancer Medicine Team, the Christie NHS Foundation Trust, The University of Manchester and the Christie NHS Foundation Trust, Manchester/GB

Background: Response rates for patients enrolled in early phase clinical trials have historically been reported as 5-10%. An unprecedented number of novel therapeutic options and emerging therapies in lung cancer (LC) have resulted in greater emphasis on early phase clinical trials and molecular stratification. We aimed to evaluate outcomes for patients with LC treated since 2015 with novel agents or combination strategies within an expanding early phase clinical trials unit at The Christie Hospital, Manchester, UK.

Method: A database of patients consented to phase I clinical trials was interrogated for LC patients recruited over a three-year period. Clinical characteristics including histological sub-type, line of therapy, molecular phenotype, smoking status and ECOG performance status (PS) were collected for each patient. Patient records were reviewed for clinical trial allocation, treatment response, progression-free survival (PFS), and overall survival (OS).

Result: Over a three-year period to March 2018, 153 lung cancer patients were consented to Phase I clinical trials of Investigational Medicinal Products, of whom 113 (74%) commenced treatment. The median age of patients treated was 64y (range 28-84) with a male predominance (54%). All patients had a PS of 0-1 and 25% were non-smokers. Histological subtypes included non-small cell lung cancer (NSCLC), small cell lung cancer (SCLC) and mesothelioma. The overall response rate (RR) by RECIST criteria was 27% across all patients, with a disease control rate of 72%. Median PFS was 6 months, and median OS was 11 months in the entire cohort. Compared with patients with NSCLC, patients with SCLC had worse PFS (7mo vs 3mo, p=0.001) and RR (35% vs 0%). The 28 trials recruiting LC patients in the unit during this period involved therapies targeting EGFR and ROS1, PI3K-mTOR-AKT and RAS-RAF-MEK signalling. DNA repair genes, cell-surface protein overexpression and genes implicated in immune signalling. Novel agents included small molecule inhibitors, monoclonal antibodies, and antibody-drug conjugates, in addition to immunotherapies combined with chemotherapy or immune checkpoint inhibitor combinations. Patients had between 0-5 prior lines of therapy with no difference in PFS, OS or RR regardless of prior treatment lines.

Conclusion: Our data demonstrate clear benefit for lung cancer patient participation in early phase clinical trials. Novel therapeutic agents and evolution of early phase clinical trial design have resulted in promising options for patients with NSCLC, with RR>30% within our unit, regardless of prior treatment status. However, outcomes for SCLC patients lag behind and new therapeutic options are urgently needed.

Keywords: Phase I clinical trials, novel agents, NSCLC
Background: For sensitizing EGFR mutation positive lung cancer patients, EGFR-TKIs can be used as the first-line or second-line (after chemotherapy) therapy according to NCCN guideline. However, whether different lines of EGFR-TKIs therapy or different PFS would affect the incidence of T790M was significant lower in L858R carrier treated with first-line EGFR-TKIs compared with second-line EGFR-TKIs; and for the 24 (25.00%) L858R carriers vs 66.67%, p=0.082). To further analyzed whether different PFS affected the incidence of T790M mutation, we divided patients into 3 groups as PFS≤13 months (31.67% vs 62.5%, p=0.001). The incidence of T790M was significant lower in L858R carrier treated with second-line compared with first-line EGFR-TKIs (25.00% vs 53.19%, p=0.023), however, there was no difference for EX19del carrier (50.00% vs 64.00%, p=0.26). To further analyzed whether different PFS affects the appearance of T790M, we divided patients into 3 groups as PFS≤13 months (50.00% vs 64.00%, p=0.001). The difference was also significant if only counting the L858R carriers (18.52% vs 59.26%, p=0.002), but not significant in the EX19del carriers (42.42% vs 66.67%, p=0.082). Conclusion: 1) First-line or second-line EGFR-TKIs generally did not increase the appearance of T790M mutation. But for the L858R mutation carriers, the incidence of T790M is significantly decreased if treated as a second-line EGFR-TKIs therapy. In addition, patients with longer PFS were associated with higher incidence of T790M mutation.

Keywords: T790M, EGFR-TKIs therapy, next generation sequencing (NGS)
polymeric micelle formulation of paclitaxel allowed administration of results were obtained in lung cancer. Therefore, the use of CrEL-free, were limitations as an intermediate result, but good efficacy and safety included grade 2 nausea, vomiting and alopecia in all 30 patients. The major non-hematologic toxic effects 40.0%), grade1 thrombocytopenia(n=1, 3.3%) and grade 1/2 anemia(n=8, (CR) and 21 partial responses (PR). There weren't any patients with was 6. Overall response rate was 76.67% with 2 complete responses and adverse events.

Result:

The rationale for developing an alternative paclitaxel formulation concerns Cremophor EL-related side effects, and a novel micelle formulation is composed of hundreds of low molecular weight, non-toxic, and biodegradable amphiphilic diblock copolymers which include monomethoxy poly (ethylene glycol)-block-poly(L-lactide). PAXUS-PM is used to breast cancer, non-small cell lung cancer, and ovarian cancer as 3 week regimen. In other words the data of weekly therapy in NSCLC is not published. Method: This prospective, single-arm, clinical study was designed to evaluate the efficacy and safety of the combination of Genexol-PM and carboplatin for the treatment of advanced non-small-cell lung cancer (NSCLC). Subjects with nonsmall cell lung cancer who met the inclusion/exclusion criteria underwent the tests required per treatment plans and then received Genexol-PM 100mg/m2 and carboplatin 5 AUC(or 6AUC) on day 1, 8, 15 of every 3-week cycle. The choice of therapy was based on the objective response rate as primary objective, and other variables including overall survival (OS), progression free survival (PFS), time to tumor progression (TTP), duration of overall response and adverse events (AE). Result: Thirty patients were enrolled and analyzed intermittently in this study. The median number of administered cycles was 6. Overall response rate was 76.67% with 2 complete responses (CR) and 21 partial responses (PR). There weren't any patients with progressive disease. The Hematological toxicities were manageable and the major hematological toxic effects were grade 1/2 neutropenia(12, 40.0%), grade1 thrombocytopenia(n=1, 3.3%) and grade 1/2 anemia(n=8, 26.7%). There were no grade3/4 adverse events, such as neutropenia and hypersensitivity reactions. The major non-hematologic toxic effects included grade 2 nausea, vomiting and alopecia in all 30 patients. Conclusion: Genexol-PM plus carboplatin combination chemotherapy showed excellent antitumor activity. In this study, there was no significant risk of hematologic and non-hematologic adverse events of grade 3/4. Among the paclitaxel formulations developed to allow high doses, there were limitations as an intermediate result, but good efficacy and safety results were obtained in lung cancer. Therefore, the use of CrEl-free, polymeric micelle formulation of paclitaxel allowed administration of higher doses of paclitaxel and showed safe and efficacious results.

Keywords: Anaplastic lymphoma kinase, crizotinib, non-adenocarcinoma

Background: The clinical benefit of chemotherapy and the appropriate regimen for non-small-cell lung cancer (NSCLC) patients with interstitial lung disease (ILD) remain unclear. We conducted a phase II study to elucidate the efficacy of S-1 in combination with carboplatin (CBDCA) in NSCLC patients with ILD. Method: A total of 33 advanced or recurrent NSCLC patients with ILD were prospectively enrolled in this multicenter, open-label, phase II study (UMIN000010148). A 4-weekly CBDCA at a dose of AUC 5 on day 1 and S-1 at a dose of 80 mg/m2 daily for 14 days were administered. The primary endpoint was the investigator-assessed objective response rate. Result: The median age at initiating chemotherapy was 70. Sixteen patients (48.5%) had squamous cell carcinoma histology. With respect to the types of ILD, the usual interstitial pneumonia pattern was dominant (66.7%). The median number of cycles administered was 3, and the overall response rate and disease control rate were 33.3% and 78.8%, respectively. The median progression-free survival, the median survival time and the 1-year survival rate were 4.8 months, 12.8 months and 51.4%, respectively. Acute exacerbation of ILD caused by chemotherapy was noted in 2 patients (6.1%). Conclusion: This is the first and largest prospective study designed to evaluate the efficacy of a specific chemotherapeutic regimen as the primary endpoint in patients with advanced NSCLC with ILD. The combination of S-1 with CBDCA may be a treatment option for advanced NSCLC patients with ILD.

Keywords: non-small-cell lung cancer, interstitial lung disease, acute exacerbation

Background: Bevacizumab (BEV) combined with platinum-based chemotherapy is a standard treatment for advanced non-squamous non-small-cell lung cancer (non-Sq NSCLC). Cisplatin (CDDP) + pemetrexed (PEM) is suggested as the most chemotherapy regimen in combination with BEV. However, no study has been conducted to evaluate the efficacy and safety of CBDP+P+BEV compared with carboplatin (CBDCA) + paclitaxel (PTX) + BEV for advanced non-Sq NSCLC. Method: Treatment-naïve patients with advanced or recurrent EGFR/ALK-negative

Keywords: Anaplastic lymphoma kinase, crizotinib, non-adenocarcinoma
non-Sq NSCLC from 55 sites across Japan were randomly assigned in a 2:1 ratio to either CDDP+PEM+BEV (4 cycles of CDDP [75 mg/m²] + PEM [50 mg/m²] + BEV [50 mg/m²] on days 1, 8, and 15) or CDDP+PEM (CDDP [75 mg/m²], followed by maintenance PEM [25 mg/m²] q3wk) + BEV [50 mg/m²] q3wk, followed by maintenance BEV [q3wk until progression]. The primary endpoint was progression-free survival (PFS) by central review. The secondary endpoints were PFS by investigators, overall survival (OS), overall response rate (ORR) and safety profile. The target numbers of patients and events were determined to be 210 and 170, respectively, to observe a point estimate of HR for PFS (CDDP+PEM+BEV/CBDCA+PTX+BEV) <0.83 with a 90% power (80%) when the true HR was 0.72. **Result:** Between May 2014 and May 2016, 199 patients were randomly assigned to receive CDDP+PEM+BEV (N=132) or CBDCA+PTX+BEV (N=67). The median follow-up duration was 20.6 months. PFS events occurred in 171 patients. The HR for PFS on review (CDDP+PEM+BEV/CBDCA+PTX+BEV) was 0.825 (95% CI 0.600-1.134, median PFS, 7.6 vs 7.0 months). The median PFS by investigators was longer with CDDP+PEM+BEV than with CBDCA+PTX+BEV (HR 0.634, 95% CI 0.464-0.867, median PFS, 7.4 vs 6.8 months). The median OS was 24.5 months for CDDP+PEM+BEV and 23.6 months for CBDCA+PTX+BEV (HR 0.955, 95% CI 0.620-1.470). The ORR was 57% for CDDP+PEM+BEV and 55% for CBDCA+PTX+BEV. The most common ≥3 adverse events in both arms (CDDP+PEM+BEV/ CBDCA+PTX+BEV) were neutropenia (24%/64%), hypoaatremia (11%/9%) and hypertension (30%/23%). **Conclusion:** CDDP+PEM is the most effective chemotherapy regimen combined with BEV for advanced non-Sq NSCLC.

**Keywords:** Non-small-cell lung cancer, chemotherapy, bevacizumab

P1.01 ADVANCED NSCLC

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-34 DOCETAXEL PLUS RAMUCIRUMAB WITH PROPHYLACTIC PEG-G-CSF SUPPORT FOR CHEMO-NAIVE ELDERLY NSCLC PATIENTS: A PHASE II STUDY (WJOG4167L)

**Background:** Docetaxel monotherapy is the standard of care for chemonaive Japanese elderly patients with advanced non-small cell lung cancer (NSCLC), according to our results of phase III trial comparing docetaxel and vinorelbine (WJOG9904). In a pivotal phase III study (WJOG9904), docetaxel plus ramucirumab demonstrated superior response rate (RR) and progression-free survival (PFS) over docetaxel monotherapy in second-line setting for advanced NSCLC. These differences in RR and PFS were translated into overall survival benefit. This led us to investigate docetaxel plus ramucirumab for chemotherapy-naive elderly patients. However, in a similarly designed Japanese randomized phase II trial (JVCG trial), febrile neutropenia (FN) was observed in 34.2% of docetaxel plus ramucirumab arm. This high incidence of FN is a clinical concern when using docetaxel plus ramucirumab for chemotherapy-naive elderly patients. The ASCO practice guideline recommends primary prophylactic granulocyte-colony stimulating factor (G-CSF) when the risk of FN is 20% or higher. PEGylated-G-CSF (pegfilgrastim) administered once a cycle demonstrated reduction of FN incidence in many types of cancers.

Based on the above background, we considered that primary prophylactic PEG-G-CSF would be beneficial for elderly NSCLC patients who received docetaxel plus ramucirumab maintenance therapy. **Method:** This is a prospective multicenter, single-arm, phase II study conducted by West Japan Oncology Group (WJOG). Main inclusion criteria includes: chemo-naive; aged ≥75; histologically or cytologically confirmed NSCLC; ECOG PS 0/1; adequate organ function review; with measurable disease; without contraindication of ramucirumab; written informed consent; and estimated life expectancy of at least 3 months. Intravenous docetaxel (60 mg/m², day 1) plus ramucirumab (10 mg/kg, day 1) with subcutaneous PEG-G-CSF (3.6 mg/m², day 1 every 3 weeks) is administered until progression. Continuous docetaxel or ramucirumab monotherapy is permitted when intolerable toxicities occur but clinical benefit is obtained by each drug. The primary endpoint is objective response rate (ORR). Secondary endpoints are PFS, OS, disease control rate, and safety. We assumed that the threshold and expected ORR were 20% and 35%, respectively. Based on this, the number of patients was calculated to be 59 to provide a power of 80% with probability of one-sided type I error being 0.05. Taking ineligible patients into account, the sample size was set at 65. When study results are promising, we plan to conduct a phase III trial to compare docetaxel plus ramucirumab with PEG-G-CSF support vs. docetaxel monotherapy for chemo-naive elderly NSCLC patients. Clinical trial information: UMIN000030598. **Result:** Section not applicable

**Conclusion:** Section not applicable

**Keywords:** docetaxel, ramucirumab, PEG-G-CSF

P1.01-35 TUMOR VOLUME ANALYSIS IN ALK-REARRANGED NSCLC TREATED WITH CRIZOTINIB: IDENTIFYING AN EARLY MARKER FOR CLINICAL OUTCOME

T. Hida1, C. Lydon2, H. Hatabu1, B. Johnson1, M. Awad2, M. Nishino3

1Radiology, Brigham and Women’s Hospital, Boston/US; 2Dana-Farber Cancer Institute, Boston/US; 3Radiology, Dana-Farber Cancer Institute, Boston/US

**Background:** Targeted inhibition of anaplastic lymphoma kinase (ALK) has been widely used for the treatment of advanced non-small cell lung cancer (NSCLC) with ALK-rearrangement. We performed tumor volume analysis of ALK-rearranged advanced NSCLC treated with crizotinib to identify an early imaging marker that can predict clinical response. **Method:** Forty-two patients with advanced NSCLC harboring ALK-rearrangement (15 men, 27 women; median age: 55.7 years) treated with crizotinib as their first ALK-directed therapy at Dana-Farber Cancer Institute between November 2008 and June 2016. All patients had a follow-up chest CT scan at 8 +/- 3 weeks of therapy and had a dominant measurable lesion in the lung (≥1 cm) on baseline CT. Tumor volume of the dominant lung lesion was measured on baseline CT and follow-up CT at 8 +/- 3 weeks of therapy, using the previously validated technique on the volume analysis software (Vitrea; Vital Images, Minnetonka, MN). The relationships between the 8-week volume change (%) and overall survival (OS) measured from the 8-week scan date were studied. **Result:** The 8-week tumor volume change ranged from -99.3% to 117.5% (median: 57.7%). Using the 25 percentile of the 8-week volume change of -74%, 11 patients with >74% volume decrease at 8 weeks had a significantly longer OS compared to 31 patients with ≤74% decrease (Median OS: 92.0 months vs. 22.8 months, log-rank p=0.0048). In multivariable analyses using Cox proportional hazards models, the 8-week volume decrease of >74% remained as a significant factor associated with prolonged OS (HR=0.14, 95%CI: 0.03-0.59; Cox p=0.008) after adjusting for other significant variables including tumor stage at presentation (stage IV vs. others, HR=5.6, 95%CI: 1.29-24.3, p=0.02). Of the 31 patients with ≤74% decrease on the 8-week scan, best overall response by RECIST was partial response (PR) in 21 (68%), stable disease in 9 (29%), and progressive disease (PD) in one (3%). None of the 42 patients experienced disease progression (PD) prior to the 8-week scan. **Conclusion:** The 8-week tumor volume decrease of >74% on CT is significantly associated with longer OS in patients with ALK-rearranged NSCLC treated with crizotinib. The 8-week tumor volume analysis helps to identify patients who may benefit from alternative therapy in the early course of crizotinib treatment.

**Keywords:** Non-small-cell lung cancer, Tumor volume, anaplastic lymphoma kinase inhibitor
P1.01-36 THORACIC SURGERY IN NON-SMALL CELL LUNG CANCER WITH EPIDERMAL GROWTH FACTOR RECEPTOR MUTANT AFTER TYROSINE KINASE INHIBITOR THERAPY

C. Hsiao1, S. Kuo2, K. Chen3, J. Chen1
1Surgery, Cheng Hsin General Hospital, Taipei/TW, 2Surgery, National Taiwan University Hospital and National Taiwan University College of Medicine, Taipei/TW, 3Department of Surgery, National Taiwan University, Taipei/TW

Background: Advanced stage non-small cell lung cancer (NSCLC) patients harboring epidermal growth factor (EGFR) mutation have benefit form treatment with tyrosine kinase inhibitors (TKI). However, the role of multidisciplinary management including neoadjuvant TKI therapy and thoracic surgery is uncertain in advanced stage NSCLC. This retrospective study assessed the impact of the multidisciplinary management in advanced stage EGFR mutation positive NSCLC patients.

Method: Advanced stage NSCLC patients were retrospectively identified at Department of Surgery, National Taiwan University Hospital from 2006 to 2013 and prospectively observed. Patients with stage IIIA N2 (unresectable), IIIB, and IV EGFR mutation positive NSCLC treated with neoadjuvant TKI without tumor progression followed by thoracic surgery (NT group) were evaluated. Patients with stage IIIB and IV NSCLC treated with cisplatin-based neoadjuvant chemotherapy without tumor progression followed by thoracic surgery (NC group) were also evaluated. Progression-free survival (PFS) and overall survival (OS) were analyzed.

Result: There were total 88 NSCLC patients in this study. There were 41 men and 47 women. The median age was 58 years. 66 patients were the NC group and 22 patients were the NT group. 60 patients and 20 patients were adenocarcinoma in the NC group and the NT group, respectively. Other patients were squamous cell carcinoma. In the NT group, EGFR status was identified before receiving neoadjuvant TKI therapy. Twelve patients (54.5%) were exon 19 deletion and ten patients were exon 21 L858R mutation. PFS was not significantly different between NC group and NT group (p = 0.028). OS was significantly longer in the NT group than in the NC group (p = 0.014). Exon 19 deletion of the NT group patients had significantly longer OS than the NC group (p = 0.014).

Conclusion: The multidisciplinary management including neoadjuvant TKI therapy and thoracic surgery may possibly have benefit in selected advanced stage NSCLC patients harboring exon 19 deletion.

P1.01-37 BPI-9016M, A NOVEL C-MET INHIBITOR, IN PRETREATED ADVANCED SOLID TUMOR: RESULTS FROM A FIRST-IN-HUMAN, PHASE 1, DOSE-ESCALATION STUDY

X. Hu1, X. Zheng2, H. Mo3, X. Cui4, L. Ding2, F. Tan1, P. Hu1, Y. Shi1
1Cancer Hospital, Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing Key Laboratory of Clinical Study on Anticancer Molecular Targeted Drugs, Beijing/CN, 2Peking Union Medical College Hospital, Beijing/CN, 3Bettapharma Pharmaceuticals Co.Ltd, Hangzhou/CN

Background: BPI-9016M (Betta Pharmaceuticals Co, Ltd, Hangzhou, China) is a potent targeted therapy that inhibits MET and Axl. This first-in-human study is to assess the safety, tolerability, and pharmacokinetics (PK) of BPI-9016M in patients with advanced solid tumor, and to determine the maximum tolerated dose (MTD) and recommended phase 2 dose (RP2D) for the phase Ib/II study. Method: Eligible patients were enrolled into sequential dose-escalating cohorts from 100 mg to 1000 mg given orally once per day continually following the conventional 3+3 design. The primary endpoint was safety and tolerability. MTD was defined as the highest dose level resulting in <1 of 3 dose limiting toxicities (DLTs). Blood levels of BPI-9016M were evaluated after single and multiple administration (NCT02478866). Result: Twenty patients were enrolled and treated in 6 of 7 predefined dose cohorts (100 mg n=4, 200 mg n=3, 300 mg n=3, 450 mg n=4, 600 mg n=3, 800 mg n=3), dose escalation stopped at 800 mg due to saturation. All had stage IV non-small cell lung cancer (NSCLC) progressed on previous systemic therapy (including previous EGFR TKI in 16 patients). BPI-9016M was well-tolerated in all dose cohorts without DLT. The incidence of overall grade 3/4 TRAEs was 85% and 45%, respectively. Common TRAEs included elevated ALT (45%), constipation (30%), elevated bilirubin (25%), and oral parasthesia (25%). Tumor response was seen in 1 patient in the 800 mg dose cohort. Systemic exposure to BPI-9016M (maximum plasma concentration and AUC) increased with increasing dose. Mean time to maximum plasma concentration and half-life were 2 to 5.33 hours and 8.09 to 22.3 hours, respectively. Two metabolites (M1, M2-2) were detected. Conclusion: BPI-9016M was well tolerated in patients with advanced solid tumor. A phase Ib study is ongoing to investigate the safety and activity of BPI-9016M in patients with c-Met-dysregulated advanced NSCLC (NCT02929290).

Keywords: First-in-human, c-Met, NSCLC
Background: Tyrosine kinase inhibitors (TKIs) benefit advanced non-small cell lung cancer (NSCLC) patients that harbor epidermal growth factor receptor (EGFR) mutations, but resistance invariably develops. Preclinical work demonstrated re-sensitization of EGFR-TKIs in cells with acquired resistance, and increased sensitivity of EGFR-mutant cells to erlotinib and hydroxychloroquine (HCQ) combination. We examine the safety and efficacy of HCQ with gefitinib in an Asian cohort of NSCLC patients.

Method: We enrolled stage IIIb/IV lung adenocarcinomas with sensitizing EGFR mutation. In the early phase of the study, non-smokers with unknown EGFR status were allowed. In the phase I lead-in study (Nov 2008-Jan 2010), maximum tolerable dose (MTD) of HCQ and gefitinib was ascertained via a 3+3 dose escalation schema. In the phase II single-arm study (Mar 2010-May 2016), all patients were treated with gefitinib 250mg om and MTD (600mg om) of HCQ, and stratified into TKI-naive and TKI-treated cohorts. In the TKI-treated cohort, patients must have prior response to gefitinib for more than 12 weeks and developed resistance. Primary end point (PEP) in the TKI-naive cohort was objective response rate (ORR) and progression-free survival (PFS). In the TKI-treated cohort, PEP was ORR, and to determine if combination treatment can re-sensitize acquired resistance to EGFR-TKIs. Result: 75 patients were treated. EGFR mutations were identified in 77.3%. In the phase I cohort (n=13), MTD of HCQ was 600mg. HCQ-gefitinib combination was well tolerated. Common adverse events were rash and diarrhea, mainly from gefitinib. There was no dose-limiting toxicity. In the TKI-naive cohort (n=37) of the phase II study, ORR was 75.8% (95% CI 57.8-88.9). Median PFS was 2.4 months, and median overall survival was 9.9 months (95% CI 5.7-14.0). Three patients achieved a progression-free interval of more than 7 months after re-challenge (7.6; 11.2; 15.9 months). Conclusion: Combination of HCQ-gefitinib is safe. In the TKI-naive cohort, combination was well tolerated. Common adverse events were rash and diarrhea, mainly from gefitinib. There was no dose-limiting toxicity. In the TKI-naive cohort (n=37) of the phase II study, ORR was 75.8% (95% CI 57.8-88.9). Median PFS was 9.4 months (95% CI 6.8-12.0). Four patients who were non-evaluable had early toxicities, including pneumonitis and hepatitis flare. In the TKI-treated cohort (n=25), 52% had received 2 or more lines of prior treatment. Disease control rate with TKI re-challenge was 50% (95% CI 18.4-71.9). ORR was 4.2% (95% CI 0.1-21.1). Median PFS was 2.4 months, and median overall survival was 9.9 months (95% CI 5.7-14.0). Three patients achieved a progression-free interval of more than 7 months after re-challenge (7.6; 11.2; 15.9 months). Combination of HCQ-gefitinib is safe. In the TKI-naive cohort, combination treatment can re-sensitize acquired resistance to EGFR-TKIs.

Keywords: non-small cell lung cancer, hydroxychloroquine, gefitinib
Background: NSCLC patients carrying EGFR mutations are diagnosed rarely. In a real-world evaluation, patients 75 years or older comprised almost a quarter of all patients with EGFR-mutant advanced NSCLC. Afatinib and chemotherapy were not used at all in this population. Gefitinib was used most commonly, with similar toxicities and health utilities between older and younger patients. Osimertinib and erlotinib were used too infrequently in this study for conclusive age comparisons.

Keywords: older adults, quality of life, Epidermal growth factor receptor

Conclusion: In a real-world evaluation, patients 75 years or older comprised almost a quarter of all patients with EGFR-mutant advanced NSCLC. Afatinib and chemotherapy were not used at all in this population. Gefitinib was used most commonly, with similar toxicities and health utilities between older and younger patients. Osimertinib and erlotinib were used too infrequently in this study for conclusive age comparisons.

P1.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-42 REAL-WORLD EVALUATION OF TOLERABILITY IN OLDER ADULT PATIENTS (<75 YEARS OLD) WITH EGFR-MUTATED NSCLC
1Princess Margaret Cancer Centre, Toronto/CA; 2Astrazeneca Canada, Toronto/CA; 3Medical Oncology and Haematology, Princess Margaret Cancer Centre, Toronto/ON/CA; 4Division of Respiratory and Thoracic Surgery, Institut Universitaire de Cardiologie Et de Pneumologie de Quebec, Quebec City/QC/CA; 5Dept of Medical Oncology and Haematology, Princess Margaret Cancer Centre and University of Toronto, Toronto/ON/CA; 6Princess Margaret Cancer Centre, Toronto/ON/CA; 7University Hospital Network, Princess Margaret Cancer Centre, Toronto/ON/CA; 8Centre d’Oncologie, Princess Margaret Cancer Centre, Toronto/CA; 9Dept of Medical Oncology and Haematology, Princess Margaret Cancer Centre and University of Toronto, Toronto/ON/CA

Background: NSCLC patients carrying EGFR mutations are diagnosed across a wide age distribution. Although EGFR tyrosine kinase inhibitors (TKIs) are generally well tolerated, there remains a paucity of real-world evidence on the treatment of older patients with these agents. Method: A longitudinal observational study evaluated health-related quality of life (HRQoL) using HUS through the EQ-5D questionnaire, and common EGFR-TKI toxicities using PRO–CTCAE in NSCLC outpatients carrying EGFR mutations. Patients were classified into two groups: older (<75 years) and younger (<75 years). Patient characteristics and outcomes were extracted from chart review; patients were classified as having stable or progressive disease according to imaging findings. HUS and PRO–CTCAE results were compared descriptively. Result: Of 240 patients and 774 encounters, 52 patients (22%; comprising 157 encounters) were aged ≥75 years. Gender and race were similarly distributed in both age groups: 63% of older patients and 70% of younger (<75 years) were female; 56% of older patients and 53% of younger patients were Asian. Use of gefitinib in older patients was much higher than other drugs: among 147 patients who received gefitinib, 27% (40 patients) were older, compared to 15% (3/5) for osimertinib and 15% (6/38) for erlotinib. Of patients receiving afatinib (n=11) and chemotherapy (n=32), none were ≥75 years. The following table describes HUS and PRO–CTCAE results by treatment and age group for stable patients.

Conclusion: In a real-world evaluation, patients 75 years or older comprised almost a quarter of all patients with EGFR-mutant advanced NSCLC. Afatinib and chemotherapy were not used at all in this population. Gefitinib was used most commonly, with similar toxicities and health utilities between older and younger patients. Osimertinib and erlotinib were used too infrequently in this study for conclusive age comparisons.

Keywords: older adults, quality of life, Epidermal growth factor receptor
we note the complexity and heterogeneity of activating EGFR-mutant lung adenocarcinoma that may confer primary resistance to EGFR TKI using NGS platform. This study highlights the advantage of using NGS in routine treatment assessment at NGS of these patients. Method: We retrospectively surveyed 5738 advanced NSCLC patients who underwent EGFR testing in our centre from 2013 to 2017 by in-house primer probes on real time PCR platform. Descriptive data was accumulated from electronic medical records. Survival plot was calculated from Kaplan Meir and compared between groups using Log Rank test. Result: Out of 1260 EGFR mutation positive patients, 83 (6.58%) had uncommon mutations in isolation or in various combinations. Uncommon mutations were more frequent in men than in women (59% vs. 41%), in never smokers than in smokers (65.1% vs. 20.5%) and in adenocarcinomas than non-adenocarcinomas (96.4% vs. 3.6%). Overall Exon18G719X, Exon20insertion, Exon20T790M, Exon20S768I, Exon21L858R/L861Q were present in 5.6%, 19.3%, 12%, 3.6% and 3.6% patients respectively. Dual mutation positivity was found in 50.6% patients. One patient (out of 83) had triple mutations: Exon18G719X, Exon20S768I and Exon21L858R. On classifying patients as per TKI sensitivity, it was found that TKI sensitive single and dual mutations were found in 15.7% and 4.8% respectively. TKI insensitive single mutations were found in 31.3% and a combination of TKI sensitive and insensitive mutations was found in 48.2% patients. The median duration of follow up was 13 months. Five patients were lost to follow up. Overall 50.6% patients received oral TKI and 34.9% received chemotherapy as first line therapy. Response to first line therapy could be assessed in 54 patients, out of whom 28 had partial response, 14 had stable disease and 12 had progression. Median progression free survival (PFS) on first line therapy was 8.2 months (95% CI = 11.4 - 12.9). Median overall survival of patients who received TKI during the course of their disease was 20.2 months (CI = 11.4 - 28.9). Median overall survival of the entire cohort was 15.8 months (CI = 10.1 - 21.5). Among all uncommon mutations, patients with dual mutations did better, with a median overall survival time of 22.6 months (CI = 8.2 - 37.0, p = 0.005). It was observed that TKI Sensitive/TKI Insensitive dual mutations had a superior overall survival of 28.2 months (CI = 15.2 - 41.2, p = 0.042) as compared to TKI Sensitive (single or dual) and TKI insensitive uncommon EGFR mutations. Conclusion: Uncommon EGFR mutations constitute a distinct heterogeneous group, hence it is imperative to understand each subgroup more to define optimal treatment.

Background: ALK mutation is observed in 4% of patients diagnosed with NSCLC. The present study aimed to evaluate the efficacy of crizotinib, an ALK inhibitor, and clinical characteristics of ALK-positive NSCLC patients. Method: In this multicenter, retrospective study, data of ALK-positive advanced stage NSCLC patients who received crizotinib were retrieved from hospital records. Result: Data of 353 ALK-positive metastatic NSCLC patients receiving crizotinib in any treatment line were analyzed. The mean age of the patients was 53.2±12.6 years [median, 53 years (21-85 years)] and 193 (54.7%) patients were male. Age at diagnosis was significantly higher in males than in females (54.8±11.8 years and 51.3±13.2 years, respectively; p=0.044). The rate of patients who never smoked was 50.1%. The most common histological subtype was adenocarcinoma (96%). The frequency of brain metastasis at the time of diagnosis was 23.4%. The most common initial symptoms were cough (66.5%) and dyspnea (53%). Initial EGFR sensitizing mutation was found in 11% in 80% of the patients. Crizotinib had been used in 37% of the patients in the 1st-line treatment, in 45% of the patients in the 2nd-line treatment, and in 18% of the patients in the ≥3rd-line treatment. Table 1. Response rates of the patients

Keywords: NSCLC, ALK inhibitor, crizotinib

ORR was 69.4% and DCR was 83.6% (Table 1). ORR and DCR in the patients received crizotinib were 70.2% and 84.7% in the 1st-line treatment, respectively and were 74.1% and 87.4% in the 2nd-line treatment, respectively. The frequency of brain metastasis was 40.2% at 12 months. Of these patients, the median PFS and OS were 11.3 and 23.4 months, respectively. The most common side effects were fatigue, visual disturbances, nausea, abdominal discomfort, and pretibial edema. Conclusion: Clinical characteristics of ALK-positive patients and crizotinib efficacy are consistent with studies. Response rates and survival outcomes are similar regardless of treatment lines. Crizotinib is safely used in these patients.

Keywords: NSCLC, ALK inhibitor, crizotinib
Keywords: response to treatment with EGFR-TKI and for early detection of resistance. Plasma ctDNA is a relatively non-invasive tool to monitor the therapeutic emergence of and resistance to osimertinib. Molecular analysis of plasma ctDNA can aid in the early detection of acquired resistance to osimertinib through the identification of additional genetic changes that may be related to osimertinib resistance. This includes the detection of mutations in EGFR and MET, which are commonly mutated in EGFR-mutant NSCLC. A previous study demonstrated that allele frequencies of mutations in baseline ctDNA 2-4 months before radiographic progression. While these early results demonstrated that allele frequencies of mutations in genes, including EGFR, PIK3CA, and TP53 closely reflected response and resistance to osimertinib, MET and EGFR amplification, as well as the emergence of EGFR C797S mutation were identified as key resistance mechanisms by NGS analysis. Full details on all patients will be presented at the meeting.

Conclusion: Quantitative assessment of plasma ctDNA is a relatively non-invasive tool to monitor the therapeutic response to treatment with EGFR-TKI and for early detection of resistance mechanisms for clinical decision making.

**P1.01 ADVANCED NSCLC**

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

**P1.01-49 IRAE, POSSIBLE PREDICTIVE MARKERS FOR IMMUNE CHECKPOINT INHIBITORS**

K. Komiyà1, T. Nakamura1, H. Hirakawa1, S. Ogusu1, C. Nakashima2, K. Takahashi2, S. Kimura1, N. Sueoka-Aragane2

1Saga University, Saga/IP, 2Internal Medicine, Saga University, Saga/IP

**Background:** Although an immune-related adverse event (irAE) in immune checkpoint inhibitors (ICIs) is a major cause of discontinuation of ICIs, few reports have examined detailed clinical background in clinical practice. **Method:** Sixty-one patients with non-small cell lung cancer who underwent treatment with ICIs (nivolumab or pembrolizumab) at the Saga University Medical School from December 2015 to January 2018 were included. Clinical background, therapeutic effect, and progression free survival (PFS) were retrospectively examined between AE discontinuation group (AEg) and progressive disease (PD) discontinuation group (Pdg). **Result:** Of the 41 patients receiving nivolumab, nine cases (22.5%) were discontinued due to AE and 22 cases (55.0%) were PD. Of 21 patients receiving pembrolizumab, nine cases (42.9%) were discontinued due to AE and 8 cases (38.1%) were PD. There was no significant difference between nivolumab and pembrolizumab in the discontinuation rate due to AE (p=0.14). When comparing the clinical background between the AEg and the Pdg, the response rate was 50.0% in the AEg and 6.7% in the Pdg, which was significantly higher in the AEg (p=0.001). The median PFS was significantly longer in the AEg, 301 days (95% CI: 193-336) in the AEg and 60 days (95% CI: 74-178) in the Pdg (Log-Rank, p=0.009). Among irAEC, the incidence of interstitial lung disease (ILD) was 3/49 (6.1%) in cases without pre-existing ILD (IP) or radiation pneumonitis (RP) or IP or radiation pneumonitis as the underlying disease (p=0.951) were not associated with differences in OS compared to those with IP or radiation pneumonitis. Thyroid changes (p=0.411) were not associated with differences in OS compared to those without thyroid changes. Among nine patients who developed ILD, grade 3 or more was 2 cases, of which 1 case was grade 5. Among nine patients who developed ILD, grade 3 or more was 2 cases. **Conclusion:** Discontinuation due to AE at treatment of ICIs may be a predictive marker for good response to ICIs and favorable outcome since anti-cancer effect continued even after discontinuation. However, the presence of IP or radiation pneumonitis as the underlying disease is a risk factor for the onset of ILD, so it is necessary to carefully consider the indication for treatment of ICIs.

**Background:** Immune related adverse events (irAE) from immunotherapy in metastatic melanoma have been correlated with efficacy; this association is less clear in mNSCLC. We aimed to evaluate the correlation between irAE and clinical efficacy of pembrolizumab (P) in mNSCLC. **Method:** We retrospectively identified 143 separate irAE of Gr 1(64), Gr 2(54), Gr 3(12), Gr 4(9), and Gr 5(4). Of 215 pts treated with P between 11/2015 to 10/2017 at BC Cancer were identified. Demographic, tumor, treatment details, and frequency and grade (Gr, CTCAE v4.0) of irAE, were collected from the start of N, and median Charlson Comorbidity Index (CCI) 6, and 72% of pts were: median age 68y (range 50-81), females 49%, non-squamous histology 81%, PO-LI status <1%/1-49%/>50%/unknown 0/12%/83%/5%, brain metastases rate 15%, and liver metastases rate 12%. ECOG PS>1 and a high CCI, the incidence of serious irAE was low. The impact of gender on response to P requires more study. Development of irAEs was compared to those without irAE. Significant difference in OS amongst pts who developed any irAE (median 10.8 months, 95% CI: 8.6-14.5; log rank test p=0.013). Thyroid changes (p=0.473), dermatitis (p=0.29), pneumonitis (p=0.318), hepatitis (p=0.135), and arthralgias (p=0.48) were not associated with different OS compared to those without irAE. Among nine patients who developed ILD, grade 3 or more was 2 cases, of which 1 case was grade 5. **Conclusion:** Among irAE, the incidence of interstitial lung disease (ILD) was 3/49 (6.1%) in cases without pre-existing ILD (IP) or radiation pneumonitis (RP) or IP or radiation pneumonitis as the underlying disease (p=0.951) were not associated with differences in OS compared to those with IP or radiation pneumonitis. Di Cristina” – Mastelli, Perugia/IT, 31Oncologia e immunoterapia, University Hospital of Siena, Siena/IT.

Background: Approximately 40% of NSCLC patients develop bone metastases (BM). Bone has active functions in regulating immune and inflammatory processes. Intra-tumor bone metastases (BoM) predict lower efficacy of immunotherapy. Hence, the aim of the present study was to investigate whether presence of BoM in modulating response to immunotherapy. Method: Two different cohorts of pretreated NSCLC patients (cohort A: Non-squamous; cohort B: Squamous) were evaluated for nivolumab efficacy in terms of objective response rate (ORR), progression free survival (PFS), and overall survival (OS) according to presence or absence of BoM. All patients received nivolumab at standard dose of 3 mg/kg every 2 weeks within the Italian Expanded Access Program. Result: Cohort A accounted for 1588 patients with non-squamous NSCLC: 626 (39%) with (BoM+) and 962 (61%) without BoM (BoM-). Cohort B accounted for 370 patients with squamous histology: 102 BoM+ (22%) and 268 BoM- (68%). In cohort A, BoM+ had a significantly lower ORR (12% versus 34%; p < 0.0001), shorter PFS (2.0 versus 4.0 months, p < 0.0001) and shorter OS (7.4 versus 15.3 months, p < 0.0001). In cohort B, BoM+ had significantly lower ORR (3% versus 22%; p < 0.04), shorter PFS (2.7 versus 5.4 months, p < 0.0001) and shorter OS (5.0 versus 10.9 months, p < 0.0001). Presence of BoM negatively affected outcome irrespective of PS (OS cohort A: PS 0-BoM+ 12.0 versus 20.9 months in PS 0-BoM-, p < 0.0001; OS cohort B: PS 0-BoM+ 5.8 versus 16.4 months in PS 0-BoM-, p < 0.0001). Multivariate analysis confirmed that presence of BoM independently associated with higher risk of death with HR 1.64 and HR 1.78, for Cohort A and B, respectively. Conclusion: Our results, the first assessing BoM in patients treated with immunotherapy, suggested that BoM predict lower efficacy of immunotherapy. BoM should be included as stratification factor in clinical trials.

P1.01-55 UNIQUE GENETIC PROFILES FROM CEREBROSPINAL FLUID COULD PREDICT SURVIVAL OF EGFR-MUTANT NSCLC WITH LEPTOMENINGEAL METASTASES

Y. Li1, B. Jiang1, M. Zheng1, H. Tu1, J.-Y. Yang1, X. Zhang1, J. Ye2, Q. Zhou1, W. Zhong1, C. Zhang1, S. Chuai3, Y. Wu4
1Guangdong Lung Cancer Institute, Guangdong Provincial Key Laboratory of Translational Medicine in Lung Cancer, Guangdong General Hospital & Guangdong Academy of Medical Sciences, Guangzhou/CN, 2Burning Rock Biotech, Guangzhou, China, Guangzhou/CN, 3Burning Rock Biotech, Guangzhou, China, Guangzhou/CN, 4

Background: Leptomeningeal metastases (LM) are more frequent in NSCLC with EGFR mutations; and cerebrospinal fluid (CSF) could reveal the unique genetic profiles of LM in our previous studies, but whether they could predict the overall survival (OS) of LM remains unknown.

Method: EGFR-mutant NSCLC patients with LM were enrolled, and clinical data and genetic profiles detected by Next-generation sequencing were collected. We further drew nomogram with endpoint of OS after LM, then performed index of concordance (C-index) and survival analysis to evaluate predictive role. Result: In total, 61 patients were enrolled and all with genetic profiles from CSF. Patients with high copy number variations (CNVs) or harboring CDK6, TP53 exon5 or FGF19 in CSF demonstrated significant poorer OS than those without (Fig. 1). Cox regression analysis indicated CNVs, CDK6, CDKN2A, TP53, MET and NTRK1 as prognostic factors and further selected for nomogram (Fig. 2). C-index of nomogram was 0.743, indicating the moderate predictive effect. In the calibration curves, we scored the patients based on the model, using bisection and trisection methods to divide into low and high points groups; and low, medium and high points groups (Fig. 3), and significant difference were found in both the survival analyses (NA versus 7.47 months, \( P < 0.01 \)) and (NA, 10.33 versus 4.43 months, \( P < 0.01 \)) respectively. Patients who received Osimertinib after LM seemed to have longer OS than those who did not (14.5 months versus 7.7 months) but without significant difference (\( P = 0.10 \)); however interestingly, in those with EGFR T790M negative who took Osimertinib after LM by themselves obtained survival benefit than those who did not.

Conclusion: Unique genetic profiles from CSF could well predict OS of LM. High CNVs, CDK6, TP53 exon5 or FGF19 in CSF in NSCLC may be related to poor prognosis of LM.

### P1.01-56 CONCURRENT MUTATIONS IN CHINESE LUNG CANCER PATIENTS CARRYING HER2 GENOMIC ABERRATIONS

**Keywords:** mutations when considering anti-HER2 targeted therapy.

**Chinese lung cancer patients was common.** The complex molecular generation sequencing (NGS) amplified. Table 1. concurrent genetic alterations in HER2-altered patients had more than 2 concurrent mutations besides HER2 mutation/mTOR signaling pathways, cell-cycle pathway, DNA repair pathway, actionable mutations across 18 genes, which involved in RTK-PIK3CA-in 48 patients, co-occurrence of HER2 amplification and mutations aberrations were diagnosed as lung cancer. The HER2 gene was deletions, rearrangements, and copy-number alterations of at least 59 genes (59-1021).

**Method:** A total of 147 cancer patients with HER2 mutations were enrolled in the study. Tumor biopsy, ctDNA and pleural effusion samples were collected for detection alterations using hybridization capture based next-generation sequencing (NGS), which enables the simultaneous detection of single-nucleotide variants, insertions/deletions, rearrangements, and copy–number alterations of at least 59 genes (59-1021).

**Result:** Sixty-two of 147 patients with HER2 genomic aberrations were diagnosed as lung cancer. The HER2 gene was amplified in 11 (18%) patients, whereas HER2 mutations were detected in 48 patients, co-occurrence of HER2 amplification and mutations were in 3 patients. Thirty of the 62 patients (48.39%) had concurrent actionable mutations across 18 genes, which involved in RTK-PIK3CA-mTOR signaling pathways, cell-cycle pathway, DNA repair pathway, RAS-RAF-MAPK pathway and some others (details in Table). Moreover, 7 patients had more than 2 concurrent mutations besides HER2 mutation/amplification. Table 1. concurrent genetic alterations in HER2-altered lung cancer patients

### P1.01-57 THE ROLE OF EGFR MUTATION AS A PROGNOSTIC FACTOR IN SURVIVAL AFTER DIAGNOSIS OF BRAIN METASTASIS IN NSCLC: A SYSTEMATIC REVIEW AND META-ANALYSIS

**Background:** The brain is a common site for metastasis in non-small-cell lung cancer (NSCLC), causing poor prognosis and reducing quality of life. This meta-analysis was designed to evaluate the relationship between the mutational status of the epidermal growth factor receptor (EGFR) and overall survival (OS) in NSCLC patients with brain metastases.

**Method:** Electronic searches were performed in PubMed, Embase, and the Cochrane Library to identify studies evaluating the association of EGFR mutation with OS in NSCLC patients with brain metastases through September 2017. Hazard ratios (HRs) with 95% confidence intervals (CIs) were used to calculate the-summary results using random-effects models.

**Conclusions:** This meta-analysis identified 18 studies involving 4,373 NSCLC patients with brain metastases. The summary results indicated that mutated EGFR associated with significantly improved OS compared with wild type EGFR (HR: 0.73; 95%CI: 0.54-0.99; P = 0.045). Subgroup analyses suggested that this relationship persisted in studies conducted in Eastern countries (HR: 0.59; P = 0.021), in studies with retrospектив design (HR: 0.70; P = 0.004), with sample size ≥ 500 (HR: 0.52; P = 0.001), mean age of patients ≥ 65 years (HR: 0.59; P = 0.043), percentage male ≥ 50.0% (HR: 0.60; P = 0.002), percentage of patients receiving tyrosine kinase inhibitor ≥ 30.0% (HR: 0.60; P < 0.001), and in studies with higher quality (HR: 0.67; P = 0.007). Finally, although significant publication bias was observed using the Egger test (P = 0.008), the results were not changed after adjustment using the trim and fill method (HR: 0.73; 95%CI: 0.54–0.99; P = 0.045). This meta-analysis suggests that EGFR mutation is an important predictive factor linked to improved OS for NSCLC patients with brain metastases. It can serve as a useful index in the prognostic assessment of NSCLC patients with brain metastases.

**Keywords:** lung cancer, EGFR, Brain metastasis
v5 was structurally stable and less sensitive to ALK inhibitors due to the lack of TAPE domain. In this study, patients harboring v3 and v5 displayed significantly inferior OS than those with other variants (31 vs 37.6 months, p=0.010). For all the ALK-rearranged patients (n=110), no significant difference was observed between the survival of EML4-ALK and non-EML4-ALK (PFS, 9.4 vs 14.5 months, p=0.61; OS, 35.1 vs 35.5 months, p=0.58) below and above 40-years (PFS, 7.3 vs 11.3 months, p=0.23; OS, 25.4 vs 35.5 months, p=0.69). Conclusion: This study demonstrated the distribution pattern of ALK rearrangements in Chinese NSCLCs, and illustrated the clinical outcomes of ALK-positive patients in different sub-groups. We hope this study could improve basic knowledge of ALK rearrangement and might be helpful for clinicians in choosing patients for appropriate medical treatment. Moreover, these findings advocate for more comprehensive ALK genomic profiling and validation of current results of clinical outcomes in large populations.

Keywords: ALK, crizotinib, NSCLC

P1.01-59 A BETTER REAL WORLD PRACTICE FOR ROS1 POSITIVE NSCLC PATIENTS, DRIVEN BY THE TARGETED NEXT GENERATION SEQUENCING (NGS) AND THE TARGETED TKI

Z. Liang1, Y. Zhang1, N. Yang1, Y. Li2
1Department of Medical Oncology, Hunan Cancer Hospital, Changsha/CN, 2Department of Internal Medicine, National Cheng Kung University Hospital, Tainan/TW.

Background: Methodologically, Targeted NGS had been shown comparable to classical testing methods in testing sensitivity and specificity in several driver genetic aberrations. However, Data of standard TKI treatment outcome in NGS identified ROS1-positive NSCLC was rare, especially in TKI concomitant clinical trials, thus it was critical and necessary to evaluate it in the real world. Method: We carried out a real world retrospective study in our center. From September 2015 to December 2017, NSCLC in-patients with targeted NGS testing (Burning Rock Dx; 8 genes or 56 genes panel) results were included in our study. Data of NGS multiple genes testing, crizotinib efficacy and potential clinical and genetic influential factors, and safety were analyzed. Result: 1104 NSCLC patients with targeted NGS testing (Burning Rock Dx; 8 genes or 56 genes panel) results were included in our study. The occurrence rate of ROS1 rearrangement was 1.5% (N=17). Seven phenotypes of ROS1 rearrangement were detected and the most common one was CD74-ROS1, which accounted for 45% (9 of 20). Furthermore, three patients were found carrying two different ROS1 rearrangements. 41% (7 of 17) patients were discovered with other concomitant mutations: including TP53 & PIK3CA mutation (n=1), TP53 & CDKN2A mutation (n=1), TP53 & BRCAl2 mutation (n=1), PIK3CA & ALK missense mutation (p.R313H) (n=1), MET amplification (n=1), TP53 mutation (n=1), ERBB2 mutation (n=1). Among all NSCLC patients with ROS1 rearrangement, 13 patients were diagnosed at stage IV and 12 patients received crizotinib treatment. The average follow-up period since crizotinib initiation was 12.7 months (range from 1.5 to 28 months). The ORR and DCR of crizotinib were 75% and 83% (9 PR, 1 SD and 2 NA) respectively. The median progression-free survival (mPFS) of crizotinib treatment was 14 months. Of influential factors analysis, it was shown that NSCLC patients with exclusive ROS1 rearrangement had a longer PFS than those carrying concomitant mutations (mPFS 15.9months vs 8.5months; p=0.0213) and there was no significance impact on PFS considering brain metastasis, crizotinib treatment lines or rearrangement subtypes. No grade 3 and 4 adverse events were observed in this retrospective study. Conclusion: Crizotinib is highly effective and tolerable in NGS identified ROS1 rearrangement advanced NSCLC in real-word clinical practice and the data is consistent with that in the previous clinical trials applying IHC/FISH/RT-PCR as ROS1 companion diagnosis. NSCLC patients with exclusive ROS1 rearrangement had better PFS under Crizotinib treatment compared to those with concomitant mutations.

Keywords: next-generation sequence, ROS1 rearrangement, crizotinib

P1.01-60 PREVENTING AND TREATING BRAIN METASTASES WITH THREE FIRST-LINE EGFR-TKI IN PATIENTS WITH EGFR MUTATION ADVANCED NSCLC

C. Lin1, W. Su1, Y. Wu2
1Department of Internal Medicine, National Cheng Kung University Hospital, Tainan/TW, 2Department of Nursing, National Cheng Kung University Hospital, Tainan/TW

Background: Brain metastases (BM) are common in advanced non-small cell lung cancer (NSCLC), and the prognosis is poor with few therapeutic options. This retrospective study evaluated the efficacy of three epidermal growth factor receptor-tyrosine kinase inhibitors (EGFR-TKIs) in preventing and treating BM in patients with EGFR mutation-positive advanced NSCLC. Method: All patients with EGFR mutation-positive advanced NSCLC who visited a tertiary referral center from December 1, 2013, to November 30, 2017, were analyzed retrospectively. These patients received gefitinib, erlotinib, or afatinib until disease progression, death, or intolerable adverse events. The cumulative incidence of subsequent BM and the progression-free survival (PFS) and overall survival (OS) of both the BM patients and non-BM patients were estimated by the Kaplan–Meier method and compared using the log-rank test. We performed Cox proportional hazards regression for the predictors of subsequent BM and determinants of PFS and OS. Result: A total of 306 patients with newly diagnosed or recurrent NSCLC were enrolled. Among these patients, 116, 75, and 115 received first-line gefitinib, erlotinib, and afatinib, respectively. The patients who received afatinib had a better PFS (12.7 versus 9.8 months, p=0.001) and OS (39.1 versus 22.0 months, p=0.035) than those who received gefitinib. The cumulative incidences of subsequent BM were similar among the patients who received different TKIs (p=0.80). Patients with initial BM were associated with a shorter PFS (p=0.001) and OS (p=0.015) than those without BM. Among the initial BM patients, there were no differences in median PFS (p=0.34) and median OS (p=0.46) in the three EGFR-TKI groups.

Conclusion: Our data suggested afatinib provided significant benefits in terms of PFS and OS as well as preventing subsequent BM compared to gefitinib, in addition to providing the same effectiveness in treating BM as gefitinib.

Keywords: Brain metastasis, tyrosine kinase inhibitor, EGFR mutation
Background: The epidermal growth factor receptor (EGFR) T790M mutation is the most common mechanism of drug resistance to EGFR tyrosine kinase inhibitors (TKIs) in non-small cell lung cancer (NSCLC) patients with sensitizing EGFR mutations. The third generation irreversible EGFR inhibitor HS-10296 has been shown to be safe and effective against both EGFR TKI-sensitizing and T790M resistant NSCLC in several clinical studies.

Method: A Phase I, open-label, multi-center clinical trial was conducted in patients with locally advanced or distant metastatic NSCLC who have progressed following prior therapy with EGFR TKIs. The study was consisted of dose-escalation cohorts (55, 110, 220 and 260 mg) and dose-expansion cohorts (55, 110, 220 and 260 mg) and once daily administration of HS-10296. In each expansion cohort, tumor biopsies were collected for central determination of EGFR T790M status.

Patients were assessed for safety, tolerability, pharmacokinetics and efficacy of HS-10296.

Results: A total of 117 patients (median age 60) received at least one dose of HS-10296 across multiple sites in China (43 patients), Taiwan (69 patients) and the United States (5 patients). Maximum tolerated dose (MTD) has not been reached in this study. The most common adverse events grade 1/2 rash, pyrexia, upper respiratory tract infection, constipation, diarrhea and blood creatine phosphokinase elevation. Drug-related serious adverse events were anemia (0.8%), blood creatine elevation (0.8%), anemia/hypothyroidism (0.8%) and bilirubin elevation (0.8%). The overall response rate in the MTD dose cohorts with higher doses at 220 mg or 260 mg, respectively. These data demonstrated favorable tolerability and safety of HS-10296 in patients enrolled.

The pharmacokinetics of HS-10296 was dose proportional and the plasma half-life was 30.7-37.5 hours. Among 82 evaluable patients (18 in escalation cohorts and 64 in expansion cohorts) with the EGFR T790M mutation, the overall response rate (ORR) was 52.4% (43/82; 95% CI, 41.6 to 63.3), while disease control rate (DCR) was 91.5% (75/82; 95% CI, 85.4 to 97.5). 110mg cohort showed better DCR (97.2% vs. 86.1%) than 55mg cohort. Phase II study was conducted in Taiwan at the dose of 110 mg. Conclusion: HS-10296 has the potential to provide clinical benefit to locally advanced or distant metastatic NSCLC patients with EGFR T790M mutation who had disease progression following prior therapy with EGFR TKIs. The study was sponsored by Jiangsu Hansoh Pharmaceutical Co., Ltd.; ClinicalTrials.gov number, NCT02981108.

P1.01-63 CORRELATION BETWEEN IMMUNE-RELATED ADVERSE EVENTS AND EFFICACY OF IMMUNE-CHECKPOINT INHIBITORS IN PATIENTS WITH NON-SMALL CELL LUNG CANCER

M. Riudavets Meila1, I. Gabriela Sullivan1, A. Barba Joaquin1, G. Anguera Palacios1, L. Del Carpio Huerta1, C. Molto Valiente1, S. D. Camacho Arellano1, S. Moron Asensio1, P. Gomila Pons1, M. Andrés Granyó1, C. Facundo Molas2, E. Garcia Planella1, C. González Blanco1, I. Genua Trullós1, L. Tuneu Valls1, N. Stantonogy Sesé1, N. Álvarez Cuenca1, B. Hidalgo Molina1, I. Och Saladich1, M. Mijem Tarrella1

Background: Immune-checkpoint inhibitors (ICIs) are a standard treatment in advanced non-small cell lung cancer (NSCLC) patients. These drugs can induce immune-related adverse events (irAEs) that may compromise treatment continuation. Here we report our experience in patients with NSCLC, the incidence of irAEs and its correlation with efficacy. Method: We have retrospectively analyzed 101 patients with advanced NSCLC receiving ICIs in our institution from March 2014 to January 2018. irAEs were graded following CTCAE v4.0. Kaplan Meier and log-rank tests were used to evaluate progression-free (PFS) and overall survival (OS). Analyses were performed using SPSS v24 package. Result: Median age was 64 (43-78) years, 74.3% were male, 33 (32.7%) patients presented squamous and 68 (67.3%) non-squamous histology. Most frequent irCIs were nivolumab (50%), pembrolizumab (31%) and atezolizumab (16%), used as monotherapy (79.2%) or in combination with chemotherapy (20.8%). 37.6% patients were treated with ICIs in first line setting, while
Keywords: non-small cell lung cancer, immune-checkpoint inhibitors, immune-related adverse events
an anti-estrogen could overcome resistance to EGFR-TKI. **Method:** IFC7-1003 LADIE Trial was a 2x2 arms parallel-label randomized phase II trial. In this post-menopausal stage IIIB lung adenocarcinoma were treated with gefitinib (250 mg/day) vs. G + fulvestrant 500 mg / month with a supplementary dose at day 15 (G+F) in the EGFR mutated group (EGR+) in 1st or 2nd line setting or with erlotinib (E 150 mg/day) vs. E + fulvestrant (E+F) in the EGFR wild-type group (EGRWT) in 2nd or 3rd line setting until progression or unacceptable toxicity. **Primary objective** was progression-free survival (PFS) at 3 and months for EGFR WT and EGFR+ patients, respectively. **Results:** From 02/2012 to 03/2017, 204 pts (G 104, G+F 100) were enrolled in the EGFR+ and EGFR WT cohorts respectively. The median number of fulvestrant injections was 10 in the G+F group and 3 in the E+F group. The tolerance was correct (grade 3/4: 2.2% in the G+F group vs. 21.3% in the G group, 16.0% in the E+F group vs. 13.8% in the E group) and no treatment-related death in the EGFR+ cohort, the primary endpoint was reached as 54 pts in the G+F group were non-progressive at 9 months. Nevertheless, addition of F to G was not associated with significant better PFS (9.9 vs 10.1 months) or OS (29.9 months). In the EGFR wild-type group (EGRWT), the cohort, the primary endpoint was not reached as 29 patients were non-progressive at 3 months. Here also, addition of F to E was not associated with better outcome (PFS 1.8 vs 2.0 and OS 10.0 vs 7.3 months). No PFS difference was observed in the subgroup of patients with positive staining for REX. **Conclusion:** Addition of fulvestrant to EGFR-TKI is feasible and is associated with good PFS in the EGFR mutated group. Nevertheless, the lack of benefit associated with the combination of fulvestrant to EGFR-TKI does not support its future development in a phase 3 trial in women with NSCLC.

**Keywords:** fulvestrant, EGFR-TKI, NSCLC

P1.01 ADVANCED NSCLC

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-67 CORRELATION OF THE LUNG IMMUNE PROGNOSTIC INDEX (LIP) AND PD1 STATUS WITH OUTCOMES FOR IMMUNE CHECKPOINT INHIBITORS IN ADVANCED NSCLC PATIENTS

**Medical Oncology Department, Gustave Roussy, Villejuif/FR, 1**Sylvester Comprehensive Cancer Center, University of Miami, Miami/US, 2**Medical, Memorial Sloan Kettering Cancer Center, New York/NY/US, 3**Medical and Gastrointestinal Oncology Department, Genetics and Medicine, Pompidou Hospital, Paris/FR, 4**Pulmonology, Maastricht University Medical Center, Maastricht/NL, 5**Medical Oncology, Gustave Roussy, Villejuif/FR, 6**UM/sylvester Cancer Ctr, Miami/US, 7**Medical Oncology Department, University Hospital, Madrid/ES, 8**Department of Medical Oncology, Catalan Institute of Oncology, L'Hospitalet/ES, 9**Hospital Sainte-Musse, Toulon/FR, 10**Department of Oncology, University of Turin, Turin/IT, 11**Pathology, Gustave Roussy, Villejuif/FR, 12**Medical Oncology, Catalan Institute of Oncology, Hospital Duran i Reynals, Hospitalat de Llobregat/ES, 13**Hospital Bichat, Paris/FR, 14**Medical Oncology Department, Ss Antonio and Biagio and C Arrigo Hospital, Alessandria/IT, 15**Medical Oncology, Hospital Sant Pau, Barcelona/ES, 16**Hospital Universitario 12 de Octubre, Madrid/ES, 17**Department of Oncology, Univ. of Turin. **Background:** ICI outcomes in NSCLC. We assessed the correlation between LIP and PD1 for IC1 outcomes in NSCLC. **Method:** Baseline dNLR and LDH and clinical data were retrospectively collected in advanced NSCLC patients, treated with PD1/PD-L1 +/- CTLA4 inhibitors from Nov 2012 to Mar 2018, in a multicentric cohort (N=794) from 11 centers. LIP stratified 3 groups: good (dNLR<3) or low (dNLR<3 or LDH<ULN), intermediate (dNLR>3 and LDH<ULN) or high (dNLR>3 and LDH>ULN). PD1 positivity was defined as ≥1% tumor cells expression by immunohistochemistry. **Result:** 476 patients (60%) were male, 693 (87%) smokers, 695 (88%) had PS ≤1, with a median age 69; 576 (73%) had nonsquamous histology. LIP was ≥1% in 195 (70%) patients, negative in 82 (30%), and unknown in 517. The median of prior lines was 1 (0-11). The median PFS and OS were 4 months (m) [95% CI 4-5] and 12 m [10-15]. dNLR was ≥3 in 276 (35%) and median PFS and OS were 21 m [17-23] and 11 m [9-14] and 4 m [2-6], respectively (P=0.0001). Median PFS for good, intermediate, and poor risk was 5 m [7-8], 4 m [5-3], and 2 m [1-3], respectively (P=0.0005). No differences were observed in LIP groups according to the PDL1 expression.

**Keywords:** Liquid biopsy, ALK, ROS1, resistance, mutation
Background: Derived neutrophils/leukocytes-neutrophils) ratio (dNLR) and lactate dehydrogenase (LDH) level have been correlated with immune checkpoint inhibitors’ (ICI) outcomes. A lung immunogenic prognostic index (LIPI) that showed association with ICI outcomes was developed by Mezzit L et al. Based on these 2 systemic inflammation indicators (dNLR <3 and LDH > upper limit of normal (ULN)), characterizing 3 prognostic groups: good, 0 factors; intermediate, 1 factor; poor, 2 factors.

Method: This is a multicenter retrospective study with the aim to validate prognostic value of LIPI score in pretreated advanced-stage non-small-cell lung cancer (NSCLC) treated with ICI. We included consecutive patients treated with nivolumab or pembrolizumab between March 2015 and April 2018 from 7 medical centers in Spain. Investigators at each institution retrospectively reviewed patients’ medical records. Pretreatment LIPI score was calculated for all subjects and the primary endpoint was correlation with OS. Result: A total of 168 patients were included. Median age 65 years (39-85). 134(78.9%) were male and 121 (72%) were PS 0. Predominant histologies were adenocarcinoma (50%), and squamous-cell carcinoma (42.9%), 92.3% were treated with nivolumab and 7.7% with pembrolizumab. Median number of prior lines was 1 (1-5). Median number of cycles: 11 (1-68). Most were current or former smokers (94.6%). Only 2.3% had EGFR mutations, and 0.6% ALK rearrangement. PD-L1 immunohistochemistry was only available in 25% of patients (11% 0%; 3% 1%; 4% 2%; 1% 3%; 1% 4%; 15% >4%). After calculating LIPI score, 56.4% were LIPI 0 (good prognosis), 38.5% LIPI 1 (intermediate prognosis), and 5.1% LIPI 2 (poor prognosis). Response rate (RR) was 30.4% and disease control rate (DCR) 52%. The median PFS and OS were 5.6 months (95% CI 3.9-7.3) and 11.4 m (9-13.5). Median OS for good, intermediate, and poor was 14m (95% CI 11.2-16.7), 6.3m (95% CI 0.6-12) and 1.8m (95% CI 0-4.3), respectively (p=0.0001). LIPI showed correlation with OS in patients with known PD-L1 status and also in those with no information about it. PFS was also correlated (p=0.004) with LIPI score. A LIPI score of 2 was independently associated with poorer OS (HR 4.9; 95% CI, 2.18-11.1). Conclusion: Our results support the prognostic value of pretreatment LIPI score. dNLR <3 and LDH greater than ULN was correlated with worse outcomes for ICI, regardless of the knowledge of PD-L1 status. This is a useful tool, based on clinical criteria, that can help physicians to stratify patients according to the likelihood of benefit from ICI.

Keywords: NSCLC, immune checkpoint inhibitors, ICI, biomarkers
FGFR genetic alterations will be treated in 11 clinical centers in Germany with the selective FGFR1-4 kinase inhibitor erdafitinib. Archived samples, fresh and frozen tumor samples, and blood for circulating tumor DNA (ctDNA) will be collected before treatment. Patients will be treated until disease progression or unacceptable toxicity. At progression, fresh frozen tumor biopsies and ctDNA analyses will be performed to characterize resistance mechanisms. The primary objective of the trial is to analyze the efficacy of erdafitinib in sqNSCLC patients with FGFR genetic driver alterations. NSCLC patient number will be based on a statistical hypothesis aiming at increasing the response rate compared to chemotherapy/immutotherapy after standard treatment. The estimated number of patients to be included in the trial is based on a 2-stage Simon design. Patients will be recruited into 3 cohorts: Cohort 1: high confidence activating FGFR translocations (max. 15 patients); Cohort 2: high confidence activating FGFR mutations (max. 15 patients); Cohort 3: low confidence activating FGFR alteration (ca. 20 patients). Result: Section not applicable. Conclusion: The study is under development and is currently targeted to start recruitment in Q2/2018.

Background: Nintedanib is a multi-target small-molecule with anti-angiogenic and anti-proliferative activity, active in several cancer cell lines and tumors, and approved in several countries. Nintedanib is an anti-fibrosis agent that has been approved for the treatment of idiopathic pulmonary fibrosis and is under evaluation also in several tumors. We report the preliminary results of a multi-center phase II trial (SENECA) conducted in Italy with the second-line combination of nintedanib plus docetaxel in patients with non-squamous locally advanced or metastatic NSCLC, after failure of first line chemotherapy.

Methods: From January 2016 to data cut-off, on 30th March 2018, 197 patients have been evaluated: 30 were registered as screening failures, mainly for contraindications to nintedanib use. The 167 patients considered in this analysis, with a median age of 63.4 years (range 35-86), were predominantly male (68.9%), smokers or former-smokers (84.4%) and with ECOG-performance status 0 (72.5%). According to investigator’s choice, 82 patients have been treated with T1 docetaxel (49.1%), 85 (50.9%) with T2 docetaxel (median docetaxel treatment 3.5 and 3.7 21-days cycles, respectively). Significative differences in median PFS have been observed between T1 and T2 (3.83 vs 4.32 months, respectively; HR 0.889 [95% CI 0.598-1.321], p-value=0.559). After a median follow-up of 7.28 months (standard deviation=5.55), a trend of similar OS has emerged in both T1 and T2 (6.63 vs 7.91 months, respectively; HR

P1.01 FIND TRIAL: A PHASE II STUDY TO EVALUATE THE EFFICACY OF THE FGFR-INHIBITOR ERDAFITINIB IN FGFR-MUTATED AND -TRANSLOCATED SQUAMOUS NSCLC.

N. Nogova1, F. Malchers2, G. Zadoyan1, A. Hillmer3, S. Merkelbach-Bruse4, R. Riedel4, S. Michels3, B. Kharabi Masouleh1, P. De Porre5, A. Santiago-Walker5, M. Scheffler1, R. Fischer6, D. Abdulla6, R. Thomas7, R. Buttnere1, J. Wolf2
1Lung Cancer Group Cologne, Cologne/DE, 2Department of Translational Genomics, Cologne/DE, 3Institute for Pathology, Cologne/DE, 4Janssen Research & Development, Beerse/BE, 5Spring House, Janssen Research & Development, Pa/US.

Background: Genomic FGFR alterations and their oncogenic driver potential are frequently observed in various cancers, including NSCLC, bladder cancer, glioblastoma, sarcoma and head and neck cancer. Initial clinical trials with selective FGFR inhibitors showed moderate responses in FGFR amplified squamous NSCLC (sqNSCLC) patients. However, in FGFR mutated or translocated tumor types (bladder cancer, glioblastoma, endometrial cancer) a response rate of above 30% was observed. Preclinical cell line and patient-derived sqNSCLC xenograft models with FGFR mutations or translocations indicate strong oncogenic activity and potential sensitivity to FGFR inhibitors. Thus, FGFR directed treatment in FGFR mutated and translocated sqNSCLC is of special interest.

P1.01-72 FIND TRIAL: A PHASE II STUDY TO EVALUATE THE EFFICACY OF THE FGFR-INHIBITOR ERDAFITINIB IN FGFR-MUTATED AND -TRANSLOCATED SQUAMOUS NSCLC.

1Lung Cancer Group Cologne, Cologne/DE; 2Institute for Pathology, Cologne/DE; 3Janssen Research & Development, Beerse/BE; 4Spring House, Janssen Research & Development, Pa/US.

Background: Genomic FGFR alterations and their oncogenic driver potential are frequently observed in various cancers, including NSCLC, bladder cancer, glioblastoma, sarcoma and head and neck cancer. Initial clinical trials with selective FGFR inhibitors showed moderate responses in FGFR amplified squamous NSCLC (sqNSCLC) patients. However, in FGFR mutated or translocated tumor types (bladder cancer, glioblastoma, endometrial cancer) a response rate of above 30% was observed. Preclinical cell line and patient-derived sqNSCLC xenograft models with FGFR mutations or translocations indicate strong oncogenic activity and potential sensitivity to FGFR inhibitors. Thus, FGFR directed treatment in FGFR mutated and translocated sqNSCLC is of special interest. In particular as there is no approved targeted treatment in the squamous population representing about 25% of all NSCLC patients. Study challenges: Multiple FGFR translocations and mutations are known and approximately 3% of all sqNSCLC patients harbor somatic alterations within FGFR genes. However, only some of these mutations are shown to be oncogenic drivers in vitro and in vivo experiments or first in man trials. This is important given the many FGFR alterations with unknown biological significance and which confer potential resistance to FGFR inhibitors. Method: Screening for FGFR mutations/translocations will be performed within the national Network of Genomic Medicine (nNGM) in 15 screening centers in Germany. SqNSCLC patients with activating
ALK mutant lung cancers and comparable to metastases. This proportion is lower than that seen in non-SCLC patients, regardless of docetaxel schedule, suggesting higher toxicities for docetaxel q3wks.

**Keywords:** nintedanib, docetaxel, non-small cell lung cancer

4Department of Pathology, Memorial Sloan Kettering Cancer Center, New York/US

**Background:** MET exon 14 (METex14) alterations are targetable drivers found in 3-4% of lung cancers. The frequency of intracranial disease and patterns of central nervous system (CNS) progression on MET tyrosine kinase inhibitors (TKI) are not well characterized. **Method:** Patients with advanced METex14-altered lung cancers identified by next-generation sequencing (MSK-IMPACT) between January 2014 and March 2018 were eligible for analysis. A retrospective review of clinical features, patterns of metastases, and CNS progression on MET-TKI was performed. The frequency of intracranial disease was compared to cohorts single-center of EGFR-mutant (n=200), ERBB2-mutant (n=98) and KRAS-mutant (n=200) lung cancers. **Result:** 82 patients with metastatic METex14-altered lung cancers were identified. The median age was 73; 56% (n=46) were female and 54% (n=44) were former smokers. The frequency of brain metastases at baseline was 11% (n=8/72). The lifetime frequency of intracranial metastases from diagnosis of metastatic disease was 34% (n=28/82). By comparison, the frequency of brain metastases was 47% (94/200, p=0.05) with EGFR-, 47% (46/98, p=0.09) with ERBB2-, and 32% (64/200, p=0.78) with KRAS-driven tumors. 6% (n=5/82) of patients developed leptomeningeal disease. The overall survival (OS) of patients who developed intracranial disease on therapy compared to those who did not develop intracranial disease was not significantly different (HR 0.66, 95% CI 0.30-1.43, p=0.29). 51 patients received crizotinib, 26 of whom developed progressive disease. The frequency of intracranial (alone), intracranial and extracranial, and extracranial (alone) progression was 8% (2/26), 19% (5/26), and 73% (19/26), respectively. **Conclusion:** A third of patients with METex14-altered lung cancers develop intracranial disease. This proportion is lower than that seen in EGFR- and ERBB2-mutant lung cancers and comparable to KRAS-mutant lung cancers. The frequency of CNS failure on crizotinib was lower than expected compared to historical rates in ALK-rearranged lung cancers.

**P1.01-75 UTILITY OF CFDNA TESTING FOR ACQUIRED RESISTANCE: THE MEMORIAL SLOAN KETTERING EXPERIENCE WITH PLASMA EGFR T790M CLINICAL TESTING.**

M. Offin1, M. Myers2, S. Josyula1, R. Shen1, L. Borsu1, D. Tsui1, G. Riel1, C. Rudin1, H. Yu1, B. Li1, M. Arcila2

1Medical Oncology, Memorial Sloan Kettering Cancer Center, New York/NY/US
2Epidemiology and Biostatistics, Memorial Sloan Kettering Cancer Center, New York/NY/US

**Background:** Liquid biopsy for circulating tumor DNA (ctDNA) has been increasingly adopted for the detection of oncogenic drivers and drug resistance mechanisms. Practice guidelines for liquid biopsy are lacking and biologic factors influencing ctDNA detection and shedding are poorly understood. We evaluated factors influencing ctDNA detection, using EGFR-T790M as a case-study, in patients with acquired resistance to second-generation EGFR tyrosine kinase inhibitors (EGFR-TKI).

**Method:** This single-center study included metastatic sensitizing EGFR-mutant lung cancer patients (exon 19 deletions, L858R, G719S, G719E) who underwent plasma EGFR-T790M testing after acquired resistance to erlotinib, gefitinib, or afatinib between January 2016 and August 2017. Plasma T790M was performed by digital PCR. Variant allele fraction (VAF) was calculated as mutant/wildtype+mutant) allele. Concordance between plasma and tissue testing was examined if tissue analysis (MSK-IMPACT and/or targeted PCR) occurred within 90 days of blood draw. Turnaround time (TAT) was measured from date of blood draw and/or biopsy to result. OS results were correlated with metastatic site and presence of organs involved.

**Result:** 177 patients underwent plasma T790M testing; 65% female. 47% current/former smokers. Plasma T790M was positive in 32% (56/177) of patients, tissue testing was T790M+ in 46% (45/97), and overall T790M+ positivity by either platform was 49% (86/177). The median TAT was shorter for plasma T790M compared to tissue PCR (9 vs 15 days, p<0.0001), and led to osimertinib use in 84% (47/56) of positive patients. Concordance between plasma and tissue T790M was 80% (52/65). 15 patients with positive plasma had matched tissue, 87% (13/15) were concordant on tissue. 76% (19/25) of the patients that were T790M-negative on plasma also tested negative on tissue. Median plasma T790M-VAF was 0.98% (range 0.1-49.5%), lower than tissue T790M-VAF (12.8%, range 2.58-27.8, p<0.0001). Plasma T790M-VAF did not correlate with time on osimertinib (p=0.72). Plasma T790M status correlated with a higher number of metastatic sites (4 vs 3, p<0.0001). Plasma T790M detection by organ sites were: pleura (58% with metastases vs 34% without metastases, p=0.14), bone (80% vs 21%, p<0.0001), hepatic (61% vs 20%, p<0.0001), nodal (61% vs 23%, p=0.02), adrenal (64% vs 44%, p=0.60), brain (71% vs 38%, p=0.08), and bone/ hepatic concurrently (94% vs 98%, p=0.04).

**Conclusion:** Using plasma T790M as an archetypical example, ctDNA testing showed concordance and a shorter turnaround compared to tissue testing. ctDNA was more likely to result positive in patients with more metastatic sites, or osseous and hepatic metastases possibly driven by increased ctDNA shedding.

**P1.01-76 A PHASE II TRIAL OF ALBUMIN-BOUND PACLITAXEL AND GEMCITABINE IN PATIENTS WITH NEWLY DIAGNOSED STAGE IV SQUAMOUS CELL LUNG CANCERS.**

P. Paik, R. Kim, L. Ahn, A. Plodkowski, K. Ng, D. Mcfarland, A. Iqbal, J. Eng, C. Rudin

Memorial Sloan Kettering Cancer Center, New York/NY/US

**Background:** Therapeutic options for SQCLC patients are limited. The efficacy of platinum-based doublets, long the standard first-line treatments, has plateaued, with ORR≈30%. Anti-tumor synergy between gemcitabine and albumin-bound paclitaxel (ABP) was demonstrated by Frese et al. who showed that ABP downregulates cytidine deaminase, leading to increased intratumoral gemcitabine (Cancer Disc 2012). Based on these data, we sought to assess the efficacy of ABP + gemcitabine in patients with SQCLC. **Method:** This was a Simon two-stage phase 2 study of ABP + gemcitabine in chemotherapy-naive, PD-L1 low/unknown advanced SQCLC patients (NCT02525653). Primary endpoint: best ORR, HO=25% (≥2/17 responses) and HA=45% (≥16/41 responses). ABP (100mg/m²) + gemcitabine (1000mg/m²) was initially given on D1, D8, D15 of an every 4 week cycle for up to 6 cycles (A1). After clearing H0, the study was amended to a 3 week cycle (D1, D8 treatment) and to allow maintenance ABP after C4 (A2). All patients underwent NGS by MSK-IMPACT. **Result:** N=27 patients were evaluable for the primary endpoint. Median age=70, age ≥70=60%, female=30%, median KPS=80%, smokers=93%. 46% of patients had PD-L1 IHC <50% (0-20%). 54% were PD-L1 unknown. Grade ≥3 related AEs included: fatigue-13%, neuropathy-4%, diarrhea-4%, lung infection-4%, anemia-9%; decreased platelet count-4%, and decreased neutrophils (4%). Four patients (17%) experienced related SAEs including, separately, G3 febrile neutropenia, G3 WBC decrease, G3 thrombocytopenia, and G3 anemia. ORR for the entire cohort was 63% (Figure 1). ORR in A2=71% (10/14). 8 patients in A1 had dose modifications resulting in equivalency to the A2 schedule. ORR in the A2+A1 dose modified cohort=73% (16/22), meeting the primary endpoint early. Median PFS=8mo; OS not yet mature.

(See next page)
Conclusion: ABP + gemcitabine is an effective and well-tolerated regimen in patients with untreated advanced NSCLC with a response rate exceeding that associated with platinum regimens and first-line immunotherapy.

Background: Central nervous system (CNS) metastases in lung cancer are a frequent cause of morbidity and mortality. There are conflicting data on the incidence of CNS metastases in ROS1+ NSCLC at diagnosis and rate of CNS progression on crizotinib. Method: Retrospective review of 579 patients with stage IV NSCLC between June 2008 to December 2017. We described the incidence of crizotinib-related CNS metastases and CNS progression on crizotinib. Results: The incidence of CNS metastases in crizotinib-naive patients was 63.6% (361/579) and in patients with prior CNS progression was 74.1% (166/224). Conclusion: CNS metastases are common in patients with ROS1+ NSCLC on crizotinib.

Keywords: ros1, Brain metastasis, crizotinib

P1.01-79 CHECKMATE 817: SAFETY OF FLAT-DOSE NIVOLUMAB PLUS WEIGHT-BASED IPILIMUMAB FOR THE FIRST-LINE (1L) TREATMENT OF ADVANCED NSCLC
1Hospital Universitario Doce de Octubre, Cnio, Universidad Complutense & Ciberonc, Madrid/ES; 2Matrahaza Healthcare Center and University Teaching Hospital, Matrahaza/HU; 3Hospital Sainte-Marguerite, Toulon/FR; 4Ospedale Policlinico San Martino, Genova/IT; 5Hôpital Du Sacré-Coeur de Montréal, Montréal/QC/CA; 6Centre Intégré Universitaire de Santé Et De Services Sociaux de La Mauricie- Et Du- Centre- Du-Quebec, Trois-Rivières/QC/CA; 7Metropolitan Hospital, Athens/GR; 8Sеченov University, Moscow/RO; 9Klinik Löwenstein, Löwenstein/DE; 10University Hospital Zurich, Zurich/CH; 11University Medical Center Groningen, Groningen/NL; 12Ghent University Hospital, Ghent/BE; 13Centre Hospitalier Universitaire de Liége, Liège/BE; 14Klinika Nowotworów Pucia i Klatki Piernowej, Warszawa/PL; 15Winship Cancer Institute, Emory University, Atlanta/GA/US; 16Sarah Cannon Research Institute/tennessee Oncology, Pllc, Nashville/TN/US; 17University Hospitals of Leicester, Leicester/GB; 18Bristol-Myers Squibb, Princeton/NJ/US; 19Duke University Medical Center, Durham/NC/US

Background: CheckMate 227 demonstrated significant, clinically meaningful progression-free survival benefit with 1L nivolumab 3 mg/ kg every 2 weeks (Q2W) plus low-dose ipilimumab 1 mg/kg every 6 weeks (Q6W) vs chemotherapy in patients with advanced non-small cell lung cancer (NSCLC) and tumor mutational burden (TMB) ≥10 mutations/megabase. The dose and schedule for this combination regimen were optimized for 1L NSCLC in CheckMate 012 and further validated in CheckMate 568 and CheckMate 227. Flat-dose nivolumab (240 mg Q2W) may simplify treatment while providing comparable exposure, and was recently approved for previously treated NSCLC. CheckMate B17 (NCT02869789) is a multi-cohort, open-label phase 3b/4 study evaluating the safety and efficacy of flat-dose nivolumab plus low-dose ipilimumab in recurrent/metastatic NSCLC. We report safety results from Cohort A, which evaluated this regimen in the 1L setting; updated results will be presented. Method: Patients with ECOG PS ≤1 and previously untreated

ABSTRACTS IASLC 19th World Conference on Lung Cancer | 275

POSTER SESSION 11
MONDAY, SEPTEMBER 24, 2018

WWW.IASLC.ORG
NSCLC were eligible, regardless of tumor programmed death ligand 1 (PD-L1) expression and TMB. Nivolumab 240 mg Q2W plus ipilimumab 1 mg/kg Q6W was administered for 2 years or until disease progression/ unacceptable toxicity. The primary endpoint was safety assessed by the incidence of grade ≥3 select treatment-related adverse events (TRAEs; defined as AES of potential immunologic causes). Result: Enrollment occurred between October 4, 2016, and August 17, 2017, with 391 patients initiating treatment at 68 academic and community-based centers in Europe and North America. Median age was 65 years and 27.9% of patients had squamous histology. PD-L1 expression was evaluable in 91% of patients. Overall, 50% had ≥1% tumor PD-L1 expression. At database lock (March 1, 2018), minimum follow-up was 5.4 months and 34.5% of patients remained on treatment. The median (range) number of nivolumab and ipilimumab doses received was 9 (1–28) and 3 (1–10), respectively. Any grade and grade 3–4 TRAEs occurred in 74.4% and 27.6% of patients, respectively; 14.1% of patients discontinued follow-up due to TRAEs. Rates of any grade select TRAEs by category ranged from 1.3% (renal) to 28.4% (skin). The most common grade 3–4 select TRAEs by category were hepatic (4.6%), pulmonary (3.1%), and gastrointestinal (3.1%). Two treatment-related deaths were reported; one due to Guillain–Barré syndrome and one due to rhabdomyolysis leading to heart failure. Conclusion: The safety profile of flat-dose nivolumab plus low-dose ipilimumab was consistent with previous reports of weight-based nivolumab plus low-dose ipilimumab optimized for NSCLC. Toxicities were manageable with no new safety signals identified.

P01.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P01.01-80 ELIOS: A MULTICENTER, OPEN-LABEL, MOLECULAR PROFILING STUDY OF PATIENTS WITH EGFRM AND NSCLC TREATED WITH OSIMERTINIB

Z. Piotrowska1, J. Chmielecki2, D. Cripps3, M. Miranda4
1Department of Medicine, Massachusetts General Hospital, Boston/MA/US.
2Translational Science, Oncology, Imed Biotech Unit, AstraZeneca, Waltham/MA/US.
3AstraZeneca, Cambridge/GB

Background: Epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (TKIs) are standard-of-care for locally advanced/metastatic non-small cell lung cancer (NSCLC) harbouring EGFR sensitizing mutations (EGFRm). Osimertinib, a third-generation, CNS-active EGFR-TKI potently and selectively inhibits both L858R and exon19del sensitizing EGFRm and T790M mutations, is now approved for first-line treatment of EGFRm NSCLC. Studies of osimertinib resistance have focused on patients previously treated with first-/second-generation EGFR-TKIs; however, resistance mechanisms to first-line osimertinib are not well-described. Method: ELIOS (NCT03299340) is a phase 2, open-label, single-arm study designed to prospectively characterize the molecular profile of patients who progress on first-line osimertinib. The study will enroll patients (n=100) with locally advanced/metastatic non-squamous EGFRm–NSCLC nonamenable to curative surgery/chemoradiation, WHO performance status 0-1, and life expectancy ≥12 weeks. Patients eligible to be associated with EGFR-TKI sensitivity, must be EGFR-TKI treatment-naïve, and be eligible to receive first-line osimertinib therapy. Patients with clinically significant toxicities, history of interstitial lung disease, and EGFR exon 20 insertion will be excluded. All patients will receive 80 mg osimertinib orally once daily and will continue treatment beyond progression if they show continued clinical benefit. Mandatory tumor biopsies will be obtained prior to treatment initiation and following investigator-assessed disease progression. Additional follow-up may be obtained following 2-3 weeks of treatment. Longitudinal plasma samples will be collected for plasma-derived circulating tumor DNA (ctDNA) analysis. Tumor- and plasma-derived specimens will be analyzed by next-generation sequencing: secondary exploratory analyses are also planned. The primary endpoint is the proportion of patients with a given genetic/ proteomic marker at disease progression (investigator-assessed, RECIST v1.1). Relevant genetic and proteomic markers will be selected based on the profile comparison at disease progression to baseline. Relevant markers of resistance to first-line osimertinib may include, but are not limited to, EGFR resistance mutations (including C797S) and cMET/ HER2 amplification; this analysis may reveal other, potentially novel, resistance mechanisms. Secondary endpoints include progression-free survival, objective response rate, duration of response, disease control rate, assessment of osimertinib efficacy post-progression using time to treatment discontinuation, and time to first subsequent therapy. Efficacy analyses based on predefined subgroups (according to the patient molecular profile of baseline T790M mutations, EGFR Ex19del or L858R mutations, and EGFR Ex19del or L858R detectable in ctDNA, will be assessed. Safety will also be assessed. Primary analysis will be performed when ≥50 patients have paired biopsies upon progression. Recruitment is in process (May 1, 2018). Result: Section not applicable

Conclusion: Section not applicable

Keywords: EGFR mutations, non-small cell lung cancer, osimertinib

P01.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P01.01-81 PHASE 3 STUDY OF Pemetrexed platinum-improved OS and PFS over chemotherapy plus placebo in first-line, metastatic NSCLC without targetable EGFR mutations (Gandhi et al. NEJM 2018). The phase 3 KEYNOTE-789 (Clinical Trials. gov: NCT03518537) study evaluates pemetrexed-platinum combined with pembrolizumab vs placebo in EGFR-TKI–resistant, EGFR-mutated, metastatic non-squamous NSCLC. Method: Eligibility for this multicenter, randomized, double-blind, placebo-controlled study requires age ≥18 years; EGFR-TKI–resistant EGFR-mutated (exon 19 deletion or L858R mutation), histologically/cytologically confirmed stage IV, nonsquamous NSCLC; measurable disease per RECIST version 1.1; ECOG PS 0/1; and archival/newly obtained pretreatment tumor sample to evaluate PD-L1 expression. If progression on prior EGFR-TKI occurred with first- or second-generation TKIs (eg, erlotinib, afatinib, gefitinib) and T790M mutation is present, patients must have had subsequent progression on osimertinib; patients with progression on first-line osimertinib are eligible regardless of EGFR T790M mutation status. Patients are randomized 1:1 to pemetrexed 200 mg or placebo, each in combination with pemetrexed 500 mg/m2 plus platinum chemotherapy (carboplatin AUC 5 or cisplatin 75 mg/m2; investigator’s choice) Q3W for 4 cycles. Patients continue allocated treatment (pemetrexed or placebo) plus pemetrexed for up to 35 cycles, followed by pemetrexed monotherapy until documented disease progression or intolerable toxicity. Randomization is stratified by PD-L1 tumor proportion score ≥50% vs <50%, prior osimertinib vs no prior osimertinib, and geographic region of East Asia vs non-East Asia. Tumor response is assessed radiographically at baseline, week-6, then every 9 weeks through week-54 and every 12 weeks thereafter, per RECIST version 1.1 by blinded, independent central review. Treatment decisions are based on iRECIST criteria by investigator review. PFS and OS are dual primary endpoints, which will be tested with one-sided alphas of 0.001 and 0.02, respectively. Secondary endpoints are ORR; duration of response; change from baseline global health status and quality-of-life scores on the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire (QLQ)-Core 30; time to true deterioration in composite endpoint of cough, chest pain, or dyspnea on EORTC QLQ–Lung Cancer Module 13; and safety and tolerability. Severity of AEs will be graded per NCI CTCAE version 4.0. Approximately 480 patients will be enrolled beginning June 1, 2018. Result: Section not applicable

Conclusion: Section not applicable

Keywords: pembrolizumab, EGFR mutation, NSCLC
Keywords: varying chemotherapy cycles, safety analyses, and impact on OS will be
results (adjusted HRs of 0.80, 0.85, or 0.91, respectively).

4 vs 6 cycles (HR 0.83 [95% CI: 0.59, 1.17). The sensitivity analyses,
PFS analysis showed no difference between patients who completed
these 2 groups, 143 (76%) and 98 patients (58%) completed 4 and 6
baseline factors.
The objective of this exploratory analysis was
to assess the impact of chemotherapy cycles on safety and efficacy
of 3rd generation TKI (n=110) was 55 months vs. 22 months (p<0.0001). 
Conclusion: In real world, a significant number of patients treated with 1st or 2nd
treatment TKI do not reach 2nd line therapy even when 3rd generation TKI were accessible. Reasons for
not receiving 2nd line therapy are in most cases deterioration of PS and lack of possibility to test for T790M in the minority of cases (n=28/66, 42% were not tested). These data, although favorable for the small and
very selected cohort of patients treated with Osimertinib, might argue for the most effective therapy in 1st line for patients with EGFR mt+ tumors.

P1.01 ADVANCED NSCLC
MONTDAY, SEPTEMBER 24, 2018 - 09:45-18:00

Background:
The randomized Phase III IMPower150 study, an atezolizumab + bevacizumab (Arm B) and pembrolizumab + chemotherapy (Arm C) were compared to placebo + chemotherapy (Arm A) in patients with PD-L1+ tumors (PD-L1 CPS ≥ 1) in 1st line treatment with immune checkpoint inhibitors. Atezolizumab + chemotherapy (Arm B) showed statistically significant and clinically meaningful improvement in both progression-free survival (PFS) and overall survival (OS) over bevacizumab + chemotherapy (Arm C).

Method:
Out of 485 patients included in both studies, 229 were screened for EGFR mutations (65.6%). 120 and 109 in the high and low level subgroup, respectively). All patients were considered in the analyses. A significant biomarker/treatment effect was found (p=0.000). Hazard ratio (CIMAvax-EGF vs BSC) in the high egf subgroup favoured CIMAvax-EGF (0.44, p<0.000).

Conclusion: Basal level of plasmatic EGFR predicts clinical benefit from CIMAvax-EGF therapeutic cancer vaccine in advanced NSCLC after First Line of Treatment based on Platinum. Vaccinated patients in the subgroup of high EGFR levels significantly benefit from CIMAvax-EGF.

Keywords: Therapeutic Vaccine, Non Small Cell Lung Cancer, Immunotherapy

P1.01 ADVANCED NSCLC
MONTDAY, SEPTEMBER 24, 2018 - 09:45-18:00

Background:
In the atezolizumab + bevacizumab + chemotherapy arm, patients who received 4 cycles of chemotherapy appeared to have similar PFS benefit as those who received 6 cycles of chemotherapy. Detailed analyses of varying chemotherapy cycles, safety analyses, and impact on OS will be presented.

Keywords: chemotherapy, bevacizumab, Atezolizumab

P1.01-84 HIGH BASAL SERUM EGF LEVELS PREDICTS RESPONSE TO CIMAVAX-EGF, A THERAPEUTIC VACCINE FOR ADVANCED NSCLC

O. Santos Morales1, P. Luaces1, T. Crombet1, C. Rodriguez2, E. Neninger2

1Clinical Division, Cim, Havana/CU, 2Hermanos Ameijeiras Hospital (Hno), Cienfuegos/CU

Background: CIMAvax-EGF is a therapeutic vaccine for the treatment of advanced NSCLC. The rationale of its use is to create an immune response against circulating plasmatic EGF and by doing this prevent its binding to EGFR. Previous early stage trials have shown its safety and efficacy. Recently a randomized controlled phase III pivotal trial have confirmed its efficacy and safety in open population when used according to established protocols. Exploratory results from this study suggested EGF could function as prognostic and predictive biomarker. In this study we aim to evaluate whether basal EGFR plasmatic levels can predict patients response to this immunotherapeutic product. Method: To know the effect of biomarker status on CIMAvax-effect we pooled data from two previously published controlled trials that used the product in a population of advanced non small cell lung cancer after First Line platinum based chemotherapy. Low doses of cyclophosphamide (200mg/m2) were administered IV three days before the first administration of the vaccine. 2.4 mg/dose of the product were administered during induction phase and then monthly for maintenance treatment. Both studies used Best Support Care as Control Arm. The main outcome was Overall Survival. Result: Out of 485 patients included in both studies, 229 were screening for EGFR levels (65.6%), 120 and 109 in the high and low level subgroup, respectively). All patients were considered in the analyses. A significant biomarker/treatment effect was found (p=0.000). Hazard ratio (CIMAvax-EGF vs BSC) in the high egf subgroup favoured CIMAvax-EGF (0.44, p<0.000).

Keywords: advanced NSCLC, EGFR mutations, T790M

P1.01 ADVANCED NSCLC
MONTDAY, SEPTEMBER 24, 2018 - 09:45-18:00

Conclusion: Data of 912 of 1477 patients tested for EGFR mutations (treated in Oldenburg, Bremen, Hamburg) were analyzed between 2009-2017. 140/144 patients with an activating EGFR mutation (16%) and treated with systemic therapy (4 patients received no therapy) were identified and their treatments were captured as well as their outcome. 36 patients were treated before accessibility to 3rd generation TKI and 104 patients after accessibility to 3rd generation TKI. Result: 130/140 patients were treated with 1st line TKI and 10 received 1st line chemotherapy. 17 patients are still on 1st line TKI, 8 patients were lost to follow-up, 3 patients died while on 1st line TKI. 112 patients were categorized for 3rd line therapy. 34/112 (30%) of these patients did not receive 2nd line therapy. Causes for not receiving 2nd line therapy were patients refusal (n=2), bad PS (n=26) frequently due to CNS metastases, fast progression and death (n=6). After accessibility of 3rd generation TKI, 20 of 66 (30%) patients did not receive 2nd line therapy. Median OS of the overall cohort was 27 months (n=140), median OS of patients receiving 2nd line (n=78) vs. no 2nd line (n=62) was 36 vs. 14 months (p<0.0001).

After accessibility of 3rd generation TKI 30/104 patients (29%) receive a 3rd generation TKI after 1st line or 2nd line therapy. Median OS of patients receiving (n=30) and not receiving 3rd generation TKI (n=110) was 55 months vs. 22 months (p<0.0001). Conclusion: In real world, a significant number of patients treated with 1st or 2nd generation TKI do not reach 2nd line therapy when 3rd generation TKI were accessible. Reasons for not receiving 2nd line therapy are in most cases deterioration of PS and lack of possibility to test for T790M in the minority of cases (n=28/66, 42% were not tested). These data, although favorable for the small and very selected cohort of patients treated with Osimertinib, might argue for the most effective therapy in 1st line for patients with EGFR mt+ tumors.

P1.01-85 THE PREVALENCE OF DIFFERENT EGFR EXON20 MUTATIONS IN 12,833 CHINESE LUNG CANCER PATIENTS

W. Shao1, X. Tong2, X. Wang1, F. Wang1, X. Wu2

1School of Public Health, Nanjing Medical University, Nanjing/CN, 2Translational Medicine Research Institute, Geneseeq Technology Inc., Toronto/CA,

Keywords: EGFR, Chinese lung cancer patients

Background: Mutations in EGFR exon20 are relatively rare in lung cancers compared to L858R/exon19 mutations, some of which have shown sensitivity to EGFR tyrosine kinase inhibitors (TKIs), and have been actively tested in clinical trials. However, due to the high-variety of EGFR exon20 alterations, it becomes increasingly difficult for their functional studies in related to clinical practice. Method: We retrospectively screened 12,833 Chinese lung cancer patients that have undergone genotyping on their tumor and/or liquid biopsy samples using targeted
next-generation sequencing between 2014 and 2017 for EGFR exon20 mutations as well as other concurrent EGFR mutations in the same patient. Result: A total of 442 patients (3.4%) were found harboring 493 different EGFR exon20 variations, among which 49 patients (11%) carried more than one exon20 mutation. The frequencies of the most prevalent alterations were summarized in Table 1. 16% of these mutations have concurrent TKI-sensitive mutations L858R or exon19 deletion. In-frame deletion/insertions (delins or ins) and missense mutations were identified at a frequency of 53% and 47%, respectively. The short delins/ins occurred between 763–773 residues, while missense mutations dwelled at 768–820 residues, suggesting that these two types of alterations have their own manners for regulating EGFR kinase domain function. The most prevalent insertion is p.M766delinsMASV, occurred in 15.2% of all patients. Meanwhile, the diversity of inserted peptides at p.D770 and p. D771 positions is much higher than other positions with a total of 17 and 19 different insertion peptides composed of 1-5 amino acids, respectively. Missense mutations at S768 were detected in 20.4% of patients, but 60% of them were accompanied by mutations at G719.

Table 1. The most common mutations in EGFR exon20.

<table>

*--, indicates no concurrent EGFR TKI-sensitive mutations. **--** indicates exon23 insertions that were observed responsive to TKI in previous studies.

Conclusion: This is the largest cohort of Chinese lung cancers for studying EGFR exon 20 mutations, which should be informative for functional studies, the design of targeted drugs, and the testing for existing therapies.

P1.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-86 BTCRC-LUN15-017: PHASE-Ib STUDY OF IMPRIME PGG AND PEMBROLIZUMAB IN STAGE IV NSCLC AFTER PROGRESSION ON PLATINUM BASED THERAPY

A. Shergill1, M. Furgan2, J. Malhotra1, L. Liu3, N. Bose4, C. Belani5, L. Feldman2
1University of Illinois, Chicago/IL/US, 2University of Iowa Hospitals and Clinics, Iowa City/Iowa/US, 3Rutgers Cancer Institute of New Jersey, New Brunswick/NJ/US, 4Research, Biothera, Eagan/US, 5Penn State Cancer Institute, Hershey/PA/US

Background: Imprime PGG (Imprime) is a β-glucan isolated from a proprietary strain of Saccharomyces cerevisiae. It acts as pathogen associated molecular pattern, creating ‘non-self’ signals, enhancing innate immune cell killing, and possibly T-cell cross-talk, thereby enhancing efficacy of checkpoint inhibitor therapy like pembrolizumab. Clinical use of Imprime in combination with chemotherapy and monoclonal-antibodies has been reported, however no studies to date have evaluated its use with anti-PD-1 therapy. We aimed to evaluate safety and tolerability of Imprime with pembrolizumab.

Method: This is a single-arm, phase-Ib, open-label, dose-escalation trial for patients with stage IV NSCLC after progression on platinum-based chemotherapy. Key eligibility included measurable disease, adequate organ function and ECOG performance status of 0-2. Patients received 2 mg/kg or 4 mg/kg IV Imprime on day 1, 8, 15, and 200mg IV pembrolizumab on day 1, every 21 days. “3+3” design was used to establish highest tolerated dose. The dose with toxicity rate of ≤33% in first cycle would be considered the recommended phase-II dose i.e. ≤1 out of 6 patients experience dose limiting toxicity (DLT). Primary endpoint was to establish highest tolerated dose of Imprime for recommendation for phase-II study. Secondary objectives were to define safety and tolerability, and to correlate clinical benefit with biomarkers on immune cells, soluble PD-L1 levels, anti-β-glucan antibody and FCγRIIA polymorphism. This trial is registered with ClinicalTrials.gov. NCT03003468. Result: Between 07/2017-02/2018, nine patients were enrolled: three patients received 2 mg/kg and six received 4 mg/kg dose of Imprime. Eight out of nine patients had one line of treatment prior to participation, and one had two lines. Two patients received ten cycles with 4 mg/kg Imprime. To date, no DLTs have been recorded and the highest dose of Imprime was well tolerated. Five patients stopped treatment due to progression. Four patients are continuing treatment. No patients stopped treatment due to toxicity. Most common adverse event (AE) at 2 mg/kg was grade 1 sore throat in two patients. One Grade 3 diarrhea and one grade 3 neutropenia were reported. Most common AE in the 4 mg/kg group was grade 1 headache in three patients. One episode of grade 3 diarrhea was reported. There were no grade 4 or 5 toxicities. The results of the immunopharmacodynamic analysis will be reported when available.

Conclusion: Imprime in combination with pembrolizumab is well tolerated in outpatient settings and the role of this combination in treatment of NSCLC warrants further investigation. Phase-II enrollment of this trial is ongoing.

P1.01 ADVANCED NSCLC
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

**P1.01-97 A PHASE 1B STUDY OF TRC105 IN COMBINATION WITH PACLITAXEL/CARBOPLATIN AND BEVACIZUMAB IN PATIENTS WITH STAGE 4 NON-SQUAMOUS CELL LUNG CANCER**

F. Robert1, M. Jerome1, D. Miley1, M. Harris1, B. Simpson1, B. Adams2, C. Theuer1, G. Sherwood1

1University of Alabama - Birmingham - Birmingham/AL/US, 2Tracon Pharmaceuticals, San Diego/US

**Background:** Endoglin plays a critical role in angiogenesis and is implicated in resistance to VEGF inhibition. TRC105, an endoglin antibody, has been shown to potentiate the anti-angiogenic effect of bevacizumab in pre-clinical models of human angiogenesis. Given the critical role of anti-angiogenic therapy in the treatment of advanced NSCLC and the tendency of the tumor to develop escape pathways of angiogenesis following treatment with anti-VEGF agent, investigation of dual anti-angiogenic therapy in advanced NSCLC is indicated. **Method:** A standard (3+3) dose-escalation design of TRC105 with 15 mg/kg bevacizumab (B), 200 mg/m² paclitaxel (P) and 6 AUC carboplatin (C) given IV on day 1 of each 21-day cycle was employed, followed by an expanded cohort to further assess the safety and tolerability of the recommended phase 2 dose (RPTD) of TRC105. Patients completed induction therapy with TRC105 + B, P and C for a maximum of 6 cycles with those demonstrating no evidence of disease progression transitioned to a maintenance phase of TRC105 + B. Secondary endpoints: ORR, PFS, OS, DCiR, in-granulogenicity and angiogenic biomarkers. Key inclusion criteria: chemotherapy-naive stage 4 NSQ-NSCLC, ECOG < 1, measurable disease and no significant cardiovascular comorbidities. **Result:** Fifteen pts have been enrolled; three were unevaluable for efficacy due to DLT of Grade 3 rash and unrelated SAE’s of Grade 3 weakness and Grade 3 hypoxia. Four of 12 evaluable pts achieved PR, one with 81% tumor reduction. Median PFS was 6.54 months. Common adverse events regardless of relationship included epistaxis, fatigue, telangiectasia, diarrhea, headache and nausea. Common TRC105 related AEs included epistaxis, telangiectasia, fatigue and headache. One patient experienced Grade 5 neutropenic sepsis considered unrelated to TRC105 or B. Analysis of the angiogenic biomarkers will be presented. **Conclusion:** Induction treatment for six 3-week cycles with TRC105 + B, P, and C followed by maintenance therapy with selective EGFRm-positive, stage III NSCLC patients with disease progression was tolerable and did not potentiate the toxicity of B, P or C. The combination of TRC105 + B, P, and C demonstrated signs of activity including PR in 4 of 12 evaluable pts.

**Keywords:** NSCLC, TRC105, angiogenesis

**P1.01-89 ANALYSIS AND MONITORING CTCS AND CTDNA IN CSF DEMONSTRATES CLINICAL CONCORDANCE IN TESVATINIB TREATED NSCLC PATIENTS WITH LM**

V. Singh1, C.R. Vibat1, M. Poyurovsky2, L. Green2, B. Mac Gillivray2, D. Enzinger3

**Background:** Liquid biopsy using blood has emerged as a non-invasive and economical method to assess cancer biomarkers. Applying liquid biopsy methods to evaluate cerebrospinal fluid (CSF) is less well documented and provides key information to supplement routine cytology in patients with brain metastases or leptomeningeal disease (LM). The current first-line therapy for leptomeningeal disease (LM) is induction therapy with tumor-selective EGFRm-positive, stage III NSCLC patients with LM. Current first-line tyrosine kinase inhibitors (TKI) have poor penetration to the central nervous system (CNS). About 28% of patients treated with erlotinib or gefitinib progress with CNS involvement. Here we present Biocent’s Target Selector™ technology to evaluate circulating tumor cells (CTCs) and circulating tumor DNA (ctDNA) in the CSF of NSCLC patients with LM, who were treated with tesvatinib in Kadmon’s KD019-206 study. **Method:** CSF samples were collected in Biocent CEE-Sure™ blood collection tubes that are validated to preserve CTCs and ctDNA at room temperature for up to 96 hours from collection. The Target Selector™ CTC platform uses an antibody capture cocktail and microfluidic channel for CTC capture and biomarker analysis; the quantitative ctDNA platform incorporates switch-blockers, real-time PCR, and sequencing to detect a mutant allele frequency down to 0.05% against wildtype. **Result:** CSF collections from 6 NSCLC patients with LM were obtained at baseline, C1D14, and C3D1 of tesvatinib therapy. In all 6 patients, EGFR mutations detected in CSF were discordant to the original tissue mutations. Baseline or emergent T790M ctDNA that was detected in CSF, paralleled progression in 3 patients. CTC enumeration mirrored response to therapy, decrease of symptoms, or progression in 5 of 6 patients; T790M emerged at C1D14 in the patient whose CTCs decreased at progression. Serial CSF CTC and ctDNA analyses were consistent with the overall clinical course of disease. **Conclusion:** Biocent’s Target Selector™ technology in CSF analysis demonstrated both highly sensitive detection of CTCs and mutant ctDNA in NSCLC patients with LM as well as concordance with tissue and clinical course. Hence, serial monitoring of CSF with CTCs and ctDNA can be utilized to evaluate drug response and disease progression, providing pertinent vital information for disease management and care of LM patients.

**P1.01 ADVANCED NSCLC**
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

**P1.01-88 OSIMERTINIB MAINTENANCE AFTER DEFINITIVE CHEMORADIATION IN PATIENTS WITH UNRESECTABLE EGFRm-POSITIVE STAGE III NSCLC (LAURA)**

L. Shun1, T. Nash1, M. Saggese1, H. Mann2, S. Ramalingam1

1Shanghai Chest Hospital, Shanghai; 2Jiao Tong University, Shanghai/CH

**Background:** The standard of care for patients with stage III unresectable NSCLC is definitive platinum-based chemoradiation, regardless of epidermal growth factor receptor mutation (EGFRm) status. There is evidence that following chemoradiation, patients with EGFRm-positive NSCLC have superior local control but inferior distant control, including an increased incidence of CNS metastases, compared with patients with EGFR wild type (EGFRwnt)-NSCLC. This study supports the rationale for evaluation of EGFR tyrosine kinase inhibitor (TKI) maintenance in EGFRm-positive patients without disease progression following chemoradiation. Osimertinib, a third-generation, CNS-active EGFR-TKI that potently and selectively inhibits both sensitizing EGFR and T790M mutations. It has shown superior progression-free survival (PFS) vs. standard EGFR-TKIs in first-line treatment of patients with EGFRm-positive advanced NSCLC, including patients with or without CNS metastases at trial entry. These data further support the rationale for evaluation of osimertinib in the even earlier disease setting of EGFR-TKI-naive stage Ila-III NSCLC, following definitive chemoradiation, where it has the potential to prevent/delay progression, including in the CNS, and improve survival compared with chemoradiation alone. **Method:** LAURA is a double-blind, randomized, placebo-controlled, multicenter, phase 3 study designed to assess efficacy and safety of osimertinib as maintenance therapy in patients with locally advanced, unresectable, EGFRm-positive, stage III NSCLC without disease progression following definitive platinum-based chemoradiation therapy. All patients will have tumors bearing exon 19 deletion or L858R mutation (centrally or locally confirmed by cobas® EGFR Mutation Test v2), age >18 years, and a WHO performance status of 0-1. Patients will be treated with osimertinib vs. placebo for 6 months. **Result:** Approximately 200 patients will be randomized 2:1 to osimertinib 80 mg oral once daily or placebo, within 6 weeks of completion of chemoradiation, until disease progression. Stratification factors are prior chemoradiation strategy (CCRT vs SCRT), tumor stage (IIIA vs IIIB/IIIC), and China vs non-China. The primary endpoint is RECIST 1.1 assessed PFS based on blinded independent central review (BICR). Key secondary endpoints include time to CNS PFS, overall survival, objective response rate (ORR), disease-related symptoms and health-related quality of life (HRQL), safety, tolerability, and pharmacokinetics. Study enrollment will commence from July 2018. **Conclusion:** Section not applicable

**Keywords:** osimertinib, EGFR mutations, non-small cell lung cancer

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

**P1.01-90 A PILOT TRIAL ASSESSING APATINIB COMBINED WITH DOXETAXEL (DTX) AS SECOND-LINE CHEMOTHERAPY FOR EGFR NEGATIVE ADVANCED NSCLC**

T. Lv1, Y. Song2, H. Liu1, L. Miao3, W. Wang4, M. Shi1

1Respiratory, Jinling Hospital, Nanjing/CN, 2Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN, 3Nanjing Jinling Tower Hospital, Nanjing/CN, 4Cancer Medical Center, The Second Affiliated Hospital of Nanjing Medical University, Nanjing/CN, 5Jiangsu Provincial Tumor Hospital, Nanjing, Jiangsu/CN

**Background:** Apatinib is a new tyrosine kinase inhibitor against vascular endothelial growth factor receptor 2 and improves outcomes in patients (pts) with metastatic gastric cancer as a third-line treatment of recent. It has been reported effective as third- or later-line treatment in advanced NSCLC. This prospective study tried to assess the efficacy and safety of apatinib combined with DTX as second-line treatment of EGFR negative NSCLC. **Method:** In this open-label single-arm study, pts received oral apatinib (500mg, p.o. qd) with DTX(60mg/m2, i.v. d1 q3w) as second-line therapy. The primary endpoint was progression-free survival (PFS) and the tumor response was determined according to the RECIST 1.1. Treatment was continued until disease progression, death, or intolerable toxicity. **Result:** Between September 2016 and April 2018, 27 pts were enrolled. In 27 pts, there were 23 pts available for efficiency evaluation and 27 pts available for safety evaluation. In the first evaluation of efficacy at on-study, the contoured tomography scan evaluation revealed that partial response (PR) occurred in 7 of 23 pts and another 15 showed stable disease (SD). The median PFS was 4.0667 months (95% CI: 2.5333–6.3333 months). The median OS was 10.5667 months (95% CI: 10.5667–21.5667 months). The objective response rate (ORR) was 30.43% and disease control rate (DCR) was as high as 95.65 %. Most of the adverse reactions (AEs) were grade 1 or 2. The grade 3 AEs were hypertension (n=12, 44.44%), hand-foot syndrome (n=3, 11.11%), diarrhea (n=2, 7.41%), mouth ulceration (n=3, 11.11%), thrombocytopenia (n=1, 3.70%). No grade 4 AE or drug-related mortality occurred. **Conclusion:** Apatinib has a potential application prospect in second-line therapy combined with DTX for EGFR negative NSCLC pts. The research team will continue the study.

**Keywords:** NSCLC, Apatinib, second-line chemotherapy

**P1.01-91 A PHASE I STUDY OF FIXED DOSE VINORELBINE AND ESCALATING DOSES OF IFOFOSAMIDE IN FIRST-LINE ADVANCED NON-SMALL CELL LUNG CANCER**

1London Regional Cancer Centre, London/CA, 2Internal Medicine, Schulich School of Medicine and Dentistry, London/CA, 3Medical Oncology, Tom Baker Cancer Centre, Calgary/AB/CA, 4Medical Oncology, London Regional Cancer Program, London/CA, 5Department of Oncology, London Regional Cancer Program - Western University, London, London/ON

**Background:** Platinum doublet chemotherapy is generally the backbone treatment of advanced NSCLC (aNSCLC), although toxicity and limited benefit necessitated the need for investigation of alternatives. We examined vinorelbine and ifosfamide combination chemotherapy as a possible alternative in first-line aNSCLC. **Method:** 31 patients were enrolled and treated between January 2004 and July 2006. Vinorelbine (25 mg/m²) and escalating doses of ifosfamide were given on days 1 and 8 q21 days. The starting dose of ifosfamide was 2.0 g/m². If ≤ 2/6 patients experienced dose-limiting toxicities (DLT) in cycle 1, the next cohort was recruited and given an additional 0.25 g/m² of ifosfamide if ≥ 2/6 patients within a cohort experienced DLT, recruitment was halted, and the tumor response was determined according to the RECIST 1.1. Treatment was continued until disease progression, death, or intolerable toxicity. **Result:** The ideal phase II ifosfamide dose was determined to be 2.0 g/m². Median PFS and OS were 5.5 and 9.2 months, respectively. The ORR was 12.9% and the 1-year OS was 21%, both lower than historical reports of platinum doublet efficacy and even vinorelbine monotherapy at 30 mg/m². Six “excellent responders” were identified who survived between 20 and 45 months. DLT were experienced by 58% of patients. DLT were largely hematologic, but higher doses of ifosfamide produced non-hematologic toxicities. **Conclusion:** There was no significant evidence that vinorelbine and ifosfamide combination could provide an alternative to platinum doublet chemotherapy based on inferior efficacy and the high rate of DLT. The 6 “excellent responders” may be explained by chance or secondary to subsequent treatment with erlotinib while harbouring occult EGFR mutations. Further study may be relevant to examine synergy between vinorelbine or ifosfamide with modern targeted therapies.

---

**P1.01 ADVANCED NSCLC**

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

**P1.01-91 A PHASE II STUDY OF AFATINIB TREATMENT FOR ELDERLY PATIENTS WITH PREVIOUSLY UNTREATED ADVANCED NSCLC HARBORING EGFR MUTATIONS**

1Division of Internal Medicine, Toyama Prefectural Central Hospital, Toyama/JP, 2Department of Respiratory Medicine, Gunma Prefectural Cancer Center, Ota/JP, 3Department of Oncology, National Hospital Organization Shikukawa Medical Center Hospital, Shikukawa/JP, 4Division of Respiratory Medicine, National Hospital Organization Ibarakihigashi National Hospital, Takai/JP, 5Division of Pulmonary Medicine, Kyoto Prefectural University, Kyoto/JP, 6Division of Respiratory Medicine, Sakai Central Hospital Advanced Care Center, Sakai/JP, 7Division of Internal Medicine, Iseshikijip Municipal Hospital, Iseshiki/JP, 8Respiratory Medicine, Gunma Prefectural Cancer Center, Ota/JP, 9Department of Respiratory Medicine, Gunma University Graduate School of Medicine, Maebashi/JP

**Background:** The efficacy and safety of afatinib (an epidermal growth factor receptor [EGFR] tyrosine kinase inhibitor) in elderly patients with EGFR mutated non-small cell lung cancer (NSCLC) has not been evaluated. Therefore, the aim of this study was to assess the efficacy and safety of afatinib in elderly chemotherapy-naive patients with NSCLC harboring sensitive EGFR mutations. **Method:** We prospectively assessed the clinical effects of afatinib as a first-line treatment for elderly (≥ 70 years) NSCLC patients with EGFR mutations (exon 19 deletion or exon 21 L858R mutation). All patients were initially administered afatinib (30 mg/day) at the Japanese institutions. **Result:** Between May 2014 and August 2017, 40 patients (13 men, 27 women) with a median age of 77 years (range, 70–85 years) were included in our analysis. All patients had adenocarcinoma. Dose reduction was recognized in 19 patients. The objective overall response and disease control rates were 72.5% and 100%, respectively, and the median progression-free survival and overall survival were 15.2 months and 30.0 months, respectively. Common adverse events included diarrhea, rash, acne, and anemia. Major grade 3/4 adverse toxicities included diarrhea (12.5%), mucositis (7.5%), and pneumonitis (7.5%), respectively. Afatinib treatment was discontinued owing to adverse events of elevation of amylase in 1, liver dysfunction in 1, rash/acne in 1, nail change in 1, anorexia in 2 patients, pneumonitis in 2, and diarrhea in 2. Two treatment-related death because of pneumonitis occurred. **Conclusion:** This is the first study that verified efficacy and feasibility of first-line chemotherapy with afatinib of 30mg/day in elderly patients with advanced NSCLC harboring sensitive EGFR mutations. First-line afatinib of 30mg/day could be a preferable treatment in this population.

**Keywords:** EGFR mutations, afatinib, Elderly patients

**P1.01-93 QUALITY OF LIFE IN PATIENTS WITH ADVANCED NSCLC TREATED IN SECOND- OR THIRD-LINE WITH NAB-PACLITAXEL + DURVALUMAB: ABOUNDP.2L+**

1University Hospitals NHS Foundation Trust, Oxfordshire/GB, 2West of England University School of Medicine, St. Louis/AL/US, 3Hospital Universitario Málaga Regional, Ibiña, Málaga/ES, 4Unidad de Investigación Clínica de Cáncer Pulmón H120-Chio, Madrid/ES, 5Clatterbridge Cancer Center, Liverpool/GB, 6Charing Cross Hospital, London/GB, 7Centre René Gauducheau Centre de Lutte Contre le Cancer Nantes Atlantique, Nantes, Loire-Atlantique/FR, 8Lungenklinik Löwenstein, Löwenstein, Baden-Württemberg/DE, 9Hospital Universitari i Politecnic La Fe, Valencia/ES, 10Ottawa Hospital, Ottawa, Ontario/CA, 11Azienda Ospedaliero Universitaria Di Bologna - Policlinico S. Orsola-Malpighi, Bologna/IT, 12Celgene
**P1.01-94 PHASE I TRIAL TO ESTABLISH MAXIMUM TOLERATED DOSE SAFETY AND PHARMACOKINETIC PROFILE OF ORAL PACLITAXEL**

S. Thungappa1, R. Rajappa2, I. Sreevalika3, S. Alurkar4, S. Patel5, B.K. Khamara6

1Medical Oncology, Spandana Oncology Centre, Bangalore/IN, 2Anaestheology, Kidwai Cancer Institute, Bangalore/IN, 3Clinical Research, Sri Venkateshwar Hospital, Bangalore/IN, 4CSE Department, Apollo Hospitals International Limited, Ahmedabad/IN, 5Be Clinical, Cadila, Ahmedabad/IN

**Background:** Paclitaxel has been the mainstay of chemotherapy for the treatment of solid tumors like lung, ovarian, breast, esophageal, bladder, and head and neck cancers. It is a novel anti microtubule agent which arrests a cell mitotic phase of the cell cycle. Intravenous Paclitaxel is given every 3 weeks (high dose) or every one week (low dose; metronomic) for many solid tumors. Therapeutic concentration above 85ng/ml for four hours is adequate for efficacy if given every week and is associated with lower toxicity but more frequent clinic visits. To reduce visits, attempts are made to prepare oral formulation without Cremophor. This phase I trial investigated second- or third-line nab-paclitaxel either alone or in combination with CC-486 or durvalumab in patients with advanced NSCLC. The objective of this analysis is to report QoL outcomes in patients treated with nab-paclitaxel + durvalumab from the ABOUND.2L+ trial. **Method:** Enrolled patients were ≥ 18 years with advanced NSCLC and no more than 1 prior line of platinum-containing chemotherapy. Immunotherapy in a prior line, first or second, was allowed. Patients were treated with nab-paclitaxel on days 1 and 8 + durvalumab 1125 mg on day 15 of a 21-day cycle. Treatment continued until unacceptable toxicity or disease progression per Response Evaluation Criteria In Solid Tumors (RECIST) v1.1 or immune-related RECIST v1.1. The primary endpoint was progression-free survival. QoL was a prespecified exploratory endpoint assessed using the Lung Cancer Symptom Scale (LCSS), EuroQol 5D-5L, and EORTC QLQ-C30 on day 1 of each cycle, and was examined through 6 cycles of treatment for this analysis. **Result:** A total of 79 patients were assigned to the nab-paclitaxel + durvalumab arm. The median age was 63.0 years. Most patients were white (97.5%), male (68.4%), and had ECOG PS of 1 (77.2%). For the entire study, baseline and >1 postbaseline QoL assessments were completed by 58 (73.4%) patients. 41 patients completed 6 cycles of treatment with nab-paclitaxel + durvalumab. After cycle 6, the mean change from baseline in LCSS total score and pulmonary symptom score was 0.1 and −0.2, respectively. LCSS hemoptyis score improved relative to baseline at every treatment cycle; mean change from baseline after 6 cycles was 0.8. Mean change from baseline in the EuroQol 5D-5L visual analog scale score and EORTC QLQ-C30 global health status/QoL scale score after 6 cycles of treatment was 2.5 and −1.19, respectively. **Conclusion:** In general, patients with advanced NSCLC treated with second- or third-line nab-paclitaxel + durvalumab maintained their QoL through 6 cycles of treatment. NCT02250326.

**P1.01-95 CRIZOTINIB TREATMENT IN 29 ADVANCED NSCLC CHINESE PATIENTS WITH ROSI REARRANGEMENT—A SINGLE CHINESE CANCER INSTITUTE EXPERIENCE**

C. Liu1, J. Wang1, J. Chang1, W. Zhao1, H. Yu1, Z. Zhu1, S. Sun1, M. Fan2

1Fudan University Shanghai Cancer Center, Shanghai/CN, 2Department of Medical Oncology, Fudan University Shanghai Cancer Center, Shanghai/CN

**Background:** Approximately 1%-2% of NSCLC patients harbor ROS1 rearrangement. Crizotinib, a tyrosine kinase inhibitor that targets ALK, MET and ROS1, has shown marked antitumor activity in patients with ROS1-positive advanced NSCLC. **Method:** A total of 29 patients with ROS1 rearrangement advanced or metastatic NSCLC were treated with crizotinib between Apr 1st, 2016 and Feb 6th, 2018 at Shanghai Cancer Center, Fudan University. Patients were administered with oral crizotinib at dose of 250 mg twice daily. **Result:** The median age was 51 years old. Twenty patients (69.0%) were female. Twenty-three (79.3%) were never-smokers. Six patients (20.7%) had brain metastases. Sixteen patients (55.2%) had received chemotherapy prior to crizotinib. **Conclusion:** In general, patients with advanced NSCLC treated with second- or third-line nab-paclitaxel + durvalumab maintained their QoL through 6 cycles of treatment. NCT02250326.

**Keywords:** treatment of solid tumors, metronomic therapy, Cmax

The table summarizes the comparison of HER2 alterations in advanced NSCLC patients from U.S. and China.

**Method:** Patients with locally advanced/metastatic EGFR+/MET+ NSCLC were recruited in China, Hong Kong, India, Singapore and Taiwan. Afatinib 40mg/day was given until disease progression (investigator-assessed) or lack of tolerability. Treatment-related AEs could be managed by protocol-specific tolerability-guided dose adjustment. Result: At data cut-off (13 Feb 2017), patient characteristics were as follows: median age 59.0 years; female. 52.4%: EGFR mutations: Del19+/+L858R+/+ /uncommon, 86.0%; uncommon only, 14.0%: EGCG PS0, 19.8%: PS1, 78.1%. Prior chemotherapy lines: 0: 59.7%: 1: 30.1%; =2: 10.2%. Overall, dose reductions from 40mg/day to 30mg/day occurred in 119 patients (25%). Incidences of the most frequently reported AEs before and after dose reduction were (any grade): diarrhea, 96/51%; rash/ acne, 69/58%; stomatitis, 65/42%; (≥ grade 3) diarrhea, 27/4%: rash/ acne, 24/11%; stomatitis, 11/5%. A total of 96 patients had a dose reduction during the first six months: median PFS was 14.1 months (95% CI: 10.0–19.3) versus 11.33 (10.7–13.6) months in those who

**Keywords:** afatinib, dose reductions, NSCLC

**Conclusion:** Objective responses/tumor shrinkage were observed in the study: highest ORR and mPFS were observed with ceritinib, although patient numbers differed between arms. All treatments were well tolerated; no new safety signals were observed. This study demonstrated the feasibility of an umbrella trial and importance of precision medicine in the management of advNSCLC with uncommon molecular alterations.

**Conclusion:** The incidence and clinical characteristics of HER2 alterations in advanced NSCLC were similar between two large cancer centers in the U.S. and China. These data support U.S.-China collaboration in clinical trials for patients with rare molecular subsets of NSCLC to accelerate new cancer drug development.

**Keywords:** non-small cell lung cancer, Target therapy, clinical trials
local therapy of 10.8 months (p = 0.009). Among intracranial group, 36 patients continued crizotinib with local treatment including whole brain radiotherapy or stereotactic radiotherapy. 23 patients were next-generation ALK inhibitors users. Continuation of crizotinib with local therapy had a non-inferior OS than next-generation ALK inhibitors (28.9 months vs 32.8 months, p = 0.538). Conclusion: Next-generation ALK inhibitors had more survival benefit than continuation of crizotinib with local therapy for extracranial oligoprogressive patients. While crizotinib continuation with local therapy might be a feasible strategy among patients with intracranial oligo progression after crizotinib resistance.

Background: EGFR-TKIs led to initial clinical response in most patients with EGFR mutated non-small cell lung cancer (NSCLC). In contrast, little is known the subpopulation of NSCLC patients with EGFR mutations who had clinical outcomes to treat for immune checkpoint inhibitors (ICIs). Therefore, to seek for the eligible cases to treat with ICIs, we retrospectively analyzed the correlation between clinical features and the efficacy of ICIs in patients with EGFR mutations. Method: We analyzed a retrospective study of patients with advanced NSCLC harboring with EGFR mutations who were treated with ICIs after the resistance to EGFR-TKIs from February 2016 and April 2018 at five institutions in Japan. The association between clinical outcome and the efficacy of ICIs was investigated. Result: We enrolled 27 patients who had EGFR activating mutation. The objective response and disease control rates were higher in patients with uncommon EGFR mutations than in those with common EGFR mutations (57.1% versus 6.3% and 71.4% versus 31.3%, p = 0.003 and p = 0.06, respectively). Patients with uncommon EGFR mutations were associated with a significantly longer median progression-free survival than those with common EGFR mutations (7.0 months versus 1.9 months, p = 0.009). Conclusion: Uncommon EGFR mutations are associated with better outcomes for the treatment with immunotherapy among EGFR mutated NSCLC in the retrospective analysis. Further research is needed to validate for the clinical biomarkers involved inICI responders.

Keywords: EGFR mutation, immune checkpoint inhibitor

P1.01 ADVANCED NSCLC MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.01-103 LEUKOCYTE TELOMERE LENGTH AS A NOVEL BIOMARKER IN ADVANCED LUNG ADENOCARCINOMA PATIENTS TREATED WITH GEFITINIB

M. Yang1, J. Li1, N. Zhang1, J. Liu1, X. Jing2

1Shandong Provincial Key Laboratory of Radiation Oncology, Cancer Research Center, Shandong Cancer Hospital Affiliated To Shandong University, Jinan/CHINA, 2Department of Radiation Oncology, Shandong Cancer Hospital Affiliated To Shandong University, Jinan/CHINA

Background: Gefitinib is currently one of the mostly used epidermal growth factor receptor tyrosine kinase inhibitors (EGFR-TKIs) recommended for treating non-small cell lung cancer. However, drug resistance was observed among the majority of patients after initial treatment. The factors that predict treatment prognosis and drug resistance to EGFR-TKIs remain elusive. Leukocyte telomere length has been previously proved to be associated with lung cancer risk. However, it is still unclear whether telomere length can be used as biomarker of EGFR-TKIs therapy. The objective of this study is to exam the association between leukocyte relative telomere length (RTL) and prognosis or drug resistance of advanced lung adenocarcinoma to gefitinib treatment.

Method: In this study, three hundred and sixty-nine patients with stage IIIb or IV lung adenocarcinoma were recruited between January 2009 and June 2013. All patients were treated with gefitinib orally at a daily dose of 250 mg as first-line therapy. Leukocyte RTL of each patient was measured using quantitative polymerase chain reaction (qPCR) protocol on an ABI PRISM 7900HT Sequence Detection System (Applied Biosystems) and calculated according to Cawthon’s formula. Differences in patients’ characteristics were calculated by Pearson’s χ2 test or Student’s t test. Cox proportional hazard regression analyses were used to calculate univariate and multivariate hazard ratios (HRs) and their 95% confidence interval (95% CIs). Multivariate analyses were adjusted for age, smoking status and EGFR mutation status, if appropriate. Survival differences were examined using the log-rank test. A P value of less than 0.05 was used as the criterion of statistical significance, and all statistical tests were two-sided. Result: Among 369 patients, EGFR mutations were positive in 181 patients (49.1%). Compared to long RTL, short leukocyte RTL was significantly associated with poor prognosis in all patients after gefitinib treatment (overall survival: 12.9 months vs. 17.8 months, P = 1.2 × 10−10; progression free survival: 7.8 months vs. 13.0 months, P = 0.043 for log-rank test). Additionally, statistically significant association between short leukocyte RTL and short OS still existed among the EGFR mutant patients with gefitinib treatment (HR = 1.65, 95% CI = 1.28-2.12; P = 0.006). Besides EGFR mutation status, short RTL also contributed to significantly elevated risk of gefitinib primary resistance (HR = 1.50, 95% CI = 1.05-2.15, P = 0.027). Conclusion: Our results highlight the potential of leukocyte RTL as a novel biomarker in advanced lung adenocarcinoma patients treated with EGFR-TKIs and the possibility of patient-tailored decisions based on leukocyte RTL.

P1.01-104 UPDATED PHASE I RESULTS OF CARBOPLATIN, PEMETREXED AND EXEMESTANE IN POSTMENOPAUSAL WOMEN WITH METASTATIC NON-SQUAMOUS NSCLC

P. Young1, D. Marquez1, Z. Nour1, R. Callahan1, B. Jones1, D. Wong1, J.W. Goldman2, S. Applebaum3, R. Rausch1, C. Yanes1, S. Bueno1, N. Garban1, D. Elashoff2, E. Baron3, R. Pietras4

1Hematology/oncology, University of California, Los Angeles, Santa Monica/US, 2Medicine, UCLA, Los Angeles/US, 3David Geffen School of Medicine at University of California, Los Angeles, Los Angeles/CA/US, 4Medicine-Hematology/oncology, UCLA David Geffen School of Medicine, Los Angeles/CA/US

Background: Estrogen receptors (ERs, ERβ) and aromatase (key enzyme for estrogen synthesis) are expressed in most human NSCLCs. High intratumoral estrogens and elevated aromatase expression in NSCLC predicts poor outcome. In vitro preclinical models show that estrogen starvation NSCLC gene expression, induces proliferation, apoptosis and enhances apotosis. Furthermore, preclinical NSCLC models demonstrate that antiestrogens or aromatase inhibitors prevent these processes and that the combination of cisplatin and aromatase inhibitors elicits dramatic growth inhibition (Marquez et al., Annals NY Acad Sci. 2009;1155:194). Additionally, depletion of estrogen/paracrine estrogen production hypersensitizes cells to DNA-damaging effects of platinum therapy, thereby providing support for this early phase trial. Method: The primary objective of this phase 1b, open-label, single-center study (NCT01664754) was to evaluate safety and tolerability of escalating doses of exemestane in combination with carboplatin and pemetrexed in postmenopausal women with stage IV non-squamous NSCLC. Key exclusion criteria included untreated CNS involvement, major surgery in prior 4 weeks to therapy, prior/concurrent investigational or standard therapy (with the exception of TKI and/or immunotherapy in prior 4 weeks). Patients received escalating doses of exemestane (starting 1-week before chemotherapy) at 25 mg PO daily (Cohort 1) or 50 mg PO daily (Cohort 2) combined with carboplatin (AUC 6 mg/m2) and pemetrexed (500 mg/m2) IV Q3 weeks for 4 cycles. After 4 cycles, patients were eligible for continued therapy with exemestane and/or pemetrexed. Area under the curve (AUC) was extrapolated using linear trapezoidal methods. Result: Ten patients consented for therapy; 2 patients screen-failed. Five patients completed therapy in Cohort 1 and five patients were treated in Cohort 2. One patient in Cohort 2 exited the trial for alternative therapy after one treatment cycle. The median number of cycles given was 15 (range 1-54). The mean of the maximum serum concentration (Cmax) of exemestane for Cohort 1 was 12.98 ng/mL and for Cohort 2 was 41.38 ng/mL. The AUCC, for the two cohorts was 51.73 and 184.17 ng x h/mL, respectively. The established maximum tolerated dose (MTD) was exemestane 50 mg PO daily with pemetrexed (500 mg/m2 IV Q3 weeks) and carboplatin (AUC 6 mg/m2 IV Q3 weeks). Patients were removed from the study for adverse events. Clinical outcome, biomarker

1 Cancer Medical Center, The Second Affiliated Hospital of Nanjing Medical University, Nanjing/CN; 2 Geneplus-Beijing, Beijing/CN; 3 Oncology, Jiangsu Province Hospital, Nanjing/CN; 4 Fujian Cancer Hospital, Fuzhou/CN; 5 Shanghai Chest Hospital, Shanghai/CN; 6 Department of Medical Oncology, Tongji Hospital, Tongji Medical College, Huazhong University of Science & Technology, Wuhan/CN

**Background:** It has been reported that about 5%-20% of EGFR-TKIs resistant NSCLC patients harbors MET amplification or activating mutations. However, the extent that MET abnormal activation contributes to EGFR-TKIs resistance remains widely unknown. Here, we describe the clinical and genetic characteristics of 29 lung cancer patients harboring concurrent EGFR and MET mutations.

**Method:** Genetic mutations were reviewed in 6000 lung cancer patients who underwent genetic testing at our institute from 2016 to 2018. Mutation profiles were analyzed using hybridization capture based next-generation sequencing (NGS), which enables the simultaneous detection of single-nucleotide variants, insertions/deletions, rearrangements, and copy-number alterations of at least 50 genes (range 59 – 1021 genes). Result: The selected patients included 24 lung adenocarcinoma patients, 1 squamous cell lung cancer patient and 3 lung cancer patients with unspecified pathology. Both MET amplification and activating mutations were included for analysis. MET amplification was present in 13.3% (4/30) of samples, while one patient was found with MET mutation.

**Conclusion:** MET amplification and activating mutations were included for analysis. MET amplification and activating mutations were included for analysis. MET amplification was present in 13.3% (4/30) of samples, while one patient was found with MET mutation.

**Keywords:** lung cancer, Concurrent EGFR and MET Mutations, EGFR-TKIs Resistance

**P1.01-106 PEBROLIZUMAB RANDOMIZED, PHASE 1 STUDY IN CHINESE PATIENTS WITH ADVANCED NSCLC: KEYNOTE-033**

Y. Ma, 1 W. Fang, 1 S. Xie, 1 J. Ge, 1 H. Zhou, 1 L. Zhang 2
1 Sun Yat-Sen University Cancer Center, Guangzhou/CN; 2 Med China, Beijing/CN; 3 Med China, Shanghai/CN

**Background:** Multicenter studies have shown improved clinical outcomes and favorable safety with pembrozumab (pembro) in 1L and 2L settings in advanced NSCLC. This study aimed to present pembrolizumab efficacy in Chinese patients (pts) with advanced NSCLC.

**Method:** This open label phase 1 study (NCT02835690) enrolled Chinese pts aged ≥18 years with histologically/cytologically confirmed advanced, unresectable NSCLC, measurable disease per RECIST v1.1; EGFR PS ≤1; and prior failure/intolerance/ineffectiveness for standard therapy. Pts were randomized (stratified by gender: 1:1) to IV pembro 2 mg/kg, 10 mg/kg, or 200 mg (each Q3W after initial 28-day cycle). Safety and PK were primary objectives. Responses were assessed centrally per RECIST v1.1. PK was based on noncompartmental analysis. Result: 42 pts received ≥1 pembro dose (2 pts randomized were not treated thus excluded from analyses; 2 mg/kg, n = 14; 10 mg/kg, n = 13; 200 mg, n = 16): median age 59 range (28–71) y, 64% male, 62% adenocarcinoma, and 76% 1–2 prior therapies. Median follow-up was 7.9 mo (range 1.1–41.4). 4 pts (9%) had treatment-related AEs, most commonly fatigue and rash (24% each). 4 pts (10%) had grade 3–4 treatment-related AEs (no grade 5); eyelid ptosis, fatigue, anaphylactic reaction, dermatitis aceneiform, and rash (1 each). AEOSIs ( predefined list with possible immune etiology) were hypothyroidism (n = 2) and hyperthyroidism, anaphylactic reaction, and rash (n = 1 each). Geometric mean PK values for 2 mg/kg, 10 mg/kg, and 200 mg, respectively, were: t1/2 (days; CV%), 15 (33), 16 (25), and 12 (41); AUC0-21d (> g/mL•h; CV%), 174 (45.7), 851 (60.6), 2919 (46.1), and 931.0 (724.4–1196.6); and Cmax (µg/mL; 95% CI), 66.7 (56.9–78.1), 268.6 (217.8–331.2), and 92.2 (81.7–104.2). Anti-drug antibodies did not impact pembro exposure. Overall, ORR was 14.3% (6/42; 95% CI, 5.4–28.5); median DOR was 5.2 mo range (2.0 [ongoing]–6.28). PFS was 2.1 mo (range 2.1–4.2), and OS was not reached. Conclusion: In Chinese pts with advanced NSCLC, pembro had approximately linear serum exposure at the dose range studied (2 to 10 mg/kg), was well tolerated, and showed antitumor activity consistent with the multicohort KEYNOTE-033 study (NCT02835690). Enrolling mostly Chinese pts, evaluates pembrolizumab versus docetaxel in pts with previously treated NSCLC with PD-L1 TPS ≥1% and is ongoing.

**Keywords:** pembrolizumab, NSCLC, biomarker

**P1.01-107 THE IMPACT OF ANLOTINIB ON QUALITY OF LIFE IN PATIENTS WITH ADVANCED NSCLC: POST-HOC ANALYSIS OF A PHASE III RANDOMIZED CONTROL TRIAL (ALTERO0303)**

X. Shi, 1 L. Zhang, 2 H. Wang, 3 M. Wang, 1 B. Han, 1 L. Li, 1 Q. Tang, 2 Y. Shi, 1 Z. Wang, 3 Y. Luo, 1 K. Nan, 1 F. Jin, 1 B. Li, 6 Y. Chen, 1 J. Zhoua, 6 D. Wang 1

**Background:** Anlotinib is a novel multi-target tyrosine Kinase inhibitor that inhibits VEGFR2/3, FGFR1-4, PDGFD a/d, E-Cit and Ret. In the phase III ALTERO-0303 trial (Clinical Trial Registry ID: NCT 02388919), anlotinib significantly improved overall survival versus placebo in advanced non-small-cell lung cancer (NSCLC) patients who had received at least two previous chemotherapy and epidermal growth factor receptor (EGFR) or anaplastic lymphoma kinase targeted therapy regimens. This study assessed quality of life (QoL) in these patients. Method: Patients were randomized (2:1) to anlotinib or placebo up to progression or intolerable toxicity. The QoL were assessed using the European Organization for Research and Treatment of Cancer (EORTC) Quality of Life Questionnaire Core 30 (QLQ-C30) and the associated EORTC Quality of Life Lung Cancer Specific Module (QLQ-LC13) at baseline, end of cycle 1, end of every two cycles, and at the final visit. The analyses were conducted in the per-protocol populations. Differences in scores of 10 points or more or from baseline were considered clinically meaningful. Result: A total of 437 patients were assigned to anlotinib (n=294) and placebo (n=143). The completion rates of the QoL questionnaires were from 96.9% to 97.0%. Mean scores of 1Q-2Q of QLQ-C30 and QLQ-LC13 subscales were similar in the anlotinib and placebo arms at baseline. Compared to placebo, anlotinib improved role functioning (at cycle 2), social functioning (at cycle 4), dyspnea (at cycle 2, 4), insomnia (at cycle 6), mouth or tongue symptom was worse in the anlotinib arm (at cycle 2, 4, 6) than in the placebo arm. Conclusion: Anlotinib improved quality of life versus placebo in advanced NSCLC patients who had received at least two previous chemotherapy. The QoL analyses provided evidence that anlotinib should be a choice for first-line treatment or beyond in advanced NSCLC.

**Keywords:** anlotinib, non-small cell lung cancer, quality of life
Background: Anlotinib is an oral tyrosine kinase inhibitor targeting VEGFR, FGFR, PDGFR and c-kit. In the phase III ALTER-0303 trial (Clinical Trial Registry ID: NCT 02389819), anlotinib significantly improved overall survival versus placebo in advanced non-small-cell lung cancer (NSCLC) patients who had received at least two previous chemotherapy and epidermal growth factor receptor / anaplastic lymphoma kinase targeted therapy regimens. This study summarized adverse event management in this trial. Method: Patients were randomized (2:1) to anlotinib or placebo up to progression or intolerable toxicity. Adverse events were graded according to the National Cancer Institute Common Terminology Criteria for Adverse Events (NCI CTCAE 4.0) and managed by investigators. Adverse events and key strategies for preventing and managing the most common adverse events were described. Proportions were compared using the χ² test or Fisher's exact test, as appropriate. Two-sided values of P < 0.05 were considered statistically significant. Analyses were calculated by SAS 9.4. Result: Between February 2015, and August 2016, a total of 437 patients were randomized to anlotinib group (n=294) and placebo group (n=143). The most common anlotinib related grade ≥ 3 adverse events were hypertension (64.6%), fatigue (46.3%), TSH elevation (44.6%), hand-foot syndrome (HFS) (43.2%), hyperglycemia (38.8%), anorexia (38.4%). The most common anlotinib related grade 1–2 adverse events were hypertension (13.3%), HFS (3.7%), and hyperglycemia (2.4%). The median onset time of hypertension, HFS, and hyperglycemia were 6 days, 30 days, and 22 days respectively. To monitor blood pressure, every patient had an electronic manometer. One hundred and eight pts in each cohort should be enrolled for PK evaluation. The most common anlotinib related grade 1–2 adverse events were hypertension (36.7%), patients required dose reduction due to hand-foot skin syndrome. Eleven (3.7%) patients received cortisone cream for topical therapy. Twenty-four patients received fructose to reduce plasma triglyceride level. Two (0.7%) patients required dose reduction due to hyperglycemia. Conclusion: Anlotinib-related adverse events could be controlled by prophylactic measures, and early intervention. Keywords: non-small cell lung cancer, adverse event, Anlotinib

Background: EGFR-TKI plus bevacizumab (anti-VEGF) has brought significant progression-free survival (PFS) improvement for advanced NSCLC patients (pts) as first-line therapy compared to EGFR-TKI alone (16.0 vs. 9.7 months, HR 0.41, Lancet Oncol, 15(11):1236-1244). Apatinib, a TKI that selectively inhibits VEGFR-2, has shown strong antitumor activity in both preclinical and clinical studies in NSCLC. This phase I study aims to evaluate the safety and efficacy of Gefitinib plus Apatinib in the first line setting. Method: Treatment-naïve advanced NSCLC pts with EGFR 19 Del or 21 L858R mutation were eligible. Two prespecified groups were designed: Cohort 1: Apatinib 500mg QD PO + Gefitinib 250mg QD PO; Cohort 2: Apatinib 250mg QD PO + Gefitinib 250mg QD PO. Pharmacokinetics (PK) profile of Apatinib plus Gefitinib was also evaluated. 6 pts in each cohort should be enrolled for PK analysis. Result: From July 2016 to April 2017, 12 pts were enrolled. Most common AEs were rash (91.7%, 12/12), diarrhea (66.7%, 8/12), proteinuria (58.3%, 7/12), hypertension (25.0%, 3/12), and hand-foot skin reaction (8.3%, 1/12). And most of AEs were grade 1-2. SAE was observed in 1 case with grade 3 hypertension (8.3%). The PK parameters in this combination setting were similar to those of single agent from the previous literature reports (Table 1). Among all evaluable patients, ORR was 83.3% (10/12), and DCR was 91.7% (11/12). Median PFS was 19.0 months (95% CI 0.0–43.9) in the Apatinib (500mg) + Gefitinib group and 13.4 months (13.0–13.8) in the Apatinib (250mg) + Gefitinib group (P=0.657). Table 1, Pharmacokinetic parameters (geometric mean, SD) of apatinib and gefitinib

Background: HER2 mutation is a potential therapeutic target for non-small cell lung cancer (NSCLC). However, HER2-targeting therapies including trastuzumab, afatinib and T-DM1 show limited and inconsistent efficacies in HER2-mutant NSCLC patients. In this study, we investigated the efficacy of afatinib in HER2-mutant NSCLC and develop NGS (next generation sequencing)-based patient selection strategy, we identified that HER2-mutant advanced NSCLC patients with specific HER2 mutations may benefit from HER2-targeting therapy. Method: To evaluate the efficacy of afatinib in HER2-mutant NSCLC patients, we included 37 HER2-mutant advanced NSCLC patients treated with afatinib, 21 of whom had at least 1 HER2 specific mutation. Result: Among 37 patients treated with afatinib, 6 achieved partial response (PR) or complete response (CR), 13 achieved stable disease (SD) and 18 had disease progression (PD). Among 21 patients who had at least 1 HER2 specific mutation, there were 3 patients with p.G776delinsVC. Same mutations were detected in five other patients. Patients harboring the three specific HER2 mutations (p.G776delinsVC (n=3); p.Y772_A775dup (n=3); p.G778_P780dup (n=2)) had marginally higher ORR (ORR=50%, P=0.077) and longer PFS (P=0.953, n=2).
Conclusion: HER2-mutant NSCLC represents a heterogenous group of diseases. Although afatinib failed to show the expected ORR in the overall population, patients harboring three specific HER2 mutations may still benefit from afatinib treatment.

P1.01-111 EGFR EXON20 INSERTION PATIENTS TREATED WITH FIRST-LINE CHEMOTHERAPY IN NON-SMALL CELL LUNG CANCER
C. Zhao1, X. Li1, C. Su2, X. Ren1, C. Zhou2
1Department of Medical Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Shanghai/CN, 2Oncology, Shanghai Pulmonary Hospital, Tongji University School of Medicine, Tongji University Cancer Institute, Shanghai/CN.

Background: Epidermal growth factor receptor exon20 insertion(EGFR 20-ins) is a low frequency mutation among EGFR mutations, and chemotherapy is a major choice for these patients. The outcomes between different types of EGFR 20-ins and with EGFR sensitive mutation and wild type are not well studied. Method: From Oct 2011 to Feb 2018, 84 patients were enrolled in China. Eligible patients: ≥18 years, Ex19del/L858R. EGFR advanced NSCLC, no prior EGFR-TKI/systemic anti-cancer therapy (CNS) active EGFR-TKI, selective for both EGFRm and T790M resistance mutations. FLAURA (NCT02296125) is a PhIII, double-blind, randomized study assessing efficacy and safety of osimertinib vs SoC EGFR-TKI (erlotinib/gefitinib) in first-line patients with EGFRm advanced NSCLC. FLAURA results (556 patients, globally) are published. We present the China cohort results. Method: The cohort included self-identified Chinese patients, enrolled in China. Eligible patients: ≥18 years, Ex19del/L858R. EGFR advanced NSCLC, no prior EGFR-TKI/systemic anti-cancer therapy for advanced disease. Neurologically stable patients with CNS metastases were allowed, if definitive treatment/corticosteroids were completed ≥2 weeks before enrolment. Patients were randomized 1:1 to osimertinib 80 mg once daily (qd) orally or SoC EGFR-TKI (gefitinib 250 mg qd orally selected by all Chinese sites), stratified by mutation status (Ex19del/ LB58R). Primary endpoint: progression-free survival (PFS) by RECIST v1.1. Results: Overall, 136 patients were randomized (osimertinib n=71; SoC n=65); 19 were also included in the global analysis. Baseline characteristics were balanced across arms (osimertinib/SoC): female 61/71%; smoking history 25/23%; WHO performance status 1 90/80%; Ex19del/L858R 51/51%, L858R 49/49%; CNS active EGFR-TKI, selective for both EGFRm and T790M resistance mutations.

*A hazard ratio <1 favours osimertinib.

PFS benefit was observed across all subgroups, irrespective of EGFR mutation status and including patients with/without CNS metastases at study entry. Median overall survival: osimertinib, 18.9 months; SoC, 13.6 months. No new safety signals were reported. Numerical increase in grade ≥3 AEs was reported in the osimertinib arm (49%) versus SoC arm (23%). Most grade >3 AEs in the osimertinib arm were investigator-reported laboratory and disease-related AEs; incidence of non-laboratory-related events was low. AEs leading to discontinuation: osimertinib, 13%; SoC, 6%. In the osimertinib arm, most AEs leading to discontinuation were fatal disease-related events. Conclusion: Osimertinib improved PFS vs SoC EGFR-TKI (HR: 0.56) as first-line treatment in Chinese patients with EGFRm advanced NSCLC, consistent with the global analysis.

P1.01-113 ANALYSIS OF CLINICOPATHOLOGICAL FEATURES AND CLINICAL EFFICACY OF CRIZOTINIB IN ROS1 POSITIVE NON-SMALL CELL LUNG CANCER

Y. Zhu1, X. Li1, L. Wu1, H. Chen3, W. Wang1, C. Xu1, M. Fang1, J. Shen1, K. Du1, W. Zhang1, Y. Chen1, G. Chen1
1Zhejiang Rongjun Hospital, Jiaxing/CN, 2Zhejiang Cancer Hospital, Hangzhou/CN, 3Fujian Cancer Hospital, Fuzhou/CN

Background: ROS1 gene-rearrangement in non-small-cell lung cancer (NSCLC) patients has recently been identified as a driver gene and benefited from crizotinib treatment. The aim of this study is to explore clinicopathological features and clinical efficacy of crizotinib in c-ros oncogene 1 receptor tyrosine kinase (ROS1) positive non-small cell lung cancer (NSCLC). Method: A retrospective analysis of 2617 cases of NSCLC from January 2013 to December 2016, ROS1 fusion gene were detected by real-time reverse transcriptase-polymerase chain reaction (RT-PCR), fluorescent in situ hybridization (FISH) or next-generation sequencing (NGS) technique and part ROS1 fusion gene positive patients were received oral treatment with crizotinib. Result: ROS1 fusion was found in 67 of 2167 cases (2.56%). 21 cases were male and 46 cases were female. The median age was 68 years old. Among these cases, 58 (88.05%) were adenocarcinoma and 8 were non-adenocarcinoma. According the TNM staging, 4 cases were I-IIIa and 63(94.02%) cases were IIb-IV. EGFR gene status included 60 cases wild type, 1 case co-mutation and 6 cases unknown. There were statistical difference in sex, TNM staging and EGFR gene status between ROS1 fusion gene positive and negative patients (P<0.001). 23 patients were received oral treatment with crizotinib and PR, SD, PD patients were 13 (56.52%), 5 (21.74%) and 5 (21.74%) respectively. The ORR was 56.52% and DCR was 78.26%. Of all the cases, median OS was 5.52+4.5 months and OS was 27.3 months. The one-year PFS was 50.4%. There were no difference of median PFS in age, sex, smoking history, PS score, pathology type, TNM staging, TPS5 gene status, EGFR gene status and the first line crizotinib treatment whether or not by single and multiple factor analysis. The adverse events were gastrointestinal disturbance, followed by increased transaminase. Conclusion: The rate of ROS1 fusion of NSCLC is lower. Crizotinib is an effective and safe drug for the treatment of ROS1 positive advanced NSCLC.

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.02-01 IMAGING OF LUNG CANCER AT THE UNIVERSITY COLLEGE HOSPITAL, IBADAN, NIGERIA: DOES NUCLEAR MEDICINE HAVE ANYTHING TO OFFER?

O. Ayeni1, A. Orunmuyi2
1Department of Nuclear Medicine and Molecular Imaging, Charlotte Maxeke Johannesburg Academic Hospital, University of the Witwatersrand, Johannesburg/ZA, 2Nuclear Medicine Department, University College Hospital, Ibadan/Nigeria

Background: Lung cancer is the most common cause of cancer mortality worldwide. Majority of lung cancer cases occur in less-developed regions. In cancer medicine, bone scintigraphy, a highly sensitive nuclear medicine technique, is often used as a simple whole-body imaging method for metastatic survey. However most recent clinical guidelines on lung cancer management do not recommend the routine use of bone scans to exclude bone metastases. PET/CT (Positron Emission Tomography/Computed Tomography) imaging being the method of choice. In a country where bone scan requests in lung cancer patients at our institution since inception of Nuclear Medicine services. Method: Bone scan requests over an eleven-year period (2006-2017) at the Nuclear Medicine Centre of the University College Hospital, Ibadan, Nigeria were reviewed. Indications involving lung cancer patients were noted and images as well as reports were reviewed. Standard procedure of planar bone scintigraphy with a gamma camera was employed in all patients following intravenous injection of 15-25mCi 99mTc- Methylene Diphosphonate (MDP). Result: Of over 6,000 patients who had bone scintigraphy during the period under review, only 12 scans (in eleven patients) were done for detection of bone metastases in known lung cancer patients. The mean age was 50.3 years (range 33 – 84) with male to female ratio of 1:2.1. Histologic sub-type of all but one was non-small cell lung cancer (NSCLC). All of these patients had skeletal related events, primarily severe bone pains requiring radiation therapy/ analgesia, while two had known metastases prior to imaging. Bone scan revealed multiple foci of bone metastases in the vast majority (75%) of the cases. Two cases were negative and one equivocal. Only one required additional tomographic (SPECT) imaging to arrive at a conclusive report. Conclusion: With an average of one bone scan per year and <0.2% of total bone scans in an eleven-year period, bone scintigraphy appears to be underutilized in the setting of lung cancer in our environment. In the absence of PET/CT imaging, bone scintigraphy still has an important role to play in patients’ management and referring physicians are encouraged to embrace this imaging modality.

P1.02-02 ‘LISTEN TO YOUR LUNGS’ – AN AWARENESS CAMPAIGN FROM THE MARIE KEATING FOUNDATION

A. Baird1, L. Yeates2
1Lung Cancer Europe, Dublin/IE, 2The Marie Keating Foundation, Dublin/IE

Background: In Ireland, lung cancer is the biggest cancer related killer in both men and women, accounting for over 2,300 cancer cases and over 1,800 deaths. Incidence and mortality rates are projected to increase further in the coming years, particularly in women. In the absence of a national screening programme, there is a need to improve lung cancer awareness, particularly as in 1 in 4 Irish people cannot identify one lung cancer symptom. Recent research undertaken by our Foundation has also established that only 7% of adults believe that lung cancer is the leading cause of cancer related deaths in Irish women, and 98% believe that only smokers get lung cancer. These figures underscore the necessity for a national awareness campaign. Method: During Lung Cancer Awareness Month, our Foundation launched an accessible multifaceted national campaign to reach out to, and educate men and women on symptoms and risk, to aid in the early detection of lung cancer. Our campaign aligned with the National Cancer Strategy and focused on symptom awareness, specifically those of a persistent cough, linked with a change in a long-term cough and breathlessness. Our campaign slogan was ‘Listen To Your Lungs’ and our call to action ‘If you have a cough lasting longer than 3 weeks, go see your GP’. The campaign consisted of videos, activities on social media and our website, a radio advertisement and a bigger outdoor advertising which included Ireland’s first ‘coughing billboard’. A central part of our campaign was a video produced in conjunction with a lung cancer survivor who talked about his journey and his main symptom – a persistent cough. Result: The campaign to reach out to, and educate men and women on symptoms received an average of 1.2 million adults. Images on 12 standard bus shelters and the ‘coughing billboard’ were shared widely and generated significant social media activity. Through the Foundation’s own channels, engagement rate was high on Twitter, Facebook and Instagram. Indeed some posts were the best performing posts in the history of the Foundation’s social media channels. The campaign video was the best performing post of the campaign: it attained a reach of nearly 200,000 people with approximately 150,000 views. Conclusion: Our first multifaceted national awareness campaign was well received and generated much needed conversation around lung cancer symptoms and risk. We believe that a campaign of this nature can contribute in a meaningful way to the early detection of lung cancer.

P1.02 ADVOCACY

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00
March 2018, a roundtable was convened consisting of executives from lung cancer advocacy organizations and key opinion leaders in the lung cancer field to discuss trends in biomarker testing for patients with lung cancer. The main objective of the roundtable was to develop an action plan to increase awareness of biomarker testing to ensure all lung cancer patients receive the most effective treatment. Result: Several barriers were identified that may hinder optimal biomarker testing, including lack of patient and physician awareness, inadequate tissue sampling, slow turn-around time, limited availability in some community settings, and health policy issues surrounding access, cost, and reimbursement. Patient advocacy groups are well positioned to address the lack of patient awareness with education campaigns. However, the lack of consistent language to describe biomarker testing among organizations is a barrier. To address this issue, advocacy groups need to align on common terminology and messaging with regard to biomarkers. Two potential approaches to achieve this goal include: 1) collaboration to develop joint educational material or 2) collaboration to develop a shared consensus statement including best practices and common core items or ‘building blocks’ for use by each organization to develop their own materials. As a first step, consistent messaging with regard to the Who, What, When, Where, Why, and How of biomarker testing are needed. Understanding gaps in physician knowledge regarding biomarker testing and development of initiatives to address these gaps are also warranted.

Conclusion: Additional patient and physician education are needed to establish biomarker testing as part of standard of care in patients with advanced-stage NSCLC, with the ultimate goal being that the patient has a full biomarker panel available (or at least tests in progress) at their first appointment with an oncologist. A unified effort from lung cancer advocacy organizations, healthcare providers, and industry partners is needed to achieve this goal.

P1.02-04 THE EGFR RESISTERS LUNG CANCER GROUP: A PATIENT-DRIVEN INITIATIVE TO UNDERSTAND & IMPROVE TREATMENTS FOR EGFR+ LUNG CANCER
J. Feldman, I. Elkins
Egfr Resisters, Deerfield/US

Background: Lung cancer patients harboring mutations in the EGFR gene represent a significant amount of patients diagnosed with non-small cell lung cancer (NSCLC). Approximately 10-15% of patients with NSCLC in the United States (U.S.) and 35% in Asia have an EGFR mutation. In the U.S., more than 20,000 people with EGFR-positive lung cancer are diagnosed each year. Although there has been an increase in progression-free survival in patients due to EGFR tyrosine kinase inhibitors (TKIs), patients eventually develop resistance. With each generation of TKIs developed, more mechanisms of resistance are discovered; therefore the development of drugs to target resistance mutations and other mechanisms of resistance are desperately needed. Method: The EGFR Resisters is a group of people living with and/or personally affected by EGFR-positive lung cancer. The purpose of founding the group is to build a community of survivors and caregivers to share knowledge, provide support, and confidentiality collect patient data (such as patient demographics, details of lung cancer diagnosis, specific type of EGFR mutation, acquired resistance and mechanism of resistance). Patient data will be aggregated and analyzed to identify trends such as commonalities and differences in mechanisms of resistance. The goal of the EGFR Resisters is to improve outcomes for people with EGFR-positive lung cancer by accelerating research. Our ultimate objective is changing and differences in mechanisms of resistance. The goal of the EGFR Resisters is to improve outcomes for people with EGFR-positive lung cancer by accelerating research. Our ultimate objective is changing and differences in mechanisms of resistance. The goal of the EGFR Resisters is to improve outcomes for people with EGFR-positive lung cancer by accelerating research. Our ultimate objective is changing and differences in mechanisms of resistance. The goal of the EGFR Resisters is to improve outcomes for people with EGFR-positive lung cancer by accelerating research. Our ultimate objective is changing and differences in mechanisms of resistance.

Conclusion: The EGFR positive community is a crucial component of the “patient-first” movement that has been gaining momentum in the lung cancer field recently. Just in the first four months of 2018 alone, the ALK Positive group grew close to twenty percent (20%), and the trend is likely to continue, as patients become more educated about their disease and increasingly desire to truly be partners with the medical community in their care.

Keywords: patient, ALK
**Background:** Here in India most of the cancer patient including lung cancer patient die a sad death of neglect due to lack of awareness about palliative care and low economic level. Surveys in India show that two third of cancer patient do not get proper care during the terminal phase of their life. Palliative care through volunteers can make a significant difference in this respect. To identify and try to solve, to the extent possible, the main difficulties in giving palliative care to the terminal cancer patients of the area. And evaluate the impact of volunteer’s direct care of palliative patients and their families. **Method:** Feedback from patients and their relatives regarding the palliative care they receive from nursing home and from volunteers and compare the two. Also feedback from volunteers regarding their positive and negative experience while delivering palliative care service. Then evaluate the data to compare and improve the quality of service. **Result:** We carried out two studies. One study was undertaken in nursing home palliative care and another was in home setting by volunteers. Both studies were in adult palliative care services. Since January 2015, 496 cases were studied to enquire about their experience in both home based care and nursing home care. Both the studies fulfilled our quality appraisal criteria. One found that those families and patients who received home visits from volunteers were significantly more satisfied. The study highlighted the value of the role of volunteers in better satisfaction of patients and their families. **Conclusion:** Further research is needed to evaluate the role of volunteers in palliative care and how it can be delivered appropriately and effectively. We also wish to compare our findings with similar studies elsewhere.

**Background:** As in any developing countries state of West Bengal in India has a huge burden of metastatic lung cancer patients in advanced stage coming from rural area where awareness regarding the usefulness of palliative care in rather poor. Our goal is to give a pain free good quality of life in these advanced stage lung cancer patients. Objective of this study is to identify the main difficulties in achieving the above goal in a rural village setting in India. **Method:** Advanced lung cancer patients in need of palliative care in various villages in of rural India were selected for this study. Their symptoms and managements in that rural surroundings were evaluated by an NGO (under the guidance of a senior palliative care specialist) working in that area. An attempt was made to identify the main obstacles in getting proper palliative care in a rural setting. **Result:** Pain, fatigue, respiratory distress are the main symptoms effecting these patients. In most patients pain and other symptoms control were grossly inadequate due to lack of properly trained manpower in the rural India. However regular homemcare visits by a group of social workers were of immense help in the last few months of life. NGO team was well guided by a palliative care specialist. **Conclusion:** There is a wide gap of trained manpower in this filled in rural areas of India. Dedicated groups from rural area itself need encouragement, repeated home visit, awareness built up, proper training to home care giver, so that difficult symptoms can be managed locally along with necessary social and psychological support to these patients.

**Background:** Since 2015, the US Food and Drug Administration has approved more than fifteen lung cancer treatment approaches, the majority of which are biomarker-driven. However, not all eligible patients benefit from these treatments, partly due to lack of tumor testing. To help assess whether inconsistent messaging could be a contributor to the suboptimal biomarker testing rates, we conducted a messaging audit to determine the messages being conveyed to lung cancer patients and healthcare providers (HCP). **Method:** We analyzed marketing and education materials from 7 lung cancer patient advocacy groups (PAGs), 2 professional associations, 10 pharmaceutical companies, and 5 diagnostic companies that provide genomic testing to lung cancer patients. The materials included were those used by PAGs geared toward patients and those used by industry and testing companies for both patients and HCPs (oncologists). Privately used marketing materials were solicited from pharmaceutical companies. All materials were de-identified, and the rubric of analysis involved assessing whether materials answered six key questions: What is biomarker testing? Why is it important? Who (which patients) should get tested? When (at what point in the treatment journey)? How and where is testing done? Materials were audited by two independent reviewers and checked for inter-reviewer reliability. The audit was presented to a stakeholder group (organizations included in the audit) to elicit feedback, discuss gaps, and identify solutions.

**Result:** When analyzing patient-facing materials, PAGs were successful in answering Why, Who, and What, whereas pharmaceutical industry-developed campaigns were adept at answering the Why, How, and What. Deeper analysis revealed that patients were receiving mixed messages from PAGs and industry developed—campaigns. PAGs analyzed did not produce HCP-facing materials. However, industry-generated HCP-facing materials’ strength was their responses to Why patients should be tested and their gap was their responses to When patients should be tested. A qualitative trend noted was that most HCP-facing materials did not focus on the benefit to a patient that testing provides. All materials audited lacked a consistent “call-to-action” to patients. **Conclusion:** Our audit identified gaps in education materials, and highlights the importance of consistent and actionable messages for lung cancer patients and HCPs so that the importance of biomarker testing is appropriately conveyed. When presented to the stakeholder group, meeting participants agreed that all materials should at least answer the Why, Who, and When. Furthermore, they suggested that educational materials should include the importance to patients of tissue—based biopsies and tissue acquisition for biomarker testing.

**Background:** Each year, 1.8 million people are diagnosed with lung cancer globally. Compared with other cancers, lung cancer patients experience higher levels of distress and have greater unmet physical and emotional needs. A significant unmet need is social support. Face-to-face support groups can meet this need and may increase feelings of control and decrease distress. While lung cancer patients tend to prefer lung cancer-specific over general cancer groups, for many reasons these groups can be challenging to start and maintain. The number of lung cancer support groups in the world is not known. In the US, where over 230,000 people are diagnosed annually, there are typically fewer than 100 groups running. **Method:** We analyzed marketing and education materials from 7 lung cancer patient advocacy groups (PAGs), 2 professional associations, 10 pharmaceutical companies, and 5 diagnostic companies that provide genomic testing to lung cancer patients. The materials included were those used by PAGs geared toward patients and those used by industry and testing companies for both patients and HCPs (oncologists). Privately used marketing materials were solicited from pharmaceutical companies. Conclusion: No country has room for complacency on lung cancer symptom awareness, irrespective of country income. Approaches in countries with higher symptom recognition, like Mexico, should be examined for lessons. More must be done to reach and educate those who cannot name any symptoms of lung cancer to encourage symptom recognition and earlier presentation.

P1.03-01 ASSOCIATION OF APC MUTATIONS WITH CHINESE PATIENTS WITH NON-SMALL-CELL LUNG CANCER

S. Feng1, C. Xu2, W. Wang1, Q. Zhang1, W. Zhuang1, Y. Zhu1, Y. Huang1, Y. Chen2, G. Chen1, M. Fang1, T. Lv3, Y. Song3

1Xiamen Haicang Hospital, Xiamen/CN, 2Fujian Cancer Hospital, Fuzhou/CN, 3Zhejiang Cancer Hospital, Hangzhou/CN, 4Pathology, Fujian Cancer Hospital, Fuzhou/CN, 5Zhejiang Rongjun Hospital, Jiaxing/CN, 6Respiratory, Jinling Hospital, Nanjing/CN, 7Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: The role of adenomatous polyposis coli (APC) gene in mitosis might be critical for regulation of genomic stability and chromosome segregation. APC gene mutations have been associated to have a role in colon cancer and since gastric and colon tumors share some common genetic lesions, it is relevant to investigate the role of APC tumor suppressor gene in gastric cancer. While the genetic sites of APC mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring APC mutations.

Method: A total of 294 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of APC mutation and other genes were detected by next generation sequencing.

Result: APC gene mutation rate was 4.08% (12/294) in non-small cell lung cancer, including R232* (1 patient), Y159* (1 patient), R564* (1 patient), E846fs (21 patient), K534N (1 patient), K1437* (1 patient), K1437* (1 patient), T1556Nfs*3 (1 patient), N32S (1 patient), R259W (1 patient) and N372D (1 patient), and median overall survival (OS) for these patients was 9.0 months. Among them, all patients were APC gene with co-occurring mutation. Briefly, patients with (n=8) or without (n=4) co-occurring EGFR mutations had a median OS of 9.0 months and 6.0 months respectively (P=0.01); patients with (n=6) or without (n=6) co-occurring TP53 mutations had a median OS of 16.5 months and 11.0 months respectively (P=0.04); patients with (n=4) or without (n=8) co-occurring KRAS mutations had a median OS of 16.5 months and 9.0 months respectively (P=0.27); patients with (n=2) or without (n=10) co-occurring CDKN2A mutations had a median OS of 6.5 months and 11.5 months respectively (P=0.68).

Conclusion: The present study expanded the database on APC gene mutations in NSCLC and enriched the spectrum of known somatic mutations of the APC gene. Chemotherapy may be considered as a possible treatment for carriers of the mutation. EGFR mutated accompanied mutations might play a good prognosis in APC gene mutation NSCLC.

Background: Mothers against decapentaplegic homolog 4 (SMAD4) is an important protein in cancers. It plays pivotal roles in cellular pathways, and an important subset of genetic lesions that drive oncogenesis in this disease. While the genetic locus of SMAD4 mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring SMAD4 mutations.

Method: A total of 451 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of SMAD4 mutation and other genes were detected by next generation sequencing.

Result: SMAD4 gene mutation rate was 1.77% (8/451) in non-small cell lung cancer, including R232* (1 patient), Y159* (1 patient), R564* (1 patient), E846fs (21 patient), K534N (1 patient), K1437* (1 patient), K1437* (1 patient), T1556Nfs*3 (1 patient), N32S (1 patient), R259W (1 patient) and N372D (1 patient), and median overall survival (OS) for these patients was 27.5 months respectively (P=0.67).

Conclusion: The present study expanded the database on APC gene mutations in NSCLC and enriched the spectrum of known somatic mutations of the APC gene. Chemotherapy may be considered as a possible treatment for carriers of the mutation. EGFR mutated accompanied mutations might play a good prognosis in APC gene mutation NSCLC.

P1.03-03 MOLECULAR CHARACTERISTICS OF CHINESE PATIENTS WITH TSC2-MUTATED NON-SMALL-CELL LUNG CANCER: A RETROSPECTIVE STUDY

Z. Huang1, C. Xu2, W. Wang1, Q. Zhang1, W. Zhuang1, Y. Zhu1, Y. Chen1, G. Chen1, M. Fang1, T. Lv3, Y. Song3

1Fujian Cancer Hospital, Fuzhou/CN, 2Zhejiang Cancer Hospital, Hangzhou/CN, 3Pathology, Fujian Cancer Hospital, Fuzhou/CN, 5Zhejiang Rongjun Hospital, Jiaxing/CN, 6Respiratory, Jinling Hospital, Nanjing/CN, 7Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: Tuberous sclerosis complex 2 (TSC2) is a rare autosomal dominant disorder causing benign tumors in the brain and other vital organs. There is some clinical evidence for the use of TSC2 mutations as prognostic and predictive biomarker. The aim of this study is to investigate mutations and prognosis of NSCLC harboring TSC2 mutations.

Method: A total of 554 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of TSC2 mutation and other genes were detected by next generation sequencing.

Result: TSC2 gene mutation rate was 4.51% (25/554) in non-small cell lung cancer, including M286V (2 patients), R1743W (1 patient), V595G (1 patient), D1004Y (1 patient), E546K (1 patient), K1065E (1 patient), R1329P (1 patient), K1585R (1 patient), S1221L (1 patient), A678T (1 patient), F15V (1 patient), D1406N (1 patient), P237L (1 patient), V1144M (1 patient), V1034I (1 patient), D2241N (1 patient), Q371H (1 patient), P1770S (1 patient), R1268G, A1141T (1 patient), R537C (1 patient), M649I (1 patient) and A1294V (1 patient), and median overall survival (OS) for these patients was 20.0 months. Among them, 23 patients with co-occurring mutations had a median OS of 20.0 months, and median OS of the 2 patients without complex mutations was 7.0 months. No statistically significant difference was found between the two groups (P>0.15). Briefly, patients with (n=8) or without (n=17) co-occurring EGFR mutations had a median OS of 19.0 months and 20.0 months respectively (P=0.93); patients with (n=18) or without (n=7) co-occurring TP53 mutations had a median OS of 20.0 months and 27.5 months respectively (P=0.67).

Conclusion: There is no significant difference of molecular features in TSC2 gene mutations in NSCLC. Patients with complex mutations benefited more from therapy than those with single mutations. Next generation sequencing provides a simplified strategy and reasonably high detection rate for TSC2 mutation, which suggested application of the strategies into clinical molecular diagnostics.

Background: Anaplastic lymphoma kinase (ALK) gene rearrangements have been identified in lung cancer at 3-7% frequency, thus representing an important subset of genetic lesions that drive oncogenesis in this disease. While the genetic locus of ALK primary point mutations NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring ALK primary point mutations.

Method: A total of 339 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of ALK primary point mutation and other genes were detected by next generation sequencing.

Result: ALK gene primary point mutation rate was 8.55% (29/339) in non-small cell lung cancer, including V163L (3 patients), F9216fs*16 (2 patients), K1416N (2 patients), A585T (2 patients), P1442Q (1 patient), A348T (1 patient), K1525E (1 patient), S737L (1 patient), P115L (1 patient), Q515E (1 patient), S1219F (1 patient), S541L (1 patient), P1543S (1 patient), G129V (1 patient), Q167H (1 patient), L550F (1 patient), T1012M (1 patient), D302Y (1 patient).

P1.03-06 MOLECULAR LANDSCAPE OF FGFR1 POINT MUTATIONS
IN CHINESE NON-SMALL-CELL LUNG CANCER PATIENTS: A
RETROSPECTIVE STUDY
H. Wang1, C. Xu2, W. Wang3, Q. Zhang4, W. Zhuang5, Y. Zhu5, Y. Huang6, Y. Chen1, G. Chen1, M. Fang1, T. Lv4, Y. Song7
1Affiliated Hospital of Academy of Military Medical Sciences, Beijing/CN, 2Fujian Cancer Hospital, Fuzhou/CN, 3Zhejiang Cancer Hospital, Hangzhou/CN, 4Pathology, Fujian Cancer Hospital, Fuzhou/CN, 5Zhejiang Rongjun Hospital, Jiaxing/CN, 6Respiratory, Jinling Hospital, Nanjing/CN, 7Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: Mutations of the fibroblast growth factor receptor 1 (FGFR1) is believed to predict response to FGFR inhibitors, but the genetic spectrum of FGFR1 mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring FGFR1 mutations.

Method: A total of 469 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of FGFR1 mutation and other genes were detected by next generation sequencing. Result: FGFR1 gene mutation rate was 2.99% (14/469) in non-small cell lung cancer, including 599L (3 patients), S107L (2 patients), N546K (1 patient), R756H (1 patient), R661Q (1 patient), V94I (1 patient), R50Q (1 patient), D312V (1 patient), R661Q (1 patient), V94I (1 patient), R50Q (1 patient), D312V (1 patient), R661Q (1 patient) and M427V (1 patient), and median overall survival (OS) for these patients was 11.4 months. Among them, all patients were FGFR1 gene with co-occurring mutation, briefly, patients with (n=3) or without (n=11) co-occurring EGFR mutations had a median OS of 16.7 months and 11.0 months respectively (P=0.56); patients with (n=11) or without (n=3) co-occurring TP53 mutations had a median OS of 11.4 months and 20.7 months respectively (P=0.48); patients with (n=2) or without (n=12) co-occurring STK11 mutations had a median OS of 5.0 months and 11.4 months respectively (P=0.57); patients with (n=3) or without (n=11) co-occurring PTC12 mutations had a median OS of 5.7 months and 11.4 months respectively (P=0.11). Conclusion: It demonstrated that FGFR1 mutation was an independent prognostic factor. In these patients, and we found FGFR1 mutation also was an independent delayed adverse prognostic factor only in early stage NSCLC patients, suggesting that FGFR1 mutation may be a viable prognostic factor in these patients.

P1.03-07 A COMPARISON OF CONSISTENCY OF DETECTING HER2 GENE MUTATIONS IN PERIPHERAL BLOOD AND TUMOR TISSUE OF NON-SMALL-CELL LUNG CANCER PATIENTS
C. Xu1, W. Wang1, Q. Zhang1, Y. Zhu1, W. Zhuang1, Y. Huang1, Y. Chen1, G. Chen1, T. Lv4, Y. Song7
1Fujian Cancer Hospital, Fuzhou/CN, 2Zhejiang Cancer Hospital, Hangzhou/CN, 3Pathology, Fujian Cancer Hospital, Fuzhou/CN, 4Zhejiang Rongjun Hospital, Jiaxing/CN, 5Respiratory, Jinling Hospital, Nanjing/CN, 6Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: HER2 is expressed in solid carcinomas including cancers of the breast, stomach, lung and pancreas. Preclinical and clinical studies have confirmed that HER2 is a driver gene in non-small-cell lung cancer (NSCLC). Three principal mechanisms of HER2 alteration include: protein overexpression, gene amplification and gene mutations. In NSCLC, HER2 mutations were identified to represent a distinct subset of driver genes that usually excluded with other common driver genes like EGFR, KRAS and ALK, based on published studies. The aim is to detect the consistency of the HER2 gene mutation in peripheral blood and tumor tissue of patients with NSCLC and discuss the clinical application value of HER2 gene mutation in peripheral blood. Method: Real-time fluorescent quantitative PCR was used to determine the HER2 gene mutation of peripheral blood and tumor tissue specimens collected from 185 cases of NSCLC. A comparison of HER2 gene mutation consistency of peripheral blood and tumor tissue specimens was conducted. The correlation
between HER2 gene mutations and clinical characteristics of the patients was analyzed. **Result:** The HER2 gene mutation rate was 3.78% in peripheral blood. In patients with NSCLC, the mutation consistency was 75.00% in peripheral blood. **Conclusion:** The incidence of HER2 gene mutation in peripheral blood tissue correlated with gender and smoking history (P=0.05), but did not correlate with age, gender, and pathological type (P>0.05). The incidence of HER2 gene mutation in tumor tissue correlated with gender and smoking history (P=0.05, but did not correlate with age and pathological type.

**Conclusion:** The consistency of the HER2 gene mutation in peripheral blood and tissue is high. HER2 gene mutations of peripheral blood could be used for clinical diagnosis and treatment in cases when tissue specimen is hard to get.

**Keywords:** HER2 mutations, Consistency, Non-small-cell lung cancer

**P1.03-08 DETECTION OF PTCH1 GENE VARIANTS IN NON-SMALL CELL LUNG CANCER PATIENTS FROM CHINA**

T. Xu1, C. Xu2, W. Wang3, D. Zhang4, W. Zhang5, Y. Zhu6, Z. Huang7, Y. Chen8, G. Chen9, M. Fang10, T. Li10, Y. Song10

1The Second Affiliated Hospital of Fujian Medical University, Quanzhou/CN; 2Fujian Cancer Hospital, Fuzhou/CN; 3Zhejiang Cancer Hospital, Hangzhou/CN; 4Pathology, Fujian Cancer Hospital, Fuzhou/CN; 5Zhejiang Rongjun Hospital, Jiaxing/CN; 6Respiratory, Jinling Hospital, Nanjing/CN; 7Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

**Background:** Recently, the Patched homolog 1 gene (PTCH1) gene mutation has been found in non-small lung cancer. While the genetic spectrum of PTCH1 mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring PTCH1 mutations. **Method:** A total of 269 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of PTCH1 mutation and other genes were detected by next generation sequencing. **Result:** PTCH1 gene mutation rate was 6.32% (17/269) in non-small cell lung cancer, including S827G (2 patients), G445S (1 patient), A1130T (1 patient), L1036F (1 patient), E173D (1 patient), P1210L (1 patient), A1130T (1 patient), F614Y (1 patient), F681S1 (1 patient), V1381G1 (1 patient), G37R (1 patient), A741V (1 patient) and P1282L plus R893H (1 patient), and median overall survival (OS) for these patients was 18.0 months. Among them, all patients were PTCH1 gene with co-occurring mutation. Briefly, patients with (n=5) or without (n=12) co-occurring EGFR mutations had a median OS of 22.0 months and 18.0 months respectively (P=0.25); patients with (n=11) or without (n=6) co-occurring TP53 mutations had a median OS of 18.0 months and 14.0 months respectively (P=0.96); patients with (n=2) or without (n=15) co-occurring BRAF mutations had a median OS of 4.0 months and 18.0 months respectively (P=0.14); patients with (n=2) or without (n=8) co-occurring PIK3CA mutations had a median OS of 17.0 months and 18.0 months respectively (P=0.96). **Conclusion:** PTCH1 gene mutation coexists with other gene mutation in NSCLC. EGFR, TP53, BRAF and PIK3CA gene accompanied may have less correlation with PTCH1 mutation in NSCLC patients. Analysis of PTCH1 mutations shows promise as a way to refine individual patients with NSCLC, and provides more insight into effective treatment strategies for patients with PTCH1 mutations.

**Keywords:** Non-small-cell lung cancer, PTCH1 mutation, Prognosis

**P1.03-09 ROS1 rearrangement in Pulmonary Sarcomatoid Carcinoma: A Retrospective Study of the Real World**

C. Xu1, W. Wang2, Y. Zhu3, M. Fang3, W. Zhang4, Q. Zhang5, Y. Chen6, Z. Gong7, G. Chen7, T. Li7, Y. Song8

1Fujian Cancer Hospital, Fuzhou/CN; 2Zhejiang Cancer Hospital, Hangzhou/CN; 3Zhongshan Medical University Zhongshan Hospital, Guangzhou/CN; 4Medical Oncology, Fushan Cancer Hospital, Fuzhou/CN; 5Pathology, Fujian Cancer Hospital, Fuzhou/CN; 6Shanghai Chest Hospital, Shanghai/CN; 7Pathology, Fujian Cancer Hospital, Fuzhou/CN; 8Respiratory, Jinling Hospital, Nanjing/CN; 9Jinling Hospital, Nanjing/CN

**Background:** Pulmonary sarcomatoid carcinoma (PSC) is a recognized category of highly aggressive and poorly differentiated non-small-cell lung carcinoma (NSCLC), with five different subtypes: pleomorphic, spindle, giant cell, carcinosarcoma, and pulmonary blastoma. Although uncommon (0.1% to 0.4% of all pulmonary malignancies), the clinical importance is underscored by poorer prognosis and higher rate of resistance to conventional chemotherapy than other NSCLCs. And the incidence of c-ros oncogene 1, receptor tyrosine kinase (ROS1) rearrangement in PSC is controversial. The aim of this study was to reveal the reliable freaq and the clinical-pathologic characteristics of PSC with ROS1 rearrangement in Chinese population. **Method:** A total of 35 patients with PSC were recruited between September 2007 and December 2017. The status of ROS1 rearrangement was detected by reverse transcription polymerase chain reaction (RT-PCR). **Result:** Of this study, three patients were identified with ROS1 rearrangement in Chinese PSC population (2.86%, 1/35). The patient was a pulmonary pleomorphic carcinoma (PPC). **Conclusion:** The incidence rates of ROS1 rearrangement in PSC in the Chinese population are more than those of other subtypes of NSCLC. Crizotinib may serve as an effective treatment for ROS1 rearranged PSC.

**Keywords:** Pulmonary sarcomatoid carcinoma, ROS1 fusion, RT-PCR

**P1.03-10 THE MOLECULAR SPECTRUM OF NFI VARIANTS IN CHINESE NON-SMALL-CELL LUNG CANCER PATIENTS**

Q. Zhang1, C. Xu2, W. Wang3, W. Zhuang4, Y. Zhu5, Z. Huang6, Y. Chen7, G. Chen8, M. Fang9, T. Li9, Y. Song9

1Pathology, Fujian Cancer Hospital, Fuzhou/CN; 2Fujian Cancer Hospital, Fuzhou/CN; 3Zhejiang Rongjun Hospital, Jiaxing/CN; 4Respiratory, Jinling Hospital, Nanjing/CN; 5Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

**Background:** Activation of the RAS/MAK pathway is critical in non-small cell lung cancer. Non-small-cell lung cancer can be grouped into four molecular subtypes based on their main genetic driver: EGFR-mutation, ALK-fusion, ROS1-rearrangement, and triple wild-type tumors. The NFI protein, neurofibromin 1, negatively regulates RAS proteins through GTPase activity. Somatic mutations in NFI cause neurofibromatosis type 1, a common genetic tumor syndrome caused by dysregulation of the RAS/MAK pathway, ie, RAS pathway. While the genetic sites of NFI mutation NSCLC patients are unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring NFI mutations. **Method:** A total of 337 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of NFI mutation and other genes were detected by next generation sequencing. **Result:** NFI gene mutation rate was 6.23% (21/337) in non-small cell lung cancer, including M645S (3 patients), A1998V (1 patient), Q83E (1 patient), P654T (1 patient), Q912* (1 patient), C324* (1 patient), C1032S (1 patient), I1628M (1 patient), L43V (1 patient), A6101fs*17 (1 patient), Q239E (1 patient), D1632N (1 patient), T586Vfs*18 (1 patient), R2328C (1 patient), E41* (1 patient), V437Nfs*35 (1 patient), P2046L plus G1219* (1 patient), D2055Mfs*6 plus T21335fs*41 (1 patient) and C1288F plus K2252* (1 patient), and median overall survival (OS) for these patients was 10.0 months. Among them, all patients were NFI gene with co-occurring mutation. Briefly, patients with (n=3) or without (n=18) co-occurring EGFR mutations had a median OS of 15.5 months and 10.0 months respectively (P=0.49); patients with (n=19) or without (n=17) co-occurring TP53 mutations had a median OS of 10.0 months and 5.5 months respectively (P=0.21); patients with (n=3) or without (n=18) co-occurring R81 mutations had a median OS of 19.5 months and 9.0 months respectively (P=0.19). **Conclusion:** Patients with complex mutations benefited more from therapy than those with single mutations. NFI genetic alteration occurs in a subset of NSCLC, and improved understanding of the implications of NFI aberrations is critical for the identification of therapeutic target candidates.

**P1.03-11 ANALYSIS OF T-CELL REPERTOIRES IN BENIGN AND MALIGNANT SOLITARY PULMONARY NODULES TO EVALUATE TUMOR IMMUNE MICROENVIRONMENT**

M. Li1, S. Deng1, S. Liu1, B. Zhao1, J. An1, P. Deng1, L. Cao1, H. Yang1, Q. Gu1, H. Sun1, Y. Wang1, Y. Guan1, X. Xia1, X. Yi1, C. Hu1

1Department of Respiratory Medicine, Xiangya Hospital, Central South University, Changsha/CN; 2Geneplus-Beijing Institute, Beijing/CN

**Background:** The identification of malignancy of solitary pulmonary nodules (SPN) is important for lung cancer early detection. Carcinogenesis may result from accumulation of molecular evolution and escaping from
host immunodetition. However, the immune landscape such as T cell repertoire of benign and malignant SPNs have not been systematically studied. Method: We have collected resected solitary pulmonary nodules (SPNs) and peripheral blood including benign SPNs (N=10), LUSC (N=11) and LUAD (N=38) from 59 patients. T cell repertoire of infiltrating T cells in SPNs were sequenced their T cell receptor b genes (TCRb), as well as their abundance in peripheral blood. Enrichment clonotypes were defined as 500 fold enrichment as compared to blood. Result: Comparison to the peripheral blood, T cell repertoire diversity of infiltrating T cells in SPNs showed significant differences among benign and malignant T cell clonality was higher in the benign SPNs than Malignant, however no significant differences among LUSC and LUAD. Additionally, we observed that Tumors from smokers had higher T cell clonality than no-smokers as reported earlier. Interestingly, many T cell clones, including major clones, were shared between lung tissues and matched peripheral blood; furthermore, the higher shared clonotypes of T cell clones between lung tissues and blood in benign SPNs than Malignant. Enrichment analysis demonstrated more enriched clonotypes observed in LUSC and LUAD.

Conclusion: Our preliminary data demonstrate the distinct immune microenvironment may be associated with the benign and malignant features. And implies a significant proportion of infiltrating T cells in SPNs may be a function of constant lung infiltrating rather than an anti-tumor response.

P1.03-12 PD-L1 EXPRESSION IS PREDOMINANT IN CD68+ TUMOR-ASSOCIATED MACROPHAGES IN STAGE I-II NON-SMALL CELL LUNG CANCERS

1Thoracic and Cardiovascular Surgery, MD Anderson Cancer Center, Houston/TX/US; 2University of Texas MD Anderson Cancer Center, Houston/TX/US; 3Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 4Pathology, MD Anderson, Houston/TX/US; 5Medicine, UT Southwestern Medical School, Dallas/TX/US; 6Thoracic and Head Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 7Thoracic/Head & Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 8Thoracic/Head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 9Thoracic and Head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 10Thoracic/head and Neck Medical Oncology, MD Anderson, Houston, TX/US; 11Thoracic/head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/TX/US; 12Thoracic/head and Neck Medical Oncology, MD Anderson, Houston, TX/US

Background: PD-L1 tumor expression is a leading biomarker in metastatic non-small lung cancer (NSCLC). Its role and expression in surgically resectable lung cancers is not yet defined. The association between PD-L1 expression on tumor and CD68+ tumor-associated macrophages (TAMs) and the inflammatory cells within the tumor microenvironment continues to be studied. We analyzed 97 surgically resected lung cancers utilizing immunofluorescence profiling and flow cytometry (n=47) with the aim of defining the PD-L1 expression and its association with tumor inflammatory cells. Method: Multiplex immunofluorescence profiling of lung cancers was performed with the focus on malignant cells (MC), MC PD-L1%, CD3+, CD8+, PD-1+ cells, CD68+, CD68+ PD-L1%, and CD20+ cells. Data on cell populations were estimated as the number of cells per mm2. PD-L1 expression as percentage. Flow cytometry was performed on freshly disaggregated tumor samples. The associations of cell populations with clinical and pathologic characteristics were assessed using Spearman’s rank correlation coefficient and Wilcoxon rank-sum test. Result: 97 patients, 55 (57%) female and 42 (43%) male, with median age 65 years (range 36-86). MC PD-L1% was higher in the Malignant group (median 47.5% vs 7.0%, p<0.0001). PD-L1 expression was significantly higher on CD68+ MC within tumor (median 33% vs 0.02%, p<0.0001); this was true for all stages. CD68+ PD-L1% in SCC was higher compared to adenocarcinoma (median 29% vs 11%, p=0.06). Induction chemotherapy increased CD68+ PD-L1% (median 31% no chemo vs 58%, p=0.05) without affecting the proportion of effector CD8+ TIL expressing its receptor, PD-1 (p=0.757). Tumors with > median CD68+ PD-L1% expression were associated with higher CD3+ (p=0.008), CD8+ (p=0.06), and CD68+ (p=0.004) cell numbers within the tumor. Conclusion: In early NSCLC PD-L1% expression appears to be predominant in CD68+ TAMs rather than in malignant cells. PD-L1 expression on CD68+ is associated with increased CD3+ and CD8+ T cells. Further studies are required to understand the role of CD68+PD-L1 cells within tumor microenvironment, the influence of neoadjuvant chemotherapy or immunotherapy regimens on these cells, and their effect on outcomes.

P1.03-13 EIF2, A SUBUNIT OF TRANSLATION-INITIATION FACTOR EIF2, AS A POTENTIAL THERAPEUTIC TARGET FOR NON-SMALL CELL LUNG CANCER

D. Goto1, I. Tanaka1, M. Sato1, T. Kato1, A. Miyazawa1, T. Hase1, M. Morise1, Y. Sekido2, L. Girard3, J. Minna4, L. Byers1, J. Heymach1, K. Coombes1, M. Kondo1, Y. Hasegawa1

1Nagoya University Graduate School of Medicine, Nagoya/JP; 2Molecular Oncology, Aichi Cancer Center Research Institute, Nagoya/JP; 3Hammon Center for Therapeutic Oncology Research and the Simmons Comprehensive Cancer Center, Dallas/US; 4Thoracic/Head & Neck Medical Oncology, UT MD Anderson Cancer Center, Houston/TX/US; 5Thoracic and Head Neck Medical Oncology, TX/US, 6Department of Biomedical Informatics, Ohio/US; 7Respiratory Medicine, Fujita Health University, Toyoake/JP

Background: To identify potential therapeutic targets for non-small cell lung cancer (NSCLC), we recently performed a semi-genome wide shRNA screen in a NSCLC cell line H460. Through this approach, we identified multiple potential targets for NSCLC (Kakumoto et al. Cancer Sci, 2017). In the present study, to search for genes with more generalized potential as therapeutic targets, we did shRNA screening using the alternative NSCLC cell line H358 and combined its results with those of our previous screen. Method: 19 NSCLC cell lines, two cdh4/HER2-immortalized normal human bronchial epithelial (HBEC) cell lines and primary NHBE culture were used. A semi-genome wide shRNA screen was performed with the DECIPHER library in H358, and its results were integrated with those of our previous screen in H460. Gene silencing was done with RNA interference followed by growth and cell cycle analyses. Result: 24 genes overlapped between results of two shRNA screens in H460 and H358 and we identified these as more generalized targets. Gene-annotation enrichment analysis showed that the RNA transport pathway including three genes is one of the overrepresented pathways in the 24 genes. Among the three genes, we decided to focus on eif2j2, a subunit of translation-initiation factor EIF2 because other two genes included in the RNA transport pathway, XPO1 and RAN are well characterized therapeutic targets for human cancers including lung cancer. eif2j2 protein was more abundantly expressed in all the 19 lung cancer cell lines analyzed than in NHBE used as a control. To determine the clinical relevance of eif2j2 in lung cancer, we examined eif2j2 mRNA expression in lung adenocarcinoma tissues using TCGA dataset. These analyses showed significantly higher expression of eif2j2 mRNA in lung adenocarcinoma tissues than in normal adjacent tissues. Importantly, we found that expression of eif2j2 mRNA correlated with worse prognosis in patients with lung adenocarcinoma in multiple independent datasets, suggesting its potential as a prognostic marker. Next, we examined the effects of eif2j2 knockdown on the growth of the H460 and H1975. Colorimetric growth and colony formation assays showed that eif2j2 knockdown in H460 and H1975 suppresses cell growth and colony formation. Conclusion: eif2j2 is highly expressed in NSCLC cells, and its expression correlates with poor prognosis in patients with lung adenocarcinoma. Knockdown of eif2j2 caused G1 arrest in lung cancer cell lines. These results suggest that eif2j2 is a potential therapeutic target for NSCLC and that it is a prognostic marker for lung adenocarcinoma.

P1.03-14 INTERACTION BETWEEN CELECOXIB AND CISPLATIN IS DEPENDENT ON THE P53 STATUS IN HUMAN NSCLC CELL LINES

M. Jiang, W. Li, L. Ma, L. Zhang, J. Tan, S. Zheng, Y. Liu

Beijing Chest Hospital, Capital Medical University / Beijing Tuberculosis and Thoracic Tumor Research Institute, Beijing/CN

Background: As a cyclooxygenase-2 inhibitor, the potential of celecoxib, to enhance the efficacy of chemotherapy is being investigated in clinical
trials related to cancer treatment. **Method:** In this study, we investigated whether celecoxib would increase the anti-proliferative effects of cisplatin in human lung cancer cell lines. **Result:** The results demonstrated the synergistic effects of celecoxib with cisplatin in wild-type p53 cells and their antagonistic effects in mutated or deleted p53 cells. Combination indices of 0.82–0.93 reflected a synergistic effect between celecoxib and cisplatin in lung cancer cells with wild-type p53. Combination indices of 1.63–3.00 reflected antagonism between celecoxib and cisplatin in lung cancer cells with mutated or deleted p53. Apoptosis was shown to increase with the addition of celecoxib and cisplatin. Apoptosis was accomplished by the downregulation of slug expression. Celecoxib increased the nuclear localization of active p53 in lung cancer cells of wild-type p53. **Conclusion:** Taken together, our data demonstrated clear synergistic effects in wild-type p53 cells and antagonistic effects in mutated or deleted p53 cells when celecoxib and cisplatin are combined.

**Keywords:** lung cancer, p53, celecoxib

**P1.03.15 TMS REDUCED GEFITINIB RESISTANCE IN NSCLCS VIA SUPPRESSING MAPK/AKT/BCL-2 PATHWAY BY UPREGULATION OF MIR-345 AND MIR-498**

P. Liu, M. Lu, B. Liu
Department of Oncology, The Second Xiangya Hospital, Central South University, Changsha/CN

**Background:** Despite initial dramatic efficacy of EGFR tyrosine kinase inhibitors (EGFR-TKIs) in EGFR-mutant lung cancer patients, subsequent emergence of acquired resistance is almost inevitable. Resveratrol and its derivatives have been found to exert some effects on EGFR-TKI resistance in non-small cell lung cancer (NSCLC), but the underlying mechanisms remain unclear. **Method:** We screened several NSCLC cell lines with gefitinib-resistance by MTT assay, and analyzed the miR-345/miR-498 expression levels. NSCLC cells were pre-treated with a resveratrol derivative, trans-3, 5, 4-trimethoxystilbene (TMS), and subsequently challenged with gefitinib treatment. The changes of apoptosis and miR-345/miR-498 expression were analyzed by flow cytometry and q-PCR, respectively. The functions of miR-345/miR-498 were verified by CCK-8 assay, cell cycle analysis, dual-luciferase reporter gene assay and immunoblotting analysis.

**Result:** Our results showed that the expression of miR-345 and miR-498 significantly decreased in gefitinib-resistant NSCLC cells. TMS pre-treatment significantly upregulated the expression of miR-345 and miR-498, increasing the sensitivity of NSCLC cells to gefitinib and inducing apoptosis. MiR-345 and miR-498 were verified to inhibit proliferation by cell cycle arrest, and regulate the MAPK/c-Fos and AKT/Bcl-2 signaling pathways by directly targeting MAPK1 and PIK3R1, respectively. The combination of TMS and gefitinib promoted apoptosis also by miR-345 and miR-498 targeting the MAPK/c-Fos and AKT/Bcl-2 signaling pathways. **Conclusion:** Our study demonstrated that TMS reduced gefitinib resistance in NSCLCs via suppressing MAPK/Akt/Bcl-2 pathway by upregulation of miR-345/498. These findings would lay the theoretical basis for the future study of TMS for the treatment of EGFR-TKI resistance in NSCLCs.

**Keywords:** TMS, NSCLC, gefitinib resistance
**P1.02-16 ANLOTINIB INHIBITS ANGIogenesis OF REFRACTORY ADVANCED NON-SMALL CELL LUNG CANCER VIA BLOCKING CCL2 EXPRESSION**

J. Lu², B. Han², X. Zhan², L. Li², J. Sun², R. Zhong³, Y. Yang³, M.S. Alam², Y. Lou¹, X. Zhu¹, P. Zhang¹, J. Wu¹, X. Li¹, X. Zhao¹, K. Li¹, L. Liu¹, B. Han¹

**Background:** Anlotinib has been demonstrated to be effective in prolonging progression free survival (PFS). Anlotinib: 3.37 months vs Placebo: 1.40 months and overall survival (OS): Anlotinib: 9.63 months vs Placebo: 6.30 months) of refractory advanced Non-Small Cell Lung Cancer (NSCLC) patients in clinical trials. Clinical evidences suggested that Anlotinib-induced anti-tumor efficacy could be attributed to anti-angiogenesis. However, the underlying molecular mechanisms and predictive biomarker of Anlotinib is still unclear. **Method:** 437 patients with advanced NSCLC enrolled in clinical study, and 294 patients received Anlotinib therapy. Retrospective analysis of the Anlotinib-administered 294 NSCLC patients was performed to screen out underlying biomarker for Anlotinib-responsive patients. Transcriptome and functional assays were performed to understand the anti-angiogenic molecular mechanism of Anlotinib in vitro. CCL2 levels and their roles in angiogenesis were evaluated by ELISA detection, RT-qPCR quantification, and immunofluorescence assay, in vivo. Changes in serum CCL2 levels were analyzed to reveal the correlation of Anlotinib response between responders and non-responders. **Result:** Anlotinib therapy is more beneficial to prolong OS for NSCLC patients harboring positive driver gene mutations, especially for patients harboring EGFR790M mutation. Moreover, our data indicated that Anlotinib-induced cell viability downregulation, cell apoptosis induction, cell invasion inhibition, cell cycle arrest, and cell migration inhibition are associated with CCL2 levels in vitro. We demonstrated that Anlotinib inhibits angiogenesis of NCI-H1975 derived xenografts model via inhibiting CCL2 in vivo. Lastly, we found that Anlotinib-induced decreased CCL2 level decrease are associated with the benefits of PFS and OS, in refractory advanced NSCLC patients (n = 28). **Conclusion:** Our study reports a novel anti-angiogenic mechanism of Anlotinib via inhibiting CCL2 in NCI-H1975-derived xenografts model, and suggests the changes in serum CCL2 levels may be used to monitor and predict clinical outcome in Anlotinib-administered refractory advanced NSCLC patients. The biomarker of serum CCL2 alteration may guide precision therapy of Anlotinib for NSCLC patients at third-line or over third-line.

**P1.03-17 FUNCTIONAL MECHANISM OF GLDcE GENE ALTERNATIVE SPlicing IN NON-SMALL CELL LUNG CANCER**

Y. Yuan, K. Ma

The First Hospital of Jinlin University, Changchun/CN

**Background:** Lung cancer is the leading cause of death in the world and non-small cell lung cancer (NSCLC) accounts for approximately 85%. While, the mechanism is not fully understood. Therefore, exploring new molecules is of great significance to clarify the mechanism. Glycine decarboxylase (GLDC) is an oncogene associated with lactic acid metabolism, highly expressed in cancer stem cell-riched NSCLC. Both growth and tumorigenicity are dependent on the expression of high levels of GLDC, so which can be used as a stem cell surface marker to identify cancer stem cells. Alternative splicing (AS) is one of the important mechanisms of human gene regulation, which is closely related to the occurrence of tumor. However, the mechanism of AS regulation for GLDC in NSCLC has not been reported. Therefore, understanding the biological role of GLDC and its regulatory mechanism can lay a theoretical foundation for the early diagnosis and treatment of tumors. This experiment aims to clone GLDC cDNA, analyze biological functions, and clarify the role of alternative splicing for NSCLC development mechanism. **Method:** 1. Construction of cloning vectors: Primers were designed based on the full length of GLDC (GLDCfl) and GLDC variant 1 (GLDCV1) cDNA, and mRNA expression in A549 and MRC5 cells was determined by RT-PCR combined with DNA sequencing. 2. Functional experiments: MRC5 cells were transfected with overexpression plasmids, MTT assay, plate clone, western blot, lactic acid formation assay, and tumor-bearing test in vivo were used to detect MRC5 cells viability and proliferation. **Result:** 1. Both GLDCfl and GLDCV1 of A549 and MRC5 existed at the RNA level, the expression of which is only in A549. Transfection of the target gene in MRC5 cells showed increased expression of both GLDCfl and GLDCV1. 2. GLDCfl and GLDCV1 were over-expressed in MRC5 cells, and the cell viability was increased by MTT assay. Plate clone experiments proved the proliferation of MRC5 cells, and the expression of P-ERK and P-P38 proteins on the ERK/MAPK signaling pathway were increased. The supernatants of the cells for 24 hours were collected and assayed for lactic acid, then both GLDCV1 and GLDCf1 promoted lactic acid production. Meanwhile, in vivo nude mice tumor test, each 100 µl dose was inoculated subcutaneously at the back shoulder of 4-6 week old nude mouse, and the GLDCV1 group showed the tumorigenicity. **Conclusion:** This study first analyzed the expression pattern of GLDC gene AS in tumor tissues and revealed the biological effects in tumor cells. 2. Both GLDCfl and GLDCV1 can enhance cancer cell viability, promote luciferase activity, enhance cell clonal formation, and also find that GLDCV1 can enhance the tumorigenic ability. 3. Both GLDCV1 and GLDCfl have effect on the expression of ERK/MAPK pathway protein. **Keywords:** non small cell lung cancer, GLDC, Alternative splicing

**P1.03-18 MECHANOBIOLOGY OF LUNG CANCER CELLS: REGULATION OF PD-L1 EXPRESSION BY MATRIX STIFFNESS**

A. Miyazawa¹, S. Ito¹, S. Asano¹, T. Tanaka¹, M. Sato¹, M. Kondo², Y. Hasagawa²

¹Respiratory Medicine, Nagoya University Graduate School of Medicine, Nagoya/JP, ²Respiratory Medicine and Allergology, Aichi Medical University, Nagakute/JP, ³Respiratory Medicine, Fujita Health University, Toyoake/JP

**Background:** Expression of programmed death-ligand 1 (PD-L1) in tumor cells plays an important role in mechanisms underlying evasion of an immune check point system. PD-L1 expression is regulated by multiple mechanisms such as the tumor microenvironment. Lung cancer tissue with increased deposition of extracellular matrix is much stiffer than normal lung tissue. There is emerging evidence that the matrix stiffness of cancer tissue affects the phenotypes and properties of cancer cells. Nevertheless, the effects of substrate rigidity on expression of PD-L1 in lung cancer cells remain elusive. This study was designed to determine whether substrate stiffness regulates the expression of PD-L1 in lung cancer cells. **Method:** We evaluated PD-L1 expression levels in HCCB27 human lung cancer cell line. Commercially available polyacrylamide hydrogels of different stiffnesses bound to 6-well polystyrene plates or polystyrene dishes coated with type I collagen were utilized. We used 2 and 25 kPa gels as substrates of normal (soft) human lung and cancer-associated (stiff) tissue. Western blotting and immunofluorescence staining were performed for evaluating PD-L1 expression levels. A colorimetric viability assay was performed for evaluating of PD-L1 expression and cell proliferation by using transfection with short interfering RNA (siRNA) for PD-L1. **Result:** Expression of PD-L1 protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment with short interfering RNA (siRNA) for PD-L1. **Conclusion:** Stiff substrates enhanced PD-L1 expression via actin cytoskeleton-dependent mechanisms in HCC827 human lung cancer cell line. Commercially available polyacrylamide hydrogels of different stiffnesses bound to 6-well polystyrene plates or polystyrene dishes coated with type I collagen were utilized. We used 2 and 25 kPa gels as substrates of normal (soft) human lung and cancer-associated (stiff) tissue. Western blotting and immunofluorescence staining were performed for evaluating PD-L1 expression levels. A colorimetric viability assay was performed for evaluating of PD-L1 expression and cell proliferation by using transfection with short interfering RNA (siRNA) for PD-L1. **Result:** Expression of PD-L1 protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment protein was higher on the stiffer substrates (25 kPa gel and plastic dish) than on the soft 2 kPa gel. PD-L1 expression was reduced by detachment
re-modelling occurs in situations like fibrosis and cancer. It promotes multiple pro-tumorigenic processes, including cell migration, invasion and the activation of latent TGFβ. Strong expression in multiple cancers is associated with poorer prognosis including a reported 54% of non-small cell lung cancers (NSCLC). Antibody blockade of αvβ6 with 264RAD antibody reduces tumour growth in breast and pancreatic cancer mouse models. The effect of αvβ6 blockade on NSCLC is unknown. Mutations in KRAS occur in approximately 30% of NSCLC. In the well described conditional transgenic KrasLG12D; P53f/f (KP) mouse model of lung cancer, adenocarcinomas develop due to adenoaviral re-combinase activation of a K-RasG12D allele and loss of P53. Tumour sections from this model show α6 expression (evidenced by αv6-specific SPECT imaging and pathology). We investigated the effect of αv6 blockade in the KP mouse. Method: KP mice tumours were initiated by intra-tracheal instillation of adenoaviral re-combinase. At 10 weeks, when significant disease was present (confirmed by MRI) treatment commenced. Four treatment groups of n=10 were allocated to either: 264RAD(10mg/kg, ip twice weekly); 264RAD (10mg/kg, ip twice weekly) + cisplatin(8mg/kg, weekly for 3 weeks); cisplatin (8mg/kg, weekly for 3 weeks); or IgG (10mg/kg, ip twice weekly). Progression (MRI) and survival was monitored.

**Conclusion:**
We have established a method to study the effects of αv6 blockade on lung tumour growth in vivo and are developing an imaging strategy using both MRI and SPECT to analyse mouse lung tumour growth in a manner that best mirrors human studies.

**P1.03-20 THE NOVEL SFN INHIBITORS APREPITANT AND TICAGRELOR EXERT ANTI-TUMOR EFFECTS THROUGH BLOCKING OF ONCOPROTEIN UBQUITINATION**

A. Shiba1, J. Hong1, T. Hirokawa2, Y. Kim1, M. Noguchi1

1Department of Pathology, Faculty of Medicine, University of Tsukuba, Ibaraki/Jp. 2Department of Chemical Biology, Faculty of Medicine, University of Tsukuba, Ibaraki/Jp

**Background:** We have previously shown that the gene encoding stratrin (SFN, 14-3-3 sigma) is differentially expressed during the course of progression from AIS to early invasive adenocarcinoma (eIA), inducing early tumor progression by binding to SKP1 and blocking the activity of SCFαv67 ubiquitin ligase. As suppression of SFN significantly reduces cell growth and tumor formation or progression, we expected that inhibition of SFN could be a promising therapeutic strategy for lung adenocarcinoma. **Method:** To identify candidate compounds that bind specifically to SFN and block SFN-SKP1 binding, we carried out in silico library screening based on putative druggable sites of SFN around the SKP1 interaction interface using molecular docking against 7,133 bioactive compounds from the DrugBank database. Experimental validation was performed for 46 compounds that showed the highest docking scores. Cell growth and dissociation of SFN-SKP1 were examined by WST-8 assay and IP/western blotting after treatment with each compound. Finally, 4 candidate compounds were subjected to in vivo evaluation. Tumor-bearing mice that had received subcutaneous injection of A549 cells were subjected to two experimental schedules: 1) Daily oral administration of each compound starting at 1 day after injection until 21 days. 2) same as 1) but starting when the tumors had reached 100 mm³ in size. **Result:** Through in silico screening and experimental validation, we identified 4 compounds as SFN inhibitors: Aprepitant, Ticagrelor, Ezetimibe, and Chlorhexidine. All of them significantly and dose dependently reduced cell growth and SFN-SKP1 binding. Notably, Aprepitant completely blocked in vivo tumor formation, and Ticagrelor markedly reduced tumor progression when administered from the day after tumor cell injection. Furthermore, Aprepitant and Ticagrelor reduced tumor progression in a dose-dependent manner even when administration was started after tumors had grown to 100 mm³. **Conclusion:** Here we have shown that inhibition of SFN-SKP1 binding results in an anti-tumor effect. Since SFN binding to SKP1 results in SCFαv67 dysfunction and allows oncoproteins such as cyclin E1 and c-Jun to evade ubiquitination and subsequent degradation, it is considered that inhibition of SFN will lead to ubiquitination of these oncoproteins. Although Aprepitant is a NK-1R (neurokinin-1 receptor) antagonist which is already approved as an antiemetic drug, and Ticagrelor is a reversible P2Y12 inhibitor exerting an anti-platelet effect, our results suggest that these agents could be applicable for treatment of lung adenocarcinoma. As overexpression of SFN starts from eIA, we believe that SFN inhibitors will provide a novel chemotherapeutic strategy for early-stage lung adenocarcinoma.

**Keywords:** Early-stage, Adenocarcinoma, stratrin
Conclusion: HAE could over-activate MEK/ERK signaling pathway and exert apoptosis-inducing effects in lung adenocarcinoma.

Keywords: Huaier aqueous extract, MEK/ERK signaling pathway, lung adenocarcinoma

Conclusion: MiR-125b might play a tumor suppressor role via inhibiting IGF-1 signaling in inflammation-related lung cancer.

Keywords: lung cancer, miR-125b, IGF-1

P1.03-23 THE MOLECULAR LANDSCAPE AND OUTCOME OF CHINESE NON-SMALL CELL LUNG CANCER HARBORING NTRK1 POINT MUTATIONS: A RETROSPECTIVE STUDY

X. Chen1, C. Xu2, W. Wang3, Q. Zhang4, W. Zhuang5, Y. Zhu6, Y. Chen7, M. Fang8, G. Chen9, T. Lv6, Y. Song6

1Fujian Cancer Hospital, Fuzhou/CN, 2Fujian Cancer Hospital, Fuzhou/CN, 3Zhejiang Cancer Hospital, Hangzhou/CN, 4Pathology, Fujian Cancer Hospital, Fuzhou/CN, 5Medical Oncology, Fujian Cancer Hospital, Fuzhou/CN, 6Zhejiang Rongjun Hospital, Jiaxing/CN, 7Pathology, Fujian Cancer Hospital, Fuzhou/CN, 8Jining Hospital, Nanjing/CN

Background: The identification and clinical validation of cancer driver genes are essential to accelerate the translational transition of cancer genomics, as well as to find clinically confident targets for the therapeutic intervention of cancers. While the genetic variability of neurotrophic receptor tyrosine kinase 1 (NTRK1) mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring NTRK1 mutations. Method: A total of 389 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of NTRK1 mutation and other genes were detected by next generation sequencing. Result: NTRK1 gene mutation rate was 4.11% (16/389) in non-small cell lung cancer, including H268Q (1 patient), V181M (1 patient), Q459R (1 patient), G726C (1 patient), R89H (1 patient), M635I (1 patient), L126G (1 patient), G138R (1 patient), E245A (1 patient), I287V (1 patient), L35O (1 patient), N293S (1 patient), E245A (1 patient), W236C (1 patient), E456K (1 patient) and F297L (1 patient), and median overall survival (OS) for these patients was 11.0 months. Among them, all patients were NTRK1 gene with co-occurring mutation in NSCLC. Briefly, patients with (n=5) or without (n=11) co-occurring BRAF mutations had a median OS of 14.0 months and 11.0 months respectively (P=0.90); patients with (n=12) or without (n=4) co-occurring TP53 mutations had a median OS of 11.0 months and 6.0 months respectively (P=0.67); patients with (n=3) or without (n=13) co-occurring EGFR mutations had a median OS of 14.0 months and 11.0 months respectively (P=0.43); patients with (n=4) or without (n=16) co-occurring CDKN2A mutations had a median OS of 3.5 months and 14.0 months respectively (P=0.01). Conclusion: NTRK1 oncogenic activation through gene fusion detected a novel and distinct subset of NSCLC: EGFR, TP53 and BRAF gene accompanied may have less correlation with KIT mutation in NSCLC patients. CDKN2A accompanied mutations might play a worse prognosis in NTRK1 gene mutation non-small cell lung cancer.

P1.03-24 TPRMPS4: A NOVEL PROGNOSTIC BIOMARKER AND THERAPEUTIC TARGET IN NSCLC

F. Esposito1, M. Villalba2, M. J. Pajares3, M. Redrado1, C. Sainz1, G. Wistuba4, C. Behrens5, E. Redin2, C. Andreia, C. Ciraquiuiz6, L. Montenguia1, R. Pio2, A. Calvo1

1Program in Solid Tumors, Center for Applied Medical Research (CIMA), The University of Navarra, Pamplona/ES, 2Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston/US

Background: Genomic analyses are identifying novel genes involved in the pathogenesis of non-small cell lung cancer (NSCLC). TPRMPS4, a membrane-anchored serine protease, was previously found as highly gene accompanied may have less correlation with KIT mutation in NSCLC patients. CDKN2A accompanied mutations might play a worse prognosis in NTRK1 gene mutation non-small cell lung cancer.

Keywords: Non-small-cell lung cancer, NTRK1 mutation, Prognosis

Reduction in S and G2/M phases of the cell cycle, increased apoptosis, and changes in gene expression of cell replication- and migration-promoting genes (i.e. MC216, TMY5 and CDKN1A/p21) were also detected. Cells lacking TPRMPS4 were highly sensitized to chemotherapy, including cisplatin, paclitaxel and gemcitabine, which significantly enhanced the antiproliferative, antitumor and proapoptotic effect of these drugs.

Conclusion: Our results show that TPRMPS4 is a biomarker of poor prognosis in NSCLC and plays an important role in tumor growth and metastasis, and suggest that its blockade may enhance sensitivity to chemotherapy.

Keywords: Prognosis, TPRMPS4, Chemosensitization

P1.03-25 THE FREQUENCY AND PROGNOSIS OF ATMS MUTATIONS IN CHINESE NON-SMALL-CELL LUNG CANCER PATIENTS

C. Han1, C. Xu1, W. Wang2, Q. Zhang3, W. Zhuang4, Y. Zhu5, Y. Huang4, Y. Chen6, G. Chen7, M. Fang8, T. Lv9, Y. Song8

1An People’s Hospital, Lu’An/CN, 2Fujian Cancer Hospital, Fuzhou/CN, 3Zhejiang Cancer Hospital, Hangzhou/CN, 4Pathology, Fujian Cancer Hospital, Fuzhou/CN, 5Zhejiang Rongjun Hospital, Jiaxing/CN, 6Respiratory, Jining Hospital, Nanjing/CN, 7Department of Respiratory Medicine, Jining Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: The ataxia-telangiectasia mutated kinase protein (ATM) plays a critical role in the cellular response to double strand DNA damage. While the genetic locus of ATM mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring ATM mutations. Method: A total of 389 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of ATM mutation and other genes were detected by next generation sequencing. Result: ATM gene mutation rate was 6.17% (24/389) in non-small cell lung cancer, including L229Y (1 patient), V2298E (1 patient), M2041V (1 patient), I346N (1 patient), E518* plus D1616V (1 patient), R7725fs*25 (1 patient), W488L (1 patient), M1064T (1 patient), E347A (1 patient), K11922 (1 patient), P13745 (1 patient), R248* (1 patient), M13212 (1 patient), I346N (1 patient), H2430R (1 patient), G494D (1 patient), N2282S (1 patient), A1945S (1 patient), E518* plus D1616V (1 patient), Q161* plus E699Q (1 patient) and D24486 plus L2261Tfs*12 (1 patient), and median overall survival (OS) for these patients was 18.0 months. Among them, all patients were ATM gene with co-occurring mutation. Briefly, patients with (n=8) or without (n=16) co-occurring EGFR mutations had a median OS of 21.0 months and 11.0 months respectively (P=0.19); patients with (n=13) or without (n=11) co-occurring TP53 mutations had a median OS of 21.0 months and 14.0 months respectively (P=0.44). Conclusion: Although EGFR and TP53 gene accompanied may have less correlation with mutation in NSCLC patients, predict which patients may harbor ATM mutations, could have implications in triaging toward ATM variant identification for potential future targeted therapy. These data have implications for the identification of therapeutic target candidates.

P1.03-26 ANALYSIS OF DDR2 GENE ABERRATIONS IN CHINESE NON-SMALL-CELL LUNG CANCER PATIENTS AND EVALUATION OF THEIR PROGNOSIS

J. Lai1, W. Wang2, C. Xu3, Q. Zhang4, W. Zhuang5, Y. Zhu6, Z. Huang4, Y. Chen6, G. Chen7, M. Fang8, T. Lv9, Y. Song8

1Fujian Medical University Union Hospital, Fuzhou/CN, 2Zhejiang Cancer Hospital, Hangzhou/CN, 3Fujian Cancer Hospital, Fuzhou/CN, 4Pathology, Fujian Cancer Hospital, Fuzhou/CN, 5Zhejiang Rongjun Hospital, Jiaxing/CN, 6Respiratory, Jining Hospital, Nanjing/CN, 7Department of Respiratory Medicine, Jining Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: Recently, Mutations in discoidin domain receptor 2 (DDR2) gene were recently identified as promising molecular targets in non-small-cell lung cancer. While the genetic spectrum of DDR2 mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring DDR2 mutations. Method: A total of 283 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of DDR2 mutation and other genes were detected by next generation sequencing. Result: DDR2 gene mutation rate was 3.18% (9/283) in non-small cell lung cancer, including S311N (1 patient), E44K (1 patient), R709Q (1 patient).
P1.03-27 SOMATIC MUTATIONS IN BRCA2 GENES ARE ASSOCIATED WITH PROGNOSIS IN CHINESE NON-SMALL-CELL LUNG CANCER PATIENTS

J. Li¹, C. Xu², W. Wang³, Q. Zhang³, W. Zhuanga, Y. Zhu³, Y. Huang³, Y. Chen⁴, G. Chen⁴, M. Fang⁴, T. Lv⁵, Y. Song⁶

¹Fujian Medical University Union Hospital, Fuzhou/CN, ²Fujian Cancer Hospital, Fuzhou/CN, ³Zhejiang Cancer Hospital, Hangzhou/CN, ⁴Pathology, Fujian Cancer Hospital, Fuzhou/CN, ⁵Zhejiang Rongjun Hospital, Jiaxing/CN, ⁶Respiratory, Jinling Hospital, Nanjing/CN, ⁷Department of Respiratory Medicine, Jinling Hospital, Nanjing University School of Medicine, Nanjing/CN

Background: The role of BRCA2 gene somatic mutations are mainly to maintain genome integrity in response to DNA damage through different mechanisms. Deregelation of BRCA2 is associated with the development of tumor and altered sensitivity to chemotherapeutic agents, but the genetic characteristics of BRCA2 somatic mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring BRCA2 somatic mutations. Method: A total of 362 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of BRCA2 gene and other genes were detected by next generation sequencing. Result: BRCA2 gene somatic mutation rate was 4.97% (18/362) in non-small cell lung cancer, including S33F (4 patients), S33C (1 patient), D32H (1 patient), G34R (1 patient), G34V (1 patient), G34del (1 patient), S44P (1 patient), S45del (1 patient) and S45del plus S33Y (1 patient), and median overall survival (OS) for these patients was 12.0 months. Among them, all patients were CTNNB1 gene with co-occurring mutations. Briefly, patients with (n=7) or without (n=6) co-occurring EGFR mutations had a median OS of 25.8 months and 17.0 months respectively (P=0.18); patients with (n=10) or without (n=3) co-occurring TP53 mutations had a median OS of 10.0 months and 17.5 months respectively (P=0.35); patients with (n=2) or without (n=11) co-occurring BRAF mutations had a median OS of 7.5 months and 13.0 months respectively (P=0.63); patients with (n=6) co-occurring KRA5 mutations had a median OS of 13.5 months and 20.0 months respectively (P=0.82); patients with (n=2) or without (n=7) co-occurring PTPTR mutations had a median OS of 15.0 months and 21.5 months respectively (P=0.96). Conclusion: DDR2 mutations were observed in 3.18 % of cases of NSCLC. DDR2-mutated NSCLC can exhibit other driver gene alterations. No clinical characteristics were significantly associated with DDR2 mutation.

Keywords: Non-small-cell lung cancer, Prognosis, DDR2 mutation

P1.03-28 ASSOCIATION BETWEEN MOLECULAR CHARACTERISTICS OF CTNNB1 MUTATIONS AND PROGNOSIS IN PATIENTS WITH NSCLC IN CHINESE PATIENTS

J. Li¹, C. Xu², W. Wang³, Q. Zhang³, W. Zhuanga, Y. Huang³, Y. Chen⁴, G. Chen⁴, M. Fang⁴, T. Lv⁵, Y. Song⁶

¹Fujian Medical University Union Hospital, Fuzhou/CN, ²Fujian Cancer Hospital, Fuzhou/CN, ³Zhejiang Cancer Hospital, Hangzhou/CN, ⁴Pathology, Fujian Cancer Hospital, Fuzhou/CN, ⁵Zhejiang Rongjun Hospital, Jiaxing/CN, ⁶Respiratory, Jinling Hospital, Nanjing/CN, ⁷Department of Respiratory Medicine, Jinling Hospital, School of Medicine, Nanjing University, Nanjing/CN

Background: Currently, CTNNB1, encoding beta-catenin, is a well-known tumor-related gene in the wnt signaling pathway. While the genetic variability of CTNNB1 mutation NSCLC patients is unclear.The aim of this study is to investigate mutations and prognosis of NSCLC harboring CTNNB1 mutations. Method: A total of 677 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of CTNNB1 mutation and other genes were detected by next generation sequencing. Result: CTNNB1 gene mutation rate was 1.92% (13/677) in non-small cell lung cancer, including S33F (4 patients), S33C (1 patient), D32H (1 patient), G34R (1 patient), G34V (1 patient), G34del (1 patient), S44P (1 patient) and S45del plus S33Y (1 patient), and median overall survival (OS) for these patients was 12.0 months. Among them, all patients were CTNNB1 gene with co-occurring mutations. Briefly, patients with (n=7) or without (n=6) co-occurring EGFR mutations had a median OS of 25.8 months and 17.0 months respectively (P=0.18); patients with (n=10) or without (n=3) co-occurring TP53 mutations had a median OS of 10.0 months and 17.5 months respectively (P=0.35); patients with (n=2) or without (n=11) co-occurring BRAF mutations had a median OS of 7.5 months and 13.0 months respectively (P=0.63); patients with (n=6) co-occurring ATM mutations had a median OS of 17.5 months and 11.0 months respectively (P=0.53). Conclusion: Accompanied gene has not well been connected with CTNNB1 gene mutations. Our finding expands the mutant spectrum of CTNNB1 gene and adds new understanding of the phenotype.

Keywords: CTNNB1 mutation, Non-small-cell lung cancer, Prognosis
Conclusion: We identified most highly mutated repair genes and quantified the increase in risk for each additional mutated repair gene. Although the TMB of individuals with mutations in specific repair gene or pathway show no significant difference, a larger dataset that comprises adequate number of samples within each explanatory variables such as incidence of cell division, tumor stages to be taken into model, can be expected to derive a more robust predictor.

Keywords: TCGA, DNA repair gene. Tumor mutation burden

Method: We obtained level 4 variant datasets from The Cancer Genome Atlas (TCGA) which comprises of 568 samples. The TMB of each individual was calculated and the population was divided into subgroups as per the status of harboring mutations in repair genes as well as the specific repair pathways. Result: In the 568 lung adenocarcinoma patients, 434 patients have somatic mutations in any of the 112 DNA repair genes. The individuals harboring mutations in repair genes have significantly higher TMB (Mean=3.019, S.E.=0.206) than those do not (Mean=11.085, S.E.=0.493), and we derived a 3.81-fold increase in TMB for mutations occurring in an additional repair gene. Those that harbor mutations in TP53 account for 63% of the population, and ATM and PRKDC account for 11% and 10, respectively.

3Thoracic Surgery, Miyagi Cancer Center, Morioka/JP

Background: Periostin is a matricellular protein that is secreted by fibroblasts and interacts with various cell-surface integrin molecules. Although periostin is known to support tumor development in human malignancies, little is known about its effect on lung cancer progression. Method: We classified 189 clinical specimens from patients with non-small cell lung cancer according to high or low periostin expression. In a syngeneic implantation model, Ex3LL cells (mouse lung cancer cell line, 1x106 in 100μL PBS) were implanted into the left thigh muscle of periostin−/− or periostin+/+ mice. Tumor formation was monitored weekly. Four weeks after implantation, the mice were then euthanized. We found a better prognosis for patients with low rather than high periostin, even in cases of advancedstage cancer. In a syngeneic implantation model, murine Ex3LL lung cancer cells formed smaller tumor nodules in periostin−/− mice than in periostin+/+ mice, both at the primary site and at metastatic lung sites. An in vitro proliferation assay showed that stimulation with recombinant periostin increased Ex3LL-cell proliferation. We also found that periostin promotes ERK phosphorylation.

Conclusion: Our results demonstrated that high periostin expression is a strong prognostic factor in lung cancer, and that periostin secreted by adjacent stromal fibroblasts may promote lung cancer proliferation and invasion. We believe that periostin represents a potential target in lung cancer progression.

Keywords: ERK, periostin, lung cancer

P1.03-32 MOLECULAR CHARACTERISTICS AND PROGNOSIS FBXW7 MUTATIONS IN CHINESE NON-SMALL-CELL LUNG CANCER PATIENTS
C. Xu1, W. Wang2, Q. Zhang1, W. Zhuang1, Y. Zhi1, Y. Chen1, M. Fang2, G. Chen1, T. Liu2, Y. Song2

Background: FBXW7 (F-box and WD repeat domain containing-7) is a tumor suppressor protein that regulates the degradation of various oncoproteins in several malignancies. However, limited information is available regarding FBXW7 mutations in non-small-cell lung cancer. While the genetic status of FBXW7 gene mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring FBXW7 mutations. Method: A total of 229 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of FBXW7 mutations was detected by next generation sequencing. Result: FBXW7 gene mutation rate was 3.06% (7/229) in non-small cell lung cancer, including G66Efs*55 (1 patient), P2273L (1 patient), E97K (1 patient), L565Q (1 patient), M1038I (1 patient), E2419K (1 patient), A22485 (1 patient), T1870S (1 patient), V2198A (1 patient), R1482P (1 patient) and E1362K (1 patient), and median overall survival (OS) for these patients was 13.0 months. Among them, all patients were M0, and median overall survival (OS) for these patients was 13.0 months. Patients with wild-type (n=2) or without (n=181) co-occurring TP53 mutations had a median OS of 17.0 months and 11.0 months respectively (P=0.33); patients with (n=15) or without (n=8) co-occurring TP53 mutations had a median OS of 11.0 months and 13.0 months respectively (P=0.42). Conclusion: Our results demonstrated that high periostin expression is a strong prognostic factor in lung cancer, and that periostin secreted by adjacent stromal fibroblasts may promote lung cancer proliferation and invasion. We believe that periostin represents a potential target in lung cancer progression.

P1.03-33 MUTATIONAL SPECTRUM AND PROGNOSIS OF NON-SMALL-CELL LUNG CANCER HARBORING MTOR MUTATIONS IN CHINESE POPULATION
C. Xu1, W. Wang1, Q. Zhang1, W. Zhuang1, Y. Zhi1, Y. Chen1, M. Fang2, G. Chen1, T. Liu2, Y. Song2
1Fujian Cancer Hospital, Fuzhou/CN, 2Zhejiang Cancer Hospital, Hangzhou/CN, 3Pathology, Fujian Cancer Hospital, Fuzhou/CN, 4Medical Oncology, Fujian Cancer Hospital, Fuzhou/CN, 5Zhejiang Rongjun Hospital, Jiaxing/CN, 6Pathology, Fujian Cancer Hospital, Fuzhou/CN, 7Jining Hospital, Nanjing/CN

Background: Mammalian Target of Rapamycin (mTOR) is a validated target in cancer. It remains to be determined whether non-small-cell lung cancer patients bearing mTOR gene mutations would benefit from mTOR inhibitor treatment with PI3K-AKT-mTOR pathway inhibitors. While the genetic spectrum of MTOR mutation NSCLC patients is unclear. The aim of this study is to investigate mutations and prognosis of NSCLC harboring MTOR mutations. Method: A total of 639 patients with non-small-cell lung cancer were recruited between July 2012 and December 2015. The status of MTOR mutation and other genes were detected by next generation sequencing. Result: MTOR gene mutation rate was 3.80% (24/639) in non-small cell lung cancer, including T18301, T1833[2-1] (3 patients), S2211N (1 patient), C1483F (1 patient), D1527H (1 patient), I1964V (1 patient), E1799K (1 patient), L88F (1 patient), P2273L (1 patient), E97K (1 patient), L565Q (1 patient), M1038I (1 patient), A1792V (1 patient), R1896Q (1 patient), G1678E (1 patient), M2327I (1 patient), E2419K (1 patient), A22485 (1 patient), T1870S (1 patient), V2198A (1 patient), R1482P (1 patient) and E1362K (1 patient), and median overall survival (OS) for these patients was 13.0 months. Among them, all patients were M0, and median overall survival (OS) for these patients was 13.0 months. Patients with wild-type (n=2) or without (n=181) co-occurring EGFR mutations had a median OS of 17.0 months and 11.0 months respectively (P=0.33); patients with (n=15) or without (n=8) co-occurring TP53 mutations had a median OS of 11.0 months and 13.0 months respectively (P=0.42). Conclusion: MTOR mutation may predict a worse prognosis of NSCLC. MTOR pathway inhibitors everolimus may be beneficial for NSCLC patients with specific MTOR mutations. EGFR and TP53 gene accompanied may have less correlation with MTOR mutation in NSCLC patients. The findings of this study could facilitate both clinical trial design and therapeutic strategies.

P1.03-34 COMBINED MOLECULAR AND RADIOLOGICAL EVALUATION UNVEILS THREE SUBTYPES OF DISEASE PROGRESSION TO A THIRD GENERATION EGFR TKI
Y. Zhang1, Z. Zhou1, Z. Chen1, C. Xu1, J.-. Yang1, X. Zhang1, X. Bai1, H. Yan1, W.-. Li1, S. Chua1, J. Ye1, H. Zhang-Han1, Z. Zhang2, Y. Wu1
1Guangdong Lung Cancer Institute, Guangdong General Hospital and Guangdong Academy of Medical Sciences, Guangzhou/CN, 2Burning Rock Biotech, Guangzhou/CN

Background: The definition of disease progression (PD) to EGFR TKIs has evolved from RECIST to a combination of clinical and RECIST evaluation. Patients with dramatic, local or gradual progression to third generation EGFR TKIs have been tailored to different subsequent treatment strategies. However, little is known about progression to third generation EGFR TKIs from molecular perspective. Method: Longitudinal plasma samples were collected from 1790M-positive patients who progressed on a third generation EGFR TKI AC0010 in a phase II/II study in Guangdong Lung Cancer Institute. A pre-defined and unified molecular and radiological evaluation of PD were performed. Ultra-deep sequencing covering 295 cancer-related genes was performed to track the changes in ctDNA to depict molecular PD, which was defined by acquired SNV/SCNV, or ≥20% increase in allelic fraction/copy number of pre-existing SNV/SCNV or both. Radiological PD was defined by RECIST. Result: As of October 2016, 1062 serial plasma samples from 23 patients with clinical PD were included. Three subtypes of PD to AC0010 were revealed (Fig1). Molecular PD occurred prior to radiological PD in 43.5% of patients (10/23), with an average lead time of 3.0 months. Molecular PD occurred concurrently with radiological PD in 39.1% of patients (9/23). Interestingly, 17.4% of patients (4/23) experienced radiological PD prior to molecular PD, with molecular PD occurring during AC0010 continuation beyond progression (CBPD) in 3 patients. Of patients experienced clinical stable PD in extracranial lesions, radiological PD occurring prior to molecular PD group (n=3) demonstrated longer duration of AC0010 CBPD than molecular PD occurring prior to (n=3) or concurrently with radiological PD groups (n=4) (Median, 5.6 months vs. 1.9 months vs. 1.8 months).
higher neoantigen burden compared with NoMut group in ADC and SQCC (mean 32.17/15.22 and 34.75/19.83 mutation/mbp, respectively, both $P<0.01$). In addition, the Mut group demonstrated higher infiltration of activated CD8 T cells compared with the NoMut group in ADC (39%/25%, $P<0.01$). However, there was no significant difference between two groups in SQCC (32%/27%, $P=0.42$). For two representative genes (SMARCA2 and PBRM1), lower expression of the two genes were associated with higher infiltration of activate CD8 T-cells in ADC (60%/6% and 37%/17%, respectively, both $P<0.01$) and SQCC (40%/21% and 43%/17%, respectively, both $P<0.01$). However, there was no difference in neoantigen burden with respect to gene expression in either ADC or SQCC.

Conclusion: Our study revealed 3 distinct subtypes of PD to AC0010, providing insights into PD by combining molecular and radiological evaluation and might guide the optimal time for treatment switch and personalized subsequent treatments.

P1.04-01 IMPACT OF CHROMATIN REMODELING GENES INCLUDING SMARCA2 AND PBRM1 ON NEOANTIGEN AND IMMUNE LANDSCAPE OF NSCLC
L.C. Park¹, S. Chang², T. Ko³, K. Rhee³, J. Anker¹, M. Bhave¹, A. Davis¹, M. Cruz³, W. Iams³, L. Zou², V. Wang², J. Chuang³, Y. Chae¹
¹Northwestern University, Chicago, IL/US; ²The Jackson Laboratory, Bar Harbor, US

Background: Epigenetic changes in tumors and their microenvironment immune cells have been the recent focus of cancer research. Aberrations in SWI/SNF complexes within the chromatin remodeling machine may play a major role in carcinogenesis. However, little is known about their impact on neoantigen and the immune landscape of NSCLC.

Method: Patients were divided into two groups; Mut group (at least one mutation in 27 SWI/SNF complex subunit genes including SMARCA2 and PBRM1) and NoMut group (no SWI/SNF mutations). We analyzed genomic, transcriptomic data from the TCGA database including patients with adenocarcinoma (ADC, n=515) and squamous cell carcinoma (SQCC, n=501) of lung cancer. The tumor immune landscape was analyzed using the signatures derived from 812 'immune metagenes' (Angelova, M. et al, 2015). We analyzed neoantigen burden and immune landscape between two groups. RNA expression of the above genes were compared. Patients were also divided by the expression levels of the above genes (1st quartile vs 4th quartile). Results: Mut group (142 samples, 14%) showed significant
Conclusion: Mutation or low expression of chromatin remodeling genes including SMARCAD2 and PBRM1 were associated with higher neoadjuvant burden and higher tumor infiltration of activated CD8 T-cells in human NSCLC.

Keywords: NSCLC, chromatin remodeling, SWI/SNF complexes, SMARCAD2, PBRM1

P1.04-02 TARGETING ESTABLISHED LUNG CANCER THROUGH COMBINATION OF DNT CELLULAR THERAPY WITH PD1 CHECKPOINT BLOCKADE
L. Fang1, D. Ly2, W. Liu1, S. Wang1, J. Lee1, H. Kang1, L. Zhang4
1Thoracic Surgery, The First Hospital of Jilin University, Changchun/CN, 2Tgri, Toronto/ON/CA, 3Division of Hematology-Oncology, Department of Medicine, The First Hospital of Jilin University, Changchun/CN, 4Laboratory Medicine & Pathobiology & Immunology, Tgri, Toronto/ON/CA

Background: Lung cancer is the leading cause of cancer-related deaths worldwide. Immune-checkpoint blockade such as anti-PD1 therapies achieved clinical benefit which correlated with presence of immune cells in tumors. Adoptive T cell therapies is another form of immunotherapy with therapeutic-potentials, but obtaining sufficient tumor-antigen specific T cells and discovery of high-expressing tumor-specific antigens remain as challenge. Recently, we have demonstrated that a population of cytotoxic T cells (CD3+CD4-CD8-) termed double negative T (DNT) cells, has potent anti-cancer effect in vitro and in patient-derived xenograft models, can be expanded ex vivo to a therapeutic quantity and quality. In this study, whether DNT cell can target established lung cancer either alone or in combination with anti-PD1 is investigated.

Method: Infiltrating T cell populations from 12 resected lung tumors were characterized and compared to resected adjacent and normal tissues using Flow-cytometry. To determine the efficacy of ex vivo DNT cell therapy on lung cancer, NSG mice subcutaneously engrafted with H460 were systemically infused with DNT cells or DNT cell with Nivolumab in three doses when tumor size reached 100mm3, the tumor size and DNT cell infiltration level were monitored. Result: The frequency of DNT cell was reduced in lung tumor when compared to the adjacent and non-tumoral tissues of the same patient. Like conventional CD4 and CD8 T cells, 36%-52% of DNT cells within tumor expressed elevated levels of PD1, suggesting that DNT cells function may be suppressed by PD-1 pathway in patients. Using xenograft mice, we show that treatment with DNT cell alone reduced tumor growth by 14%-38%. A greater reduction (30%-68%) was observed when DNT treatment was combined with PD1 blockade, where PD1 blockade alone had no significant effect. Compared to DNT cell transfer alone, DNT cells with PD1 blockade led to a greater infiltration of cells with higher expression of cytotoxicity markers NKGD2 and IFN-γ and reduced inhibitory markers TIM3 and LAG3. Conclusion: These studies indicate the potential of DNT cell for the treatment of established lung cancer and that combination of DNT cell with PD1 blockade may further enhance the treatment efficacy by increasing DNT cell infiltrating to solid tumor.

P1.04-03 SUPPRESSIVE IMMUNE CELL PROFILING IN PATIENTS WITH NON-SMALL CELL LUNG CANCER.
J. Koh1, K.Y. Lee2, B. Kim2, M.S. Kim3, H.J. Cho2, Y.H. Bae2, B.M. Ku2, J. Sun1, S. Lee1, J.S. Ahn1, K. Park1, M. Ahn4
1Department of Health Sciences and Technology, Sashst, Samsung Medical Center / Sungkyunkwan University, Seoul/KR, 2Samsung Biomedical Research Institute, Samsung Medical Center, Seoul/KR, 3Division of Hematology-Oncology, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, Seoul/KR

Background: The factors in tumor microenvironment hinder T cell activities against tumor cells. The major immunosuppressive cells in tumor sites are myeloid derived suppressor cell (MDSC), tumor associated macrophage (TAM), and regulatory T (Treg) cell, and the effector molecules released by those immunosuppressive cells also regulate T cell activities. Therefore, in this study we examined the pattern of immunosuppressive cells in patients with non-small cell lung cancer depending on their stages and we compared those immunosuppressive cells in healthy donor blood PBMC as well. Then, we tested T cell activities to verify whether suppressive immune cell populations can influence T cell activity.

Method: Granulocytic-MDSC, Monocytic-MDSC, TAM, and Treg population from patients’ PBMC (n=59) and healthy donors’ PBMC (n=20) were analyzed by FACS Verse with appropriate antibodies. For suppressive associated T cells assays, isolated T cells were incubated with anti-CD3 and anti-CD28 for an hour and then MDSC was co-cultured with T cells for a week followed by Ki-67 level analysis by FACS Verse. T cell activity and suppression were tested by FACS analysis with identified cell surface markers.

Result: G-MDSC (p-value=0.0023) and M-MDSC (p-value=0.0032) population were higher in advanced non-small cell lung cancer patients (stage III/IV) compared with stage I/II patients or healthy donor. G-MDSC isolated from patient’s blood was co-cultured with activated T cells from the same patient. After one week, T cell activity was dramatically inhibited compared with T cell alone (p<0.001, E:T = 5:1, 10:1) confirming suppressive activity of MDSC against T cells. TAM population was increased as disease progressed (p<0.001), and Treg also slightly increased (p-value=0.0373) in stage III/IV. Activated T cells were higher in stage III/IV, but suppressed T cells were also higher in stage III/IV compared with stage I/II. Conclusion: G-MDSC and M-MDSC population increased as disease progressed and G-MDSC effectively suppressed T cell activities. TAM population increased in advanced non-small cell lung cancer patients, and Treg population also slightly increased in stage III/IV. Both activated and suppressed T cells were higher in stage III/IV compared with stage I/II.

P1.04-04 EFFICIENT UPTAKE OF RECOMBINANT LIPIDATED SURVIVIN BY ANTIGEN-PRESENTING CELLS INITIATES ANTIGEN CROSS-PRESENTATION AND ANTITUMOR IMMUNITY
C. Chiang, C. Wu, S. Liu, C. Leng, H. Chen
National Institute of Infectious Disease and Vaccinology, National Health Research Institutes, Miaoli County/TW

Background: Survivin is over-expressed in various types of human cancer, but rarely expressed in terminally differentiated adult tissues. Thus, survivin is a potential target antigen for a cancer vaccine. However, self-tumor associated antigens are not highly immunogenic. Bacteria derived lipoproteins can activate antigen-presenting cells through their toll-like receptors to enhance presentation of antigen responses. In this context, lipidated survivin is an attractive candidate for cancer immunotherapy.

Method: In the present study, recombinant lipidated human survivin (LSur) was prepared from an Escherichia coli-based system. We investigated whether LSur is efficiently captured by antigen presenting cells then facilitating effective induction of survivin cross-presentation and generation of immunity against cancer cells. Result: Our results demonstrate that LSur, but not its non-lipidated counterpart, can activate mouse bone marrow derived-dendritic cells (BMDCs) to enhance cytokine (IL-6, TNF-α, and IL-12) secretion and co-stimulatory molecules (CD40, CD80, CD86 and MHC II) expression. However, the pathways involved in the capture of the recombinant lipidated antigen by antigen-presenting cells have not yet been elucidated. To this end, we employed endocytosis inhibitors to study the effect on LSur internalization. We show that the internalization of LSur is suppressed by the inhibition of various routes of endocytosis. These results suggest that endocytosis of LSur by BMDCs can be mediated by multiple mechanisms. Furthermore, LSur is trafficked to the early endosome after internalization by BMDCs. These features of LSur are advantageous for cross-presentation and the induction of antitumor immunity.

Conclusion: We demonstrate that immunization of C57BL/6 mice with LSur under treatment with exogenous adjuvant-free formulation induce survivin-specific CD8+ T-cell responses and suppress tumor growth. The antitumor responses are mediated by CD8+ cells. Our findings indicate that LSur is a potential candidate for stimulating protective antitumor immunity. This study suggests that lipidated tumor antigens may be a promising approach for raising a robust antitumor response in cancer immunotherapy.

P1.04-05 ELUCIDATING THE ROLE OF LEUKOCYTE-ASSOCIATED IMMUNOGLOBULIN-LIKE RECEPTOR 2 (LAIR2) IN LUNG CANCER DEVELOPMENT

1Department of Laboratory Medicine and Pathobiology, University Health Network, Toronto/CA, 2Division of Medical Oncology and Hematology, Princess Margaret Cancer Centre and Toronto General Hospital, University Health Network, Toronto/CA, 3Princess Margaret Cancer Centre and Toronto General Hospital, University Health Network, Toronto/ON/CA, 4Princess Margaret Cancer Centre, Toronto/ON/CA, 5Laboratory Medicine & Pathobiology & Immunology, Tgri, Toronto/ON/CA

Background: The tumor microenvironment play an important role in shaping cancer development. The contexture of stromal infiltrates have been shown promote or inhibit tumor growth and patient prognosis. In attempts to gain insight into the immune networks that regulate tumorigenesis, we used genome wide expression datasets from patients with resected early stage non-small cell lung cancer (NSCLC) to identify immune-related genes associated with patient survival.

Method: Gene expression analysis was conducted on microarray datasets from 128 early-stage NSCLC adenocarcinoma resected tumor samples. Limiting analysis to immune-related genes, we identified a minimum gene set containing LAIR2 that was diagnostic for lung adenocarcinoma. Immunohistochemistry and gene ontology analysis were used to determine the function of LAIR2. Result: From the gene signature, the gene encoding the immunoglobulin-like receptor LAIR2 was highly expressed within the high-risk patient subgroup (HR = 2.71, 95% CI = 1.49 to 4.90, P = 0.001). Gene ontology analysis revealed that LAIR2 expression correlated with negative immune regulation and associated immune signatures. Immunohistochemistry of resected lung adenocarcinoma revealed heterogeneous expression of LAIR2 within tumor epithelium and stromal immune cells, suggesting specificity and localization. ELISA for LAIR2 suggest that CD4+ Th2 cells maybe a major source of LAIR2 secretion and that recombinant LAIR2 may promote T cell exhaustion by activation of CD8+ T cells and upregulation of PD1 and LAG3. Conclusion: Our results suggest that expression of LAIR2 result in poor patient prognosis and is associated with negative immune regulation. An understanding of LAIR2 function will provide insight into factors required during lung cancer progression and targets for intervention.

P1.04-07 PEMETREXED ENHANCES ANTI-TUMOR EFFICACY OF PD-L1 BLOCKADE BY PROMOTING INTRA-TUMOR IMMUNE RESPONSE VIA TUMOR AND T CELL-INTRINSIC MECHANISMS

D. Schaer1, S. Geeganjana2, I. Amaladevi3, Z. Liu1, E. Rasmussen1, A. Sonu1, D. Chiu4, A. Capen1, Y. Di1, T. Decker5, B. Jones5, X. Huang1, S. Luo6, C. Carpenito2, K. Roth7, A. Nikolayev2, B. Tan8, M. Brahmacharya9, K. Chodavarapu1, F. Dorsey10, J. Manro11, T. Doman12, G. Donoho13, G. Hall13, M. Kalos14, R. Novosadly1
1Eli Lilly, New York/NY/US, 2Eli Lilly, Indianapolis/IN/US

Background: The combination of pemetrexed/carboplatin with the PD-1 antibody pembrolizumab demonstrates a substantial increase in overall survival in NSCLC patients (hazard ratio 0.49) based on KEYNOTE-189 Phase III data (Gandhi et al., 2018), and represents the first chemoimmunotherapy combination ever approved in Oncology. However, the mechanisms underlying the efficacy of this combination remain largely unknown. Many chemotherapies in general and antifolates in particular have detrimental effects on immune homeostasis, and differ in their ability to induce immunogenic tumor cell death. Nevertheless, KEYNOTE-189 results suggest a positive interaction between pemetrexed-based chemotherapy and immunotherapy highlighting the importance to understand the role of pemetrexed in modulating antitumor immune response to assure rational application of this therapy to the appropriate patients. Method: To characterize the effects of pemetrexed on intra-tumor immune response, murine syngeneic tumor models (MC38 and Colon 26) were treated with pemetrexed, paclitaxel with or without carboplatin, or anti-mouse PD-L1. Immune cell subsets and immune-related changes in tumor tissue and T cells were assessed by flow cytometry and gene expression analysis. Tumor and T cell-intrinsic effects of pemetrexed including ability to induce immunogenic cell death of tumor cells and enhance immune function through changes in mitochondrial respiration and gene expression in T cells were also evaluated. Result: In MC38 syngeneic mouse tumor model, pemetrexed increases frequency of intratumor leukocytes and cycling (Ki67+) T cells accompanied by gene expression changes indicative of T cell-induced immune signature. In contrast, paclitaxel exerts quantitatively and qualitatively different immune effects mainly associated with modest upregulation of myeloid cell-related genes whereas carboplatin barely exhibits any immune-related changes in monotherapy and appears to attenuate immunomodulatory effects induced by pemetrexed in MC38 tumors. Pemetrexed in combination with PD-L1 antibody demonstrates enhanced antitumor efficacy and pronounced inflamed/immune activation phenotype in Colon26 syngeneic mouse tumor model. In vitro data indicate that pemetrexed is a potent inducer of immunogenic tumor cell death as exemplified by marked release of HMGB1 in MC38 and Colon26 tumor cells and suggest T cell-intrinsic effects exemplified by enhanced mitochondrial content, oxidative respiration and increased expression of cell surface molecules and immune-related genes indicative of T cell activation. Conclusion: Pemetrexed promotes intra-tumor T cell-mediated immune response through immunogenic tumor cell death and increased activation and metabolic fitness of T cells leading to an enhanced anti-tumor efficacy in combination with PD-L1 antibody.

Keywords: pemetrexed, PD-(L)1, chemoimmunotherapy
Patient-derived xenograph (PDX) models have been shown to recapitulate many characteristics of human tumors and have been increasingly used for anticancer drug development. Molecular characterization of cancer biology, and development of precision therapies. However, because PDXs are grown in immunodeficient mouse strains, they are regarded as inappropriate for preclinical evaluation of anticancer immunotherapy. Here we evaluated whether patient-derived immune cells co-exist in PDXs derived from lung cancer patients. **Method:** First-generation PDX (F1) was established by subcutaneously implanting human tumor tissue into non-obese diabetic-severe combined immunodeficiency (NOD-SCID) mice with a null mutation of the gene encoding for interleukin-2 receptor γ (NSG). When the resulting tumors in these mice grew to about 1.5 cm in diameter, we passaged the tumors in NSG or nude mice for subsequent generations. A small piece of these PDX tissues (about 2-3 mm³) were minced into fragments and cultured in media containing human interleukin-2 (IL-2) (2000 – 6000 units/ml) for up to 6 weeks. The proliferated lymphocytes for analyzed by fluorescence-activated cell sorting (FACS) with antibodies specific for human immune cell surface markers. The provenance of cultured cells was determined by DNA fingerprinting assay together with patients’ DNA samples from primary tumors and/or peripheral blood mononuclear cells (PBMC). **Result:** The mean time of PDX growth in NSG mice before harvesting for studying tumor-infiltrating lymphocytes (TILs) was 120 days (ranging from 63-292 days). TILs were successfully cultured from 8 of 25 PDX samples (about 32%), with one from F2 PDXs and 7 from F1 PDXs. TILs from five of those PDXs were predominantly human CD3-CD8+ T cells (72% - 99%), while the remaining three were predominantly human CD19+ B cells (77% - 95%). DNA fingerprint analysis showed that genotypes of TILs were identical to patients’ primary tumors and/or PBMCs, demonstrating that the TILs were from the same patients as the PDXs. Further analysis showed that CD8 + T cells from PDXs were CD45RO+, with either CD62L+ or CD62L-. **Conclusion:** Patient-derived immune cells co-exist with PDXs in some lung cancer PDX models. Most of those immune cells would be CD8+ T cells. These results suggest that some PDXs might be used for evaluating functions of tumor resident immune cells and/or for evaluating anticancer immunotherapies.

**P1.04-09 IMMUONOMODULATORY EFFECTS OF AFAITINIB AND Pembroliizumab in EGFR-MUTANT NSCLC WITH PROGRESSION ON PREVIOUS EGFR-TKI**

J. Riess1, K. Kelly1, K. Schaler2, M. Shimoda3, S. Lim3, A. Monjazeb1, K. Danenberg1, E. Moore4, L. Beckett5, P. Mack1, E. Maverakis3, D. Gandara1

1UC Davis Comprehensive Cancer Center, Sacramento/CA/US. 2Department of Thoracic Medicine, UC Davis School of Medicine, Sacramento/CA/US. 3Department of Dermatology, UC Davis School of Medicine, Sacramento/CA/US. 4Liquid Genomics/Ananthel, Torrance/US.

**Background:** EGFR-mutant NSCLC is less responsive to single agent PD-L1 blockade than smoking associated NSCLC. Preclinical models suggest EGFR-TKI can render a more immunocompetent tumor microenvironment. This study examined the immuno-modulatory effects of combination second generation EGFR-TKI and PD-1 antibody. **Method:** In this phase 1 dose-de-escalation study, patients were treated with afatinib 40 mg oral daily and pembrolizumab 200 mg IV q21day. Key Eligibility: advanced EGFR-mutant NSCLC (EGFR-TKI progression on prior EGFR-TKI), age ≥18, ECOG PS ≤1, acceptable organ function, no significant autoimmune diseases, measurable disease and controlled brain metastases. Tissue biopsy performed baseline and week 5-6 on treatment for PD-L1 IHC (22C3) and quantitative immunofluorescence for immune cell subsets and next-generation sequencing. Blood at baseline and at serial on-treatment timepoints were collected for ctRNA of PD-L1, EGFR, HER2 and MET. Levels of circulating immune cell subsets. **Conclusion:** Gene expression profiles of immune cells and cytokine levels were evaluated by flow cytometry and Luminex. **Result:** No DLTs were observed in the first 6 patients and the 10 patient expansion cohort proceeded at afatinib 40 mg daily and pembrolizumab 200 mg IV q21day. Eleven patients enrolled to date. Key molecular and pathologic characteristics: adenocarcinoma 9, neuroendocrine 1, squamous 1. EGFR-TKI resistance mechanism: EGFR-T790M 4, EGFR-T790M/C797S 1, HER2 amp 1, MET 2, Her2 amp + neuroendocrine differentiation 1, unknown 2. Four patients had prior second line osimertinib. The 27% of patients had immune related AEs (G2 adrenal insufficiency, G2 nephritis, G3 colitis). Nine patients were evaluable for response (1 PR, 7 SD (6/7 with tumor reduction <30%). The responding patient had squamous histology, tumor prior on erlotinib, and PFS of 11 months with PD-L1 (22C3) TPS >50% and PD-L1 and PD-L2 amplification. Treatment with afatinib and pembrolizumab induced systemic immune changes including trend for increased soluble IDO, MIG, TIM3, IP-10, LA5G, PD-L1 and PD-L2 and decreased IFN-gamma. ctRNA for EGFR and PD-L1 were detected in 7/7 samples (about 32%), with one from F2 PDXs and 7 from F1 PDXs. TILs were increased significantly, the activity of TILs did not show difference. Functional evaluation of cells has been found to be more important than cell populations.
Background: Responses to immune checkpoint inhibitors (ICI) may vary between individuals because of somatic mutation differences in the tumour and/or germ-line differences in immunological tolerance. To explore the latter, this ongoing study evaluates patients with metastatic non-small cell lung cancer (NSCLC) treated with single agent PD-1 or PD-L1 inhibitors recruited from a treatment pool of 420 patients (total) / 309 with NSCLC by whole genome sequencing (WGS) (Illumina HiSeqX Ten). Exceptional responders are defined as patients with complete or partial response of more than 12 months or stable disease of more than 24 months (per RECIST), and a concurrent immune-related adverse event of any grade. Non-responders are defined as patients with best response of progressive disease, having received at least 4 cycles or 2 months of treatment. In these individuals, the burden of rare and common variants in immune tolerance genes is analysed and compared to the Medical Genome Reference Bank (MGRB), comprising WGS of 1144 well-elderly individuals. Comparison and associations are calculated using curated risk alleles and OR weightings derived from the Exome Aggregation Consortium (ExAC) frequency <$1% in MGRB and 17.5% of our cohort (p<0.0001). Multiple responders sequenced to date (n=20), including variant A, a frameshift mutation in a protein kinase not present in ExAC, with allelic frequency (AF) of 1.27% in MGRB and 17.5% of our cohort (p=0.0001). Multiple common variants (ExAC >1%) were more frequent within the cohort compared with population standard. Among these, three functional variants within gene B, encoding a protein involved in modulating immune-responsiveness, (variant B.1, B.2 and B.3, ExAC AF: 1.3%, 0.99% and 2.3%), were found seven times (total) across six individuals (one compound heterozygous B.2/B.3). The exceptional responders cohort was enriched for subjects with higher genetic risk for Disease A, psoriasis and psoriatic arthritis compared with control groups. Conclusion: Preliminary findings suggest individuals harbouring functional variants in genes promoting immune tolerance may be more responsive to PD-1/ PD-L1 inhibitors. This may be due to higher basal immune activation, requiring greater reliance on inhibitory checkpoints to maintain homeostasis. Ordinarily, this would be clinically undetectable, however the addition of a pharmacological CPI may more effectively break immune tolerance in this primed environment.

Keywords: Immunogenomics, Immunotherapy, whole genome sequencing

**P1.04-12 MASS SPECTROMETRY-BASED SERUM PROTEOMIC SIGNATURE AS A POTENTIAL BIOMARKER FOR SURVIVAL IN NSCLC PATIENTS WITH IMMUNOTHERAPY**

Northwestern University, Chicago/IL/US

Background: The Veristrat test is a serum biomarker using a mass spectrometry (MS)-based proteomic signature derived from machine learning. It is used as a prognostic marker for patients with NSCLC undergoing platinum-based chemotherapy. However, its role in patients undergoing immunotherapy has not been investigated. Method: 47 patients with advanced stage NSCLC and no activating EGFR mutation underwent VeriStrat testing from 2016 to 2017. Patients were grouped into VeriStrat ‘Good’ risk group (VS-G) or VeriStrat ‘Indeterminate’ & VeriStrat ‘Poor’ risk group (VS-IP). Kaplan-Meier survival analyses with log rank test were performed to compare the progression-free survival (PFS) and overall survival (OS) between the two groups. PFS of NSCLC patients treated with immunotherapy was derived from the time of the immunotherapy to disease progression or death. Result: 47 patients had a mean age of 65.6 (range: 30 to 91). 26 patients were female (55%). 26 patients had diagnosis of adenocarcinoma (55%), while 18 patients had squamous cell carcinoma (38%). 32 patients (68%) underwent treatment with a PD-1 inhibitor (pembrolizumab or nivolumab), whereas 15 patients (32%) did not. 32 patients (68%) demonstrated VS-G trait while 15 patients (32%) demonstrated VS-IP trait (intermediate: 1, poor: 14). Overall, VS-G demonstrated significantly prolonged PFS compared to VS-IP for all NSCLC patients regardless of treatment (median PFS, 12.0 months vs. 6 months, p=0.054), while there was not a significant difference in OS between VS-G and VS-IP. Among NSCLC patients treated with immunotherapy, VS-G classification trended towards increased PFS when compared to VS-IP (Figure 1, median PFS, 12.0 vs 4.2 months, p=0.054), while OS was not statistically different. Multivariate analysis revealed that VeriStrat was an independent predictor of PFS in this patients, regardless of various clinical factors.

P1.04-14 HLA-B44 SUPERTYPE ASSOCIATED WITH LESS FAVORABLE NEOANTIGEN BINDING IN NON- Small Cell Lung Cancer Treated with Immunotherapy

A. Cummings1, H. Lu2, J. Gukasyan1, J. Madrigal1, J. Carroll1, K. Lieskovsk1, S. Dubinett 3, E. Garon1

1University of California, Los Angeles, Los Angeles/CA/US, 2Virginia School of Medicine, Charlottesville/VA, 3Hematology/oncology, University of California, Los Angeles, Los Angeles/CA/US

Background: Human leukocyte antigen (HLA) supertypes may influence immunotherapy efficacy, particularly HLA class I b 44 supertype (B44), which is found in 35-55% of the population irrespective of race (Sidney, BMC Immunol). In melanoma patients treated with immune checkpoint inhibitors, presence of B44 correlated with improved survival (Chowell, Science), but in a cohort of 58 non-small cell lung cancer (NSCLC) patients treated with single-agent pembrolizumab, B44 was associated with poorer outcomes (Lu, ASCO 2018). Given B44’s small electropositive binding pocket, it was hypothesized that the transversions that predominate in NSCLC result in more positive tumor variant amino acids (vAAs) and that these neoantigens would have decreased binding affinity and/ or HLA B44:peptide stability. Methods: 58 advanced NSCLC patients treated with pembrolizumab had germline and tumor multiplexed paired-end Illumina WES performed. HLA typing used BWA-MEM and usage of software; supertype was determined by 2008 criteria (Sidney, BMC Immunol). Subjects with at least one strong HLA B44 supertype allele had nonsynonymous coding mutations identified with Genome Toolkit Analysis (GATK) best practices utilizing the hg38 genome reference. PvacSeq software used NetMHC algorithms to identify tumor neoantigens

9 base pairs in length matched to their corresponding HLA B44 allele (B44-specific neoantigens, BSNs). Missense BSNs were classified by transition (Ti) and transversion (Tv) ratios and vAA charge change. TiTv was compared with matched pairs analysis. Predicted NetMHC IC50 binding affinities were compared with student’s t-tests. All statistical analyses were performed with SAS JMP, Version 13.0 (Cary, NC). Results: Among the 6 subjects, 3073 BSNs were identified; 1090 were unique. There were no common BSNs among subjects. Subject tumor TiTv median was 1.58 (95% CI 1.19-1.94), mean difference compared to germline was -0.62 (95% CI -1.11 to -0.12, p=0.02). BSNs with vAAs that changed charge represented 13.5% of all BSNs. Positive vAA charge changes were expected based on the assumed TiTv distribution (12.5% Ti vs 6.3% Tv, p<0.02). In aggregate, there were 205 BSNs with negative charge change (-BSN) and 204 with positive charge change (+BSN). The anticipated HLA B44 binding affinity was lower for +BSN, with median NetMHC IC50 binding 176.2 (95% CI 170.0-171.9) vs 256.8 (95% CI 216.9-257.7) for -BSN, p<0.01. Conclusion: A potential mechanism for decreased survival in B44 NSCLC subjects treated with immunotherapy is unfavorable neoantigen binding related to increased transversions leading to tumor vAAs with positive charge changes and poorer HLA B44 binding. All subjects from this cohort were evaluated for response to BNS 8-12 base-pairs long to confirm these findings.

P1.04-15 COMPUTERIZED TOMOGRAPHY TEXTURE ANALYSIS AS BIOMARKER OF BENEFIT FROM NIVOLUMAB IN ADVANCED NON-SMALL CELL LUNG CANCER

C. Genova1, E. Barabin2, G. Ficarra1, M. Verda2, E. Rijavec1, G. Rossi1, M. Tagliamento1, F. Biello1, G. Barletta1, M.G. Dal Bello1, G. Cittadini1, F. Grossi1

1Lung Cancer Unit, Ospedale Policlinico San Martino, Genoa/IT, 2Department of Health Sciences, University of Genoa, Genoa/IT, 3Department of Radiology, Ospedale Policlinico San Martino, Genoa/IT

Background: While immune checkpoint inhibitors (ICIs) have revolutionized the management of advanced non-small cell lung cancer (NSCLC), response assessment is a challenging task. Indeed, due to the peculiar mechanism of action of ICIs, the currently employed response evaluation criteria based on dimensional assessment might underestimate their activity. Computerized tomography texture analysis (CTTA) is an emerging approach belonging to the field of “radiomics” and based on the analysis of quantitative data extracted from imaging features; recently, correlations between CTTA and histopathologic as well as molecular characteristics of solid tumors were observed. Our aim is to determine whether parameters derived from CTTA might be used to assess the benefit from ICIs in advanced NSCLC. Methods: Among 74 patients (Pts) treated with nivolumab for advanced NSCLC, 35 had CT scans evaluable for CTTA and had undergone at least two assessments (at baseline and after each cycle). Each pulmonary lesion was evaluated by a radiologist experienced in CTTA, blinded to clinical and temporal data; 295 texture analysis parameters were obtained from each image using an open source software (MaZda, version 4.6). The variations of parameters derived from pre-set gray-level co-occurrence matrices (GLCM) before and after 4 cycles of nivolumab were determined and compared with clinical outcomes. Statistical analyses were performed using MedCalc Statistical Software (version 18). Result: After a median follow up of 9.9 months, variations of GLCM features describing entropy were directly associated with overall survival (OS). Most notably, Pts with increase of entropy above the median value between baseline and the subsequent CT scan identified with a specific GLCM combination had longer OS (15.3 vs. 6.2 months; p= 0.044). This finding suggests that increased tissue heterogeneity during treatment, possibly caused by immune cells infiltration, might be associated with improved outcomes. Conclusion: CTTA might have a prognostic/predictive role during treatment with ICIs for NSCLC. Further analyses including clinical and histopathologic features are currently ongoing, in order to enlighten the biological mechanisms at the basis of our observations.

P1.04-16 COMPARISON OF CLINICAL RESPONSE TO CHECKPOINT INHIBITORS IN ADVANCED NSCLC WITH HIGH PD-L1 EXPRESSION TESTED ON CYTOLOGY VERSUS BIOPSY SAMPLES

K. Guo1, G. Kasymjanova1, H. Wang1, L. Suk1, D. Small1, V. Cohen1, C. Pepe1, A. Spatz2, J. Agulnik1

1Jewish General Hospital, Montreal/CA, 2Division of Pathology, McGill University Health Center & McGill University, Montreal/QC/CA

Background: PD-L1 immunohistochemistry (IHC) expression correlates with clinical response to checkpoint inhibitors in advanced-stage NSCLC. PD-L1 IHC testing is usually performed on tissue blocks from core needle biopsy or surgical resection, but appears to be feasible on cytology cell blocks as well. In this retrospective study, we assessed the clinical response to checkpoint inhibitors in patients with NSCLC with or without high PD-L1 expression in cytology or small biopsy blocks. In this retrospective study, we assessed the clinical response to checkpoint inhibitors in patients with NSCLC with or without high PD-L1 expression in cytology or small biopsy blocks. Methods: Between August 2015 and April 2018, 116 patients with NSCLC received immunotherapy at our institution. Only cases with known PD-L1 expression from a test performed on small biopsies or cytology cell blocks were included. A total of 65 consecutive cases were reviewed, including 40 small biopsies and 25 cytology samples. A Tumor Proportion Score (TPS) was categorized as high (≥ 50% tumor cell staining) or low (<50%). Response to treatment was categorized as no disease control (NdC, including disease progression and stable disease) or progression (PD). The primary outcome was the rate of disease control. Result: Patients were mostly current or ex-smokers (91%), Caucasians (82%) and non-squamous carcinomas (85 %). High TPS blocks as well. In this retrospective study, we assessed the clinical response to checkpoint inhibitors in patients with NSCLC with or without high PD-L1 expression in cytology or small biopsy blocks.
was seen in 44 (68%) cases. Immunotherapy was given in the first line setting in 20 (31%) patients, the second line in 36 (55%), and the third line in 9 (14%). 50 (77%) patients received Pembrolizumab, 10 (15%) Nivolumab and 5 (8%) others received immunotherapies on RCTs. Overall, there was DC in 40 (62%) patients and PD in 17 (26%). There was no significant difference in DC rate between the cytology and the small biopsy groups in high TPS group.

Conclusion: PD-L1 expression on cytology cell blocks and on small biopsies appears to have similar clinical significance. Further prospective trials are needed to confirm these findings.

Background: ICI are a novel class of agents that have revolutionized treatment for patients with metastatic non-cell lung cancer (NSCLC). Still, most patients do not benefit from PD-L1 axis inhibitors, emphasizing the need for additional markers beyond PD-L1 expression for better selection of patients. Method: This retrospective, single centre study included all consecutive patients with advanced NSCLC who were evaluated with a FDG-PET scan prior to first administration of an ICI (nivolumab or pembrolizumab) between 1/2016 and 6/2017. Tumour burden was calculated using the total body Metabolic Tumour Volume (MTV) and the sum of all measurable lesions (SOML) with accordance to the RECIST criteria. This study received IRB approval. Result: A total of 58 patients with histologically proven NSCLC were included. Patients had a median age of 65 years (43-84), 59% were male, 62% had adenocarcinoma and 83% were previously treated with chemotherapy. The median PFS for the entire cohort was 5.7 (1.7-15.8) months, and the ORR for ICI was 44.8%. The median PFS was 12.95 (0-236) millimeter³ and was significantly and inversely associated with longer PFS (p=0.036, 95%CI 1.2-1.05). The median SOML was 88 (13-305) centimetres, and was significantly and inversely associated with a longer PFS and higher ORR (PFS: P=0.004, 95% CI 1.002-1.011, ORR: OR 0.993 p=0.0067). Additionally, patients with a SOML under 56 CM (first quartile) had a longer PFS compared to patients with a higher disease volume (Table 1).

**P1.04-18 PD-L1 EXPRESSION AND ITS CORRELATION WITH TUMOR TNM STAGE IN PATIENTS WITH NON-SMALL CELL LUNG CANCER**

T. Jiang1, J. Kim2

1Kosin University Goseopel Hospital, Pusan/KR, 2Kosin University, Pusan/KR

Background: Immunotherapy has now become a standard therapy of lung cancer treatment. Programmed death ligand (PD-L1) expression has provided a predictive biomarker for anti-PD-1/PD-L1 therapy. However, the relationship between the expression of PD-L1 and the clinical and pathologic features were still unclear. The purpose of this study was to investigate the clinical factors affecting the expression of PD-L1 and the concordance of the DAKO assay with the Ventana assay. Method: We evaluated in 178 non-small-cell lung cancer patients and assessed PD-L1 expression by immunohistochemistry after staining them with antibody 22C3 (Dako) or SP263 (Ventana). Clinical features were acquired from the electrical medical records, retrospectively. We analyzed the relationship between PD-L1 expression and clinicopathological characteristics. Result: One hundred fifty four patients were available for analysis. There were 130 cases which both tests were performed. Mean age was 66.7 years-old. Male patients were 70%, and adenocarcinoma was 68%. Stages were stage I 15.6%, II 7.1%, III 28.6%, and IV 48.7% respectively. In using the 22C3 antibody, PD-L1 expression in Tumor proportion score (TPS) ≥ 50% was 27.7%, and 52.3% in TPS ≥ 1% respectively. PD-L1 expression rate in mean was higher than woman (37.6% vs 16.7%, P=0.028). In the sp263 antibody, PD-L1 expression rate (TPS ≥10%) was 52.9%, and 68.4% in TPS ≥ 1%. Age, primary tumor, regional lymph node, distant metastasis and stage grouping were not statistical different between patients with and without PD-L1 expression. All patients (n=36) with TPS ≥ 50% in the 22C3 test were found to have TPS ≥ 10% in the sp263 test. Conclusion: There were no specific predictable factor in PD-L1 expression except male factor. But, we suggest that further study will be needed by adding other factors and more patients.

**P1.04-19 NEUTROPHIL-TO-LYMPHOCYTE RATIO AND PLATELET-TO-LYMPHOCYTE RATIOS PREDICT SURVIVAL AFTER IMMUNOTHERAPY IN NON-SMALL CELL LUNG CANCER**

M. Oh1, D. Saravia2, S. Agte1, A. Rahbari1, W. Park3, G. Lopes4, Y. Chae1

1Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago/IL/US, 2Sylvester Comprehensive Cancer Center, University of Miami, Miami/FL/US

Background: Effective use of immune checkpoint inhibitors in non-small cell lung cancer (NSCLC) may be improved by identifying biomarkers that are easily measured and predictive of clinical outcomes. Peripheral complete blood counts are commonly obtained and can be indicative of systemic inflammatory response, which has been associated with poor prognosis in multiple cancer types. Here, we investigated the ability of peripheral cell counts to predict patient survival after treatment with immunotherapy for NSCLC. Method: Complete blood counts were retrospectively collected for 274 patients and analyzed for absolute neutrophil count (ANC), neutrophil-to-lymphocyte ratio (NLR), and platelet-to-lymphocyte ratio (PLR). Values were obtained immediately prior to treatment initiation. Overall survival (OS) and progression-free survival (PFS) was assessed using Kaplan-Meier analysis with log-rank test and Cox regression analysis. Result: OS was significantly associated with ANC (HR 1.63, p<0.0001) and NLR>5 (HR 1.62, p<0.0001), as was PFS (HR 1.48, p=0.0008 and HR 1.48, p=0.0012, respectively). PLR>400 was not associated with OS but did have a significant association with PFS (HR 1.39, p=0.0388). Baseline elevation of both NLR and PLR identified a particularly high-risk population, with worse OS (HR 1.69, p=0.0020) and PFS (HR 1.58, p=0.0069) when compared to the patient group with low baseline NLR and PLR (Figure 1). High NLR and PLR as a combined marker remained an independent predictor of OS in multivariate analysis after adjusting for multiple clinical variables (HR 1.91, p=0.008).

(See next page)
Conclusion: Increased baseline ANC, NLR, and PLR were associated with worse overall and progression-free survival, and the combination of both high NLR and PLR denoted a subgroup with especially poor outcomes. These findings will need to be validated in larger prospective studies to further assess their clinical utility.

P1.04-20 COMPUTATIONAL BIOLOGICAL MODEL PREDICTION OF PD-L1 EXPRESSION AND IMMUNOTHERAPY RESPONSE FOR KRAS MUTATED LUNG CANCER BASED ON CO-MUTATIONS
S. Padda1, J. Arendt1, S. Vali2, N. Singh3, S. Vasista4, U. Mitra2, T. Abbasi2, H. Wakelee1
1Stanford Cancer Institute/Stanford University School of Medicine, Stanford/CA/US, 2Cellworks Group, San Jose/CA/US, 3Cellworks Research India Pvt Ltd, Bangalore/IN

Background: Emerging data suggest that KRAS mutated non-small cell lung cancer (NSCLC) is a heterogeneous disease based on the presence of co-mutations. These co-mutations may impact PD-L1 expression, a predictive biomarker for PD-1/PD-L1 immunotherapy, and may result in differential responses to immunotherapy. Method: Genomic information of NSCLC patients, including 2888 from publically available datasets and 86 from Stanford University, was input into computational biological model (CBM) software (Cellworks Group, San Jose, CA). Customized computational protein network maps of disease characteristics were generated for each patient. CBM was used to predict PD-L1 protein expression and also response to PD-1/PD-L1 immunotherapy in KRAS co-mutation subsets using 3 key metrics: PD-L1 expression; Dendritic Cell Infiltration Index (9 chemokine markers); and Immunosuppressive Biomarker Expression (14 markers). Result: The major co-mutations observed with the KRAS mutation were in tumor suppressor genes (TP53, STK11, CDKN2A, KEAP1) and a downstream effector (PIK3CA). Using the CBM approach, KRAS mutated NSCLC tumors with TP53 co-mutations had the highest prevalence of PD-L1 protein expression whereas tumors with KRAS/KEAP1 and KRAS/STK11/KEAP1 co-mutations were associated with the lowest expression. Expression of PD-L1 in tumors with KRAS/STK11, KRAS/CDKN2A, KRAS/PIK3CA co-mutations, and KRAS without co-mutations was higher than in tumors with KRAS/STK11/KEAP1 and KRAS/KEAP1 co-mutations. Of the 30 NSCLC tumors in the Stanford dataset with available PD-L1 immunohistochemistry results, including 19 with KRAS/TP53 and 11 with KRAS/KEAP1 or KRAS/STK11/KEAP1, CBM accurately predicted PD-L1 expression in these two groups at rates of 79% and 72%, respectively. In regards to prediction of response to PD-1/PD-L1 immunotherapy, CBM predicted the majority of patients with KRAS/KEAP1 and KRAS/STK11/KEAP1 to be non-responders, whereas CBM predicted the majority of patients with KRAS/TP53, KRAS/PI3KCA, and KRAS without co-mutations to be responders. The proposed mechanism for KRAS co-mutations’ impact on PD-L1 expression from the CBM model integrates differential activation of (i) downstream pathways of KRAS (PI3K/AKT, RAF/ERK, and RAL) and (ii) transcription factors involved in PD-L1 expression (i.e., MYC, HIF1α, NFKB, AP1, and STAT1/3). Conclusion: KRAS mutated NSCLC is emerging as a diverse disease based on co-mutations. The CBM approach demonstrates that PD-L1 expression varies among KRAS co-mutation subtypes along with likelihood of response to PD-1/PD-L1 immunotherapy. CBM provides proposed mechanisms underlying these differences and therefore, provides further rationale to examine more precise delivery of immunotherapy.

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.04-21 THE UTILITY OF PD-L1/CD8 DUAL IMMUNOHISTOCHEMISTRY FOR PREDICTION OF RESPONSE TO IMMUNOTHERAPY IN NON-_SMALL CELL LUNG CANCER (NSCLC)
M. Rosenbaum1, S. Khosrowjerdi2, V. Kamesan3, S. Digumarthy4, J. Gainor5, M. Mino-Kenudson5
1Pathology, Warren 219, Massachusetts General Hospital, Boston/US; 2Tufts School of Medicine, Boston/MA/US; 3Medicine, Massachusetts General Hospital Cancer Center, Boston/MA/US; 4Massachusetts General Hospital, Boston/US;
5Massachusetts General Hospital, Boston/MA/US

Background: PD-L1 immunohistochemistry (IHC) is an important predictive biomarker for PD-L1 blockade in advanced non-small cell lung cancer (NSCLC); however, this assay is imperfect. The presence of CD8+ tumor infiltrating lymphocytes (TILs) may be a complimentary biomarker for response to immunotherapy. Thus, we examined the performance of PD-L1/CD8 dual IHC (dIHC) in two cohorts of NSCLC patients receiving immunotherapy.

Method: Patients were identified through retrospective review of medical oncology and pathology databases. The first cohort predominantly received nivolumab as a 2nd or later line treatment; tissue samples were obtained at diagnosis. The second cohort received pembrolizumab as a first line therapy, and tissue samples were procured immediately before the initiation of immunotherapy. PD-L1/CD8 dIHC was performed on those tissue samples. Percentage of tumor cells with membranous PD-L1 expression and CD8+ stromal cells were measured, and TILs were semi-quantitatively evaluated. The quantities of CD8+ T cells were dichotomized with appropriate cut-offs.

Results: Eighty-four patients were identified, including 60 in the Nivolumab cohort (NC) and 24 in the Pembrolizumab cohort (PC). In the NC, PD-L1 expression ≥1% was marginally associated with improved progression-free survival (PFS, P=0.09), and an increased rate of response. PD-L1+ TILs and stromal cells did not correlate with outcome. However, a subset of PD-L1-positive patients who showed abundant CD8+ TILs and stromal cells had significantly reduced PFS (p=0.04). In the PC cohort, all cases chosen exhibited PD-L1 expression in ≥50% of tumor cells. Increased CD8+ TILs were correlated with improved PFS (p=0.0194), and an increase in both CD8+ TILs and stromal cells was also associated with improved PFS (p=0.0238).

Conclusion: Although limited by small sample size, this study suggests that PD-L1/CD8 dIHC improves the prediction of response to the PD-L1/PD-1 blockade in advanced NSCLC patients when it is performed on tissue samples obtained immediately before the initiation of the blockade as first-line therapy. However, for the 2nd or later line of treatment, dIHC on archival tissue samples obtained before initial therapy provides a useful but less clear picture of the tumor immune microenvironment. Reduced PFS seen in patients with PD-L1 expression and abundant CD8+ TILs and stromal cells may be due to T-cell exhaustion after the chemotherapy before the initiation of immunotherapy.

P1.04-22 CD73 IMMUNOHISTOCHEMICAL EXPRESSION IN MALIGNANT CELLS AND CORRELATION WITH IMMUNE INFILTRATE IN NON-SMALL CELL LUNG CARCINOMA (NSCLC).
R. Salazar1, J. Solorzano1, L. Solis1, C. Behrens1, B. Mino1, E. Parra1, J. Zhang1, A. Vaporsciyan1, D. Rice1, N. Kalhor1, C. Moran1, D. Gibbons2, A. Weisfuss2, B. Sepesi3, I. Wistuba3
1Departments of Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston/US; 2Translational Molecular Pathology, The University of Texas MD Anderson Cancer Center, Houston/US; 3Thoracic and Head and Neck Medical Oncology, The University of Texas MD Anderson Cancer Center, Houston/US.

Background: CD73 is a potential target for lung cancer immunotherapy involved in the adenosine pathway that induces tumor microenvironment immunosuppression. We investigated the immunohistochemical (IHC) expression of CD73 in a large cohort of NSCLC and correlated with tumor's clinical, pathological, molecular and immune cells infiltration data.

Method: We examined 175 surgically resected stages I-III formalin-fixed and paraffin-embedded NSCLC tumors tissue microarrays, including 107 adenocarcinomas (ADC) and 68 squamous cell carcinomas (SqCC). For IHC, we used the anti-CD73 antibody (clone D7F9A, Cell Signaling Technology) and evaluated membrane (basolateral and luminal) expression in malignant cells.

In a subset of cases, CD73 IHC expression was correlated with data available on: a) CD73 gene mRNA expression (Illumina arrays; n=91); b) tumor status and KRAS mutations; and c) immune cells infiltration (CD3, CD4, CD8, CD68, CD45RO, CD57, FOXP3, and granzyme B) and immune checkpoints expression (PD-L1, PD-1, ICOS, TIM-3, IOD-1, B-7H3, B-7H4, VISTA and OX40) assessed by IHC and microarray analysis (n=172). Results: ADC showed higher CD73 expression than SqCC (p=0.0001). Pathological stage I ADCs showed higher CD73 expression than higher tumor stages (p=0.0419). Using any level of CD73 expression (≥1%) CD73 was expressed in 73% and 40% of ADCs and SqCCs, respectively. High expression (>50% of malignant cells) was detected in 35% of ADCs and 20% of SqCC. No other significant correlations with clinical-pathological variables, including patients' outcome were found.

Interestingly, ADCs with EGRF (p=0.04) and KRAS (p=0.02) mutation expressed higher CD73 levels than wild-type tumors. In ADC, CD73 IHC expression correlated significantly with the density of immune T CD3+, CD4+, CD8+, CD45RO+ and FOXP3+ cells, as well as macrophages CD68+ cells in tumors (r values range: 0.22-0.45; P values range: 0.01-0.12). Overall, we did not find significant correlation between CD73 immunostaining and the IHC expression of the immune checkpoints examined. CD73 IHC expression correlated positively with mRNA CD73 gene expression levels in all NSCLCs (r=0.6; P=0.0001), ADCs (r=0.6; P=0.0001), and SqCCs (r=0.49; P=0.0001) history.

Conclusion: We identified that CD73 protein expression is associated with tumor's clinical, pathological, molecular and immune cells infiltration, and notably, with tumor’s EGRF and KRAS mutation. Our data suggest that CD73 is a potential target for NSCLC, particularly for adenocarcinoma histology (Supported by grants CPRIT RP160668 and UT Lung SPORE).

P1.04-23 EXPRESSION OF EMERGING IMMUNOTHERAPY TARGETS IN EARLY-STAGE SQUAMOUS LUNG CARCINOMA
1Division of Medical Oncology, University of Colorado Anschutz Medical Campus, Aurora/CO/US; 2Division of Biostatistics and Epidemiology, Department of Healthcare Policy & Research, Weill Cornell Medicine, New York/NY/US; 3Pathology and Immunology, Washington University School of Medicine, St. Louis/US; 4Division of Medical Oncology, Washington University School of Medicine, St. Louis/US; 5University of Michigan, Ann Arbor/MI/US; 6Thoracic Surgery, Brigham and Women’s Hospital, Boston/MA/US; 7Medical Oncology, Princess Margaret Cancer Centre, Toronto/CA/Canada; 8Department of Pathology, University of Colorado, Aurora/CO/US; 9Department of Hem-Oncology, UC Davis Comprehensive Cancer Center, Sacramento/CA/US; 10Biobank & Translational Research Core, Duke University, Durham/US; 11Brigham and Women’s Hospital, Harvard Medical School, Boston/US; 12Princess Margaret Cancer Centre, Toronto/CA/Canada; 13Biorepository, ON/CAD; 14Surgery, Duke University, Durham/NC/US; 15University of Colorado Cancer Center, Aurora/CO/US

Background: Anti-PD1/PD-L1 immunotherapy has demonstrated response in approximately 20% of selected advanced non-small cell lung cancer (NSCLC) patients. Strategies involving combination immunotherapies are under investigation to improve the overall response to immunotherapy. The objective of this study was to identify the expression of emerging immune targets in a cohort of early-stage squamous lung carcinoma (SqLC), which may be used to design combination immunotherapeutic approaches.

Method: 202 early stage (I-II) SqLC resected patient tumors and corresponding clinical data were collected from 6 cancer centers as part of the SPECS II program. Fourteen emerging immune targets or targeted axis were selected based on their advanced stage of development in preclinical clinical studies. The mRNA expression level of these targets and PD-1/PD-L1 were determined by Affymetrix U133A gene expression profiling. The correlations among these targets and the overall survival were evaluated.

Result: The mRNA levels of the immune molecules which were grouped on PD-1 protein expression in early stage SqLC are shown in Figure 1. No correlation was
found between the mRNA level of PD-L1 and the other immune targets expressed on APC/tumor cells, except PD-L2 (r2 = 0.41, p < 0.00001). We found that the immune cell receptor, CD226, correlated with CD96 and CD112R respectively (r2 = 0.514, p < 0.00001; r2 = 0.476, p < 0.00001), and CD96 correlated with CD112R (r2 = 0.644, p < 0.00001) as well. In addition, higher expression of GAL-9, CD48 and ICOS were associated with better prognosis (p = 0.0358, HR = 0.249 (0.068, 0.912); p = 0.0309, HR = 1.61 (1.04, 2.49); p = 0.0429, HR = 2.47 (1.03, 5.93)).

### Conclusion

Several emerging immune targets were expressed at higher levels than PD-L1 in this early stage SqLC cohort. The mRNA levels of all immune targets evaluated were independent of PD-L1 expression, except PD-L2. The expression of GAL-9, CD48 and ICOS were identified as prognostic. These results may provide important information in the design of future combination immunotherapies for early-stage SqLC.

### Keywords

emerging immunotherapy targets, early stage squamous lung carcinoma

PD-L1, programmed death ligand 1; DCBx, Digital Core Biopsy *Based on pembrolizumab categories as: 1st line ≥50%, 2nd line 1-49%; nivolumab categories as: ≥1% (for adenocarcinoma)

**Conclusion**: In the majority of cases, three digital core biopsies achieved closest correlation with the whole tumour, with little greater accuracy achieved by assessing four cores or more. Correlation was weakest when expression was low and very focal, an important consideration in view of the importance of the ‘1% cut-off’ used commonly to guide immune checkpoint therapy. Using this model as a guide, a single good quality biopsy (2x10mm² area) is sufficient for most tumours scoring 1% or greater PD-L1 expression. However, in the lower range of expression, re-biopsy might be routinely considered if there is doubt about specimen adequacy.

P1.04-25 THE IMPLICATION OF FRAMESHIFT MUTATION BURDEN IN NEOANTIGEN AND IMMUNE CELL LANDSCAPE IN NON-SMALL CELL LUNG CANCER (NSCLC)

Y. Chae1, S. Chang1, T. Ko1, K. Rhe1, M. Cruz1, M. Hhave1, J. Anker1, A. Davis1, W. Iams1, V. Wang2, J. Chuang2, L.C. Park1

1Department of Medicine, Northwestern University Feinberg School of Medicine, Chicago/IL/US, 2The Jackson Laboratory, Bar Harbor/US

Background: Recent research has shown an association between enrichment of insertion and deletion (indel) mutations and tumor-specific neoantigens, which in turn correlated with T-cell activation in renal cell carcinomas. Furthermore, frameshift indel (fsindel) mutation counts were significantly associated with clinical response to immune checkpoint inhibitors (ICIs) in melanoma patients. However, little is currently known about such associations in NSCLC. Method: Neoantigen counts were based on CloudNeo, a cloud pipeline used for identifying patient-specific neoantigens. The immune cell signatures of 31 distinct immune cell types of samples were derived from RNA-sequencing of 812 immune metagenes obtained from The Cancer Genome Atlas. 511 lung adenocarcinoma (ADC) and 471 squamous cell carcinoma (SqCC) patient samples were divided into four quartiles (Q1-Q4) according to the number of fsindel mutations in order to compare neoantigen counts and immune cell infiltration. Fsindel mutations were identified from mutation annotations generated by the Genomic Data Commons’ MuTect2 somatic variation calling workflow. Result: The range of fsindel count of ADC and SqCC were 0-139 and 0-150, respectively, while the median fsindel count was 7 and 8, respectively. Neoantigen count showed a significant positive association with fsindel in both ADC and SqCC (p<0.0001, p<0.01 respectively). Furthermore, a higher number of fsindels was associated with significantly increased activated CD4 and CD8 T-cell infiltration in ADC (Figure 1. p<0.001, p<0.01, respectively), while a similar trend was observed in SqCC for CD4 and CDB T-cells, although not significant (Figure 1. p=0.056, p=0.341, respectively).

Conclusion: We report for the first time the association between fsindels and higher neoantigen burden and infiltration of activated CD4 and CD8 T-cells in human NSCLC. As the presence of immune cells has been shown to be an important factor in determining response to ICIs, our findings suggest that fsindels could potentially be used as a predictive marker for immunotherapy.

P1.04-26 PROSPECTIVE IMMUNO-BIOBANK IN NSCLC

C. Py, A. Addeo, G. Gutknecht, A. Friedlander, A. Vuilleumier, P. Dietrich

Hug, Genève/CH

Background: Immune system could recognize tumor cells and eliminate them. T lymphocytes play an essential role in recognizing and lysing tumor cells. However, the humoral response (antibodies) seems also important. Recently, therapeutically progresses have been obtained with monoclonal antibodies that target inhibitory molecules expressed by T lymphocytes (anti-CTLA4, anti-PD1). Those antibodies induce reactivation or improvement of T lymphocytes' lysing capacities. This clinical benefit can last for years and has been observed in several types of tumors. This is the beginning of a therapeutic revolution and hundreds of clinical trials are on-going with the objective of better exploitation of this strategy. Several steps are needed in order to increase the proportion of patients who benefit from immunotherapies. We currently do not understand completely the reason why an immune response could be efficient or not (spontaneously or after treatment), the respective role and interactions between humoral and cellular responses and mechanisms involved in the development of side effects observed in patients. Method: All NSCLC patients who are candidate for Immunotherapy treatment regardless of staging and line of treatment cancer will be identified within our oncology department. Blood sampling will be performed (50 to 100 ml) at several time points: before any immunotherapy and repeated every 3 months or, in case of side effects or in case of extra-ordinary evolution. We will investigate cellular (T lymphocytes) and humoral (B lymphocytes) immune responses. We will also do a sequencing of the tumor in order to investigate genetic alterations. We will question the correlations between immune response and tumor pathological and molecular characteristics, as well as the impact of therapies administered to the patients on their immune response. Result: We have recruited 12 patients so far, on treatment with immune checkpoint inhibitor. We are going to perform another sampling 3 months after the beginning of the treatment (9 patients at the present time). Currently, we are continuing to recruit patients. The first analysis will be performed once we have 50 patient samples were divided into four quartiles (Q1-Q4) according to the number of fsindel mutations in order to compare neoantigen counts and immune cell infiltration. Fsindel mutations were identified from mutation annotations generated by the Genomic Data Commons’ MuTect2 somatic variation calling workflow. Result: The range of fsindel count of ADC and SqCC were 0-139 and 0-150, respectively, while the median fsindel count was 7 and 8, respectively. Neoantigen count showed a significant positive association with fsindel in both ADC and SqCC (p<0.0001, p<0.01 respectively). Furthermore, a higher number of fsindels was associated with significantly increased activated CD4 and CD8 T-cell infiltration in ADC (Figure 1. p<0.001, p<0.01, respectively), while a similar trend was observed in SqCC for CD4 and CDB T-cells, although not significant (Figure 1. p=0.056, p=0.341, respectively).

Conclusion: We report for the first time the association between fsindels and higher neoantigen burden and infiltration of activated CD4 and CD8 T-cells in human NSCLC. As the presence of immune cells has been shown to be an important factor in determining response to ICIs, our findings suggest that fsindels could potentially be used as a predictive marker for immunotherapy.

P1.04-27 SAFETY OF IMMUNOTHERAPY IN NON-SMALL CELL LUNG CANCER (NSCLC) IN THE REAL-LIFE SETTING: A SINGLE-INSTITUTION EXPERIENCE FROM ARGENTINA.
M. Bluthgen1, M. Tamburelli2, C. Calderon2, J. Castillo2, C. Bas2, G. Gomez Abuin2, S. Sena1
1Thoracic Oncology, Hospital Aleman, Buenos Aires/AR, 2Oncology, Hospital Aleman, Buenos Aires/AR

Background: Immunotherapy (IO) targeting programmed death-1 receptor (PD-1) has become standard of care in NSCLC treatment. Therefore, many patients will be at risk of developing toxicities from these treatments, representing a new challenge in daily clinical practice. We assessed its safety and activity in advanced NSCLC patients in the real-life setting. Method: We conducted a retrospective analysis of patients with NSCLC treated with immunotherapy at a single institution between January 2016 and January 2018. Safety and efficacy analyses were made by treating physician according to CTCAE 4.0 and RECIST 1.1 respectively and retrospectively collected from medical records. Kaplan-Meier method was used to estimate progression-free survival (PFS) and overall survival (OS). Result: Twenty-seven patients were included. Median age was 66 years [range 45 - 79], 67% were male, 89% (n=24) had ECOG performance status (PS) of 0-1; all patients had advanced disease, with 2 up to 6 metastatic sites in 52% (n=14) of the cases; 45% (n=12) had been tested and were positive for PDL-1 (≥1%). Almost all patients received immunotherapy as first or second-line treatment (n=23, 85%). A median of 6 cycles [range 1 - 34] had been administered, with 60% exposed to nivolumab (n=16) and 40% (n=11) to pembrolizumab. Median follow-up since IO was 18 months [range 0.5 - 2.5]. Seven patients achieved partial response and eight had stable disease, giving an overall response rate of 26% and a 56% disease control rate; 44% presented progressive disease. Median PFS was 5.1 months [95%CI 2 - 8.1] and median OS was 19.3 months [95%CI 2.3 - 36.3]. A total of 10 patients (37%) developed high grade toxicity. The most common grade 3-4 related events were asthma (n=5), adrenal insufficiency (n=2), infection (n=2), hypothyroidism (n=1), hepatitis (n=1), renal insufficiency (n=1) and thrombocytopenia (n=1) among others. Seven patients should discontinue treatment, 5 of them received glucocorticoids and almost all of them had full recovered after corticoid treatment (n=5). Conclusion: Activity of immunotherapy was comparable to that reported in previous studies. However, high grade toxicity rates in our practice were much higher than those reported in clinical trials, despite the highly similar proportion of patients with good performance status in both settings. Although studies populations are highly selected, this finding must lead us to question our ability in early recognition and prompt management of adverse events in daily practice.

Keywords: NSCLC, immunotherapy, toxicity

P1.04-28 BASELINE MARKERS OF INFLAMMATION AND OUTCOME WITH NIVOLUMAB IN PRETREATED NON SMALL CELL LUNG CANCERS: A RETROSPECTIVE STUDY.
A. Russo, A. Battaglia, G. Provazza, G. Lo Certo, G. Ricciardi, M. Pignotta, A. Scimone, G. Toscano, V. Adamo, T. Franchina
Medical Oncology Unit A.O. Papardo & Department of Human Pathology University of Messina, Messina/IT

Background: Nivolumab is a novel therapeutic option in pre-treated Non Small Cell Lung Cancer(NSCLC), independently of tumor histology and PD-L1 status. However, predictive biomarkers are lacking. We aimed to evaluate whether there is a correlation between some baseline markers of inflammation and response of patients (pts) treated with Nivolumab. Method: All consecutive NSCLC pts treated with Nivolumab between Aug. 2015- Dec. 2017 at our Institution were analyzed. Baseline characteristics were collected and correlated with the outcome. Derived neutrophil-to-lymphocyte (NLR) and platelet-to-lymphocyte (PLR) ratios were calculated as: neutrophil count/white blood count – neutrophil count. Platelet-to-lymphocyte (PLR) ratio was defined as platelet count/lymphocyte count. Overall survival (OS) was defined as time from Nivolumab start to death and Progression Free Survival (PFS) as time from Nivolumab start to progression disease or death for any cause. OS and PFS survival were estimated using the Kaplan-Meier method. Survival curves were compared using the log-rank test. Result: We included 45 consecutive NSCLC pts treated with Nivolumab. Baseline characteristics were as follows: median age 69 years (range 46-78), sex male 71.1%, ECOG PS 1 (n=28), squamous histology in 51% and non-squamous in 49%. After a median follow-up of 16 months (mos), median PFS was 4.0 mos (CI 95%, 2-8) and median OS was 9.0 mos (CI 95%, 4-15). High

P1.04-29 SECOND OR THIRD LINE NIVOLUMAB VERSUS FIRST LINE NIVOLUMAB IN PATIENTS WITH PREVIOUSLY TREATED ADVANCED NON SMALL CELL LUNG CANCER (NSCLC)
Oncologia Medica, Hospital Virgen de La Salud, Toledo, Toledo/ES

Background: The aim of the study was to report outcomes in advanced NSCLC patients treated with Nivolumab after progression to one versus two or three lines of chemotherapy from our everyday clinical practice. Exploratory assessments include the progression-free survival (PFS) and overall survival (OS), the rates of chemotherapy retreatment after Nivolumab progression and toxicity profile. Method: Elegibility criteria included, histologically or cytologically confirmed stage IV NSCLC without EGFR mutated or ALK traslocated genes treated with Nivolumab when relapsed after 1 versus 2 or 3 prior lines of chemotherapy from January of 2016 to current date. Result: From January of 2016 to January of 2018 , a total of 61 patients were enrolled in the study from our Hospital . The patients demographics were: median age 63 years, 4.9% (n=3) female and 95% (n=58) male. There were 59% (n=36) non squamous-cell and 41% (n=25) squamous-cell carcinoma. 96% (n=59) have received platinum-based therapy previously to Nivolumab : 57% (n=34) combined with Premetrexed and 41% (n=25 ) with other drugs. 60.7% (n=37) received Nivolumab at second line and 39.3% (n=24) at 3 or more line . 45,9 % (n=28) received chemotheraphy after Nivolumab. These chemotherapy schemes includes Bevacizumab in 40% of cases Grade 1-2 treatment related adverse events (AEs) occurred in 32% patients and the most common ones were endocrine 16% (n=7) and neumonitis 4% (n=2) but there were one case isolated of grade 3-4 encephalitis, nephritis and hypophysitis The 4% (n=29 patients need to be admitted to the hospital due Nivolumab toxicity versus 16% due to chemotherapy toxicity. The median of PFS with Nivolumab was 3 months for both groups IC 95% (0.7-9.9) and median OS for second line Nivolumab was 6 months IC 95% (2.7-9.2) and for Nivolumab at 3rd and sucesive lines of 9 months IC 95% (3.7-14.2) Median PFS for chemotherapy after Nivolumab was 5.3 months (2-12 months) Median OS was 18 months for second line Nivolumab and 26 months for the other patients and OS for all population was 21 months IC 95% (15.2 y 26.7) Conclusion: Data suggests that Nivolumab is effective and well tolerated in no selected metastatic NSCLC enabling survival of 21 months for these patients with an acceptable toxicity profile. Chemotherapy and antiangiogenic based treatments after Nivolumab are effective and well tolerated. This support benefit in heavily chemotherapy pretrreated patients: a crucial question that we can not ignore.

P1.04-30 A POTENTIAL EFFECT OF DIABETES MELLITUS AND METFORMIN USE ON EFFICACY OF IMMUNE CHECKPOINT INHIBITORS (ICI)
O. Jacob1, Y. Landini1, D. Reinhorn1, O. Icht1, E. Dudnik1, O. Rotem1, V. Reiman1, M. Sarfatty1, I. Finkel1, D. Hendler1, N. Peled1, A. Zeir1
1Davidoff Cancer Institute, Rabin Medical Center, Petah Tikva/IL, 2Cancer Institute, Soroka University Medical Center, Beer-Sheva/IL

Background: Numerous studies have demonstrated metformin use is associated with decreased cancer risk in the general population, as well as improved overall response rate (ORR), progression free survival (PFS) and overall survival (OS) in cancer patients undergoing chemotherapy.
Recent in-vitro studies found several new mechanisms which granted metformin the potential to increase cancer patients’ response to immune checkpoint inhibitors (ICI).

In this study we aim to explore the correlation between the daily use of metformin and benefit from ICI in patients with lung cancer and other solid malignancies. **Method:** We retrospectively evaluated all consecutive patients with metastatic solid malignancies treated with ICI therapy in a single institution between February 2015 and June 2017. Patients' clinical data was obtained from electronic medical records. Cox proportional hazards model and chi squared test were used to determine the associations between metformin use and ORR, median PFS and median OS. **Result:** Of 218 patients included in the analysis (202 NSCLC, 16 non lung cancers), 49 (22.5%) suffered from type 2 diabetes mellitus (T2DM). Of them 33 (15.1%) were treated with metformin and 16 (7.3%) received other, non-metformin therapy for T2DM. Comparison between non-diabetic and diabetic cancer patient groups demonstrated that mPFS was found to be significantly higher in the non-diabetic patients – 6.0 vs. 4.0 months (HR=1.47 [1.03-2.09], p=0.036). ORR was comparable (35.5% vs. 30.6%, p=0.52).

In the T2DM subgroup - mPFS and HR suggested increased efficacy in the metformin group compared to non-metformin, but the numbers were too small to reach significance 8.0 vs. 3.2 months (HR=0.63 [0.32-1.23], p=0.17). ORR was also numerically higher (36.4% vs. 18.8%, p=0.21).

In both comparisons, no significant differences were found in OS. **Conclusion:** This data suggests T2DM might be associated with decreased efficacy of ICI. While several studies demonstrated that diabetic cancer patients receiving chemotherapy gained much benefit with metformin use, the trend we observed regarding metformin use with ICI therapy was milder and should be further explored in larger prospective cohorts.

**P1.04-31 EFFICACY AND TOLERANCE OF IMMUNE-CHECKPOINT INHIBITORS IN EGFR, ALK/ROS 1 NON-SMALL-CELL-LUNG-CANCER (NSCLC): GFPC 03-2016 IMAD STUDY**  

**Background:** Patients with molecular alterations are considered to be poor candidates for immune-checkpoint inhibitors (ICI) on the second-line phase III trials. Here, we analyze the efficacy of ICI in EGFR ALK/ROS1 NSCLC patients in real world setting. **Method:** This retrospective multicentric study in EGFR, ALK and ROS1 NSCLC treated by ICI, analyzed clinical characteristics and outcomes (progression free survival (PFS), duration of ICI treatment and overall survival (OS), since initiation of ICI.  
**Result:** 51 patients were included from 20 centers in France: 100% adenocarcinoma, 60.7% never smokers, 58.8% female, 58 ± 8.8 years at age diagnosis (36-83), 82.3% EGFR mutated, 15.7 % and 2% ALK and ROS 1 translocated respectively. ICI was a third line treatment in 35.3% of cases, a fourth and more lines treatment in 64.7% of cases. Median PFS was 2.1 [95% CI: 1.4–3.2], for EGFR patients and 2.4 [95% CI: 2.1; NR] for ALK translocated patients; 3 months-PFS were 37.3% [95% CI: 26.1; 53.2]; 8 weeks ORR were 19.6% (10 pts with partial response). The median OS for the whole population was 14.7 [95% CI: 12.1–19.2] months, 13.9 [95% CI: 8.8–20] for EGFR patients, 19.2 [95% CI: 13.1; NR] for ALK translocated: 7 (13.7%) patients were treated more than 9 months by ICI; 21.6% (11/51) of patients reported toxicities, all < grade 3.

**Conclusion:** This retrospective, real world analysis shows that ICI has a similar clinical efficacy and a manageable toxicity profile in patients with EGFR, ALK/ROS 1 NSCLC patients treated as second line, third line or more. **Keywords:** immune-checkpoint inhibitors, Non-Small-Cell-Lung-Cancer, molecular alterations

**P1.04-32 PHASE I/II STUDY OF THE AZAR ANTAGONIST NIR178 (PBF-509), AN ORAL IMMUNOTHERAPY, IN PATIENTS (PTS) WITH ADVANCED NSCLC**  
A. Chiappori1, C. Williams1, B. Creelan1, T. Tanvetyanon1, J. Gray2, E. Haurat3, D.T. Chen4, R. Thapa2, A. Berg7, T. Boyle8, M. Sangani9, E. Morris10, A. Tao10, F. Hurtado10, L. Manenti10, J. Castro10, S. Antonia1

**Background:** ATP is catabolized to adenosine in the tumor microenvironment, leading to excess adenosine and immunosuppressive effects via immune checkpoint protein adenosine 2A receptor (A2AR). NIR178 is an oral A2AR antagonist that selectively binds and inhibits A2AR, reactivating T cell-mediated antitumor immune response. This Phase I/II study evaluated NIR178 in previously treated pts with advanced NSCLC (NCT02403193). **Method:** Pts (ECOG PS 0—1) had received ≥1 prior line of therapy; EGFR/ALK pts had failed prior TKI therapy. **Objective:** primary – determine MTD of single-agent NIR178; secondary – efficacy endpoints, PK, and evaluation of PD-L1 expression. **Result:** At 13 Dec 2017 data cut-off, 24 pts had been treated: median age 68 yrs; 46% male; 79% received prior immunotherapy; 46% male; 79% received prior immunotherapy; 22/24 (92%) pts had one or more (≥1) prior line of therapy; EGFR/ALK pts had failed prior TKI therapy. **Conclusion:** NIR178 is an oral A2AR antagonist that selectively binds and inhibits A2AR, reactivating T cell-mediated antitumor immune response. This Phase I/II study evaluated NIR178 in previously treated pts with advanced NSCLC (NCT02403193).

P1.04-33 RETROSPECTIVE DESCRIPTIVE ANALYSIS OF METFORMIN WITH ATEZOLIZUMAB IN ADVANCED NON-SMALL CELL LUNG CANCER IN THE OAK TRIAL
R. Pietras1, H. Xu2, X. Hu3, C. Matheny3, A. Sandler2, M. Patel1
1UCLA Division of Hematology-Oncology and Jonsson Comprehensive Cancer Center, Los Angeles/CA/US, 2Genentech, Inc., South San Francisco/CA/US, 3Hematology/oncology/transplant, University of Minnesota, Minneapolis/Min/US

Background: The randomized Phase III OAK trial investigated atezolizumab (anti–PD-L1) for treatment of advanced or metastatic previously-treated NSCLC. Atezolizumab significantly improved OS compared with docetaxel. Given that emerging studies have identified an association between metformin use and antitumor activity/immune interactions, we retrospectively explored metformin use in patients in the OAK study. Method: Patients received atezolizumab (1200 mg IV every 3 weeks (q3w)) until PD or loss of clinical benefit or docetaxel (75 mg/m2 IV q3w) until PD/unacceptable toxicity. Patients who received atezolizumab or docetaxel and did or did not receive metformin as concomitant therapy were retrospectively evaluated for ORR, PFS and OS (data cutoff, July 7, 2016). Unadjusted and adjusted comparisons between metformin users and non-metformin users were done. Result: Of the 425 patients randomized to atezolizumab, 36 received metformin; of the 425 patients randomized to docetaxel, 35 received metformin. Key baseline characteristics are shown in the table. Most metformin users started metformin before or within 30 days of study start (92% and 7% respectively). There was a numerical improvement in ORR in Atezo-Met patients compared with Atezo-NoMet patients (25% vs 13%; unadjusted P = 0.038 [adjusted = 0.093]), whereas there was no statistically significant improvement in ORR in Doc-Met patients compared with Doc-NoMet patients (17% vs 13%; unadjusted P = 0.499 [adjusted = 0.295]). There were no observable differences in PFS or OS in either the Atezo-Met vs Atezo-NoMet or Doc-Met vs Doc-NoMet groups (median PFS, 2.8 vs 2.8 mo and 4.2 vs 4.0 mo respectively; median OS, 12.6 vs 14.1 mo and 9.1 vs 9.7 mo, respectively). Conclusion: Encouraging response rates suggest patients may benefit from receiving concomitant metformin treatment with atezolizumab. Lack of difference in PFS and OS may be due to lack of treatment effect or lack of statistical power and requires further prospective investigation.

MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.04-34 STUDY ON TREATMENT OF STAGE IV SOLID TUMORS WITH MUTANT NEOANTIGEN SPECIFIC T CELLS
S. Qi1, J. Song2, S. Shangjie1, Q. Boyu1, Z. Xiaoling1, H. Sun2, Y. Wang2, Y. Guan2, X. Xia2, Y. Xin2, J. Shunchang1
1Oncology Department, The General Hospital of People’s Liberation Army, Beijing/CN. 2Geneplus-Beijing Institute, Beijing/CN

Background: As an important tumor immunotherapy, the specificity and efficiency of PD1 inhibitor is not yet satisfactory. The treatment of solid tumor with mutant neoantigen specific T (Nas-T) cells developed in this study is an adoptive cell therapy which is specific for each patient. The aim is to explore the difference in safety and efficacy between Nas-T cells and PD1 inhibitors, and to evaluate the charateristic of immune repertoire (IR) as predictive biomarker. Method: A total number of 11 patients with advanced solid tumors who failed after multiline treatments were recruited. They were treated with Nas-T cells, PD1 inhibitors and BSC, other 11 patients were treated with PD1 inhibitors and BSC as control. Peripheral blood was collected at baseline and per cycle (21-28d) respectively. Multiple PCR and NGS on TCR beta chain was used to detect IR. Result: Nas-T cells prolonged patients’ PFS. The safety was analyzed from routine blood urine stool test, coagulation function, liver and kidney function. There was no significant difference at baseline (P>0.05). Nas-T cells showed significant changes in TCR repertoir including Shannon and Evenness, P=0.017. Elevated Clonality may indicate amplification of tumor specific T cells which could recognize mutant neoantigen specifically.

Keys: Nas-T, PD1 inhibitor, immune repertoire

Keywords: Nas-T, PD1 inhibitor, immune repertoire

(See next page)
Conclusion: The combined immunotherapy of Nas-T cells and PD1 inhibitors is more effective than PD1 inhibitor alone in prolonging the PFS, and has a good safety. IR Clonality change shows its potential as a predictive biomarker.

Keywords: Immune Repertoire, Immunotherapy, NSCLC

Background: Nivolumab has been approved in 2nd line for advanced non-small cell lung cancer (NSCLC). However, more than half of the patients had progressive disease at 16 weeks, without any response and sometimes with deleterious progressions. This descriptive prospective study aimed to assess the characteristics of non responders with QP after IO and the following treatments. Method: From September 1\textsuperscript{st}, 2016 to August 31\textsuperscript{st}, 2017, patients (pts) treated by IO (second line or more) with QP≤16 weeks were included by 20 GFPC centers. NSCLC characteristics and outcomes responses, progression free survival (PFS) according to lines of treatments were recorded. Result: The sample included 319 pts: 64.3\% of 3.6, smokers/ex-smokers: 48.0\%–42.2\%, male: 70.8\%, PS012: 92.8\%–7.2\%, stage IV at diagnosis: 71.8\%; adenocarcinoma: 63.9\%, K-Ras mutated: 25.7\%. Only 29\% of patients had a PDL1 determination. 93\% of pts received first line therapy, 32\% second line, 10.3\% third line before IO. First line PFS (PS1) was 6.9m [6.43–7.8], PS2: 9.33m [1.2-19], PFS for IO was 1.7m [0.76–4.16]. 229 (71.8\%) patients had a IO PFS<2m; 14.7\% of these patients stopped the treatment for toxicity. Among the 146 pts evaluable for response, PR was found in 23\% of cases, SD in 30\%, and PD in 47\%. The table describe a comparison between two groups of QP during IO.

Background: Immune checkpoint inhibitors have shown efficacy in patients with NSCLC as monotherapy and in combination with chemotherapy. Tislelizumab is a humanized IgG4 monoclonal antibody to PD1 specifically engineered to minimize FcγR binding on macrophages, possibly minimizing negative interactions with other immune cells. In a phase 1 study, tislelizumab was generally well tolerated and showed antitumor activity; 200mg IV Q3W was established as the recommended dose. Method: This multi-arm phase 2 study, consisting of safety run-in and dose-extension phases, assessed tislelizumab in combination with platinum-based chemotherapy (by tumor histology) as a potential first-line treatment for Chinese patients with lung cancer. All patients received tislelizumab at 200mg Q3W in combination with 4–6 cycles of platinum-doublet until disease progression. Nonsquamous (nsq) NSCLC patients received pemetrexed + platinum Q3W for 4 cycles followed by pemetrexed maintenance, while squamous (sq) NSCLC patients received paclitaxel + platinum (A) or gemcitabine + platinum (B) Q3W, and small-cell lung cancer (SCLC) patients received etoposide + platinum Q3W.

Result: As of 21 Feb 2018, 48 patients (median age: 62 years [range: 36–75], 71\% male. 71\% current/former smokers) received tislelizumab treatment (median, 3 cycles [range: 1–7]); 44 patients remain on the study. Across the four cohorts, confirmed and unconfirmed partial responses were observed in 13 and 9 patients, respectively (Table). The most frequent AEs were chemotherapy-related hematologic toxicities. The most commonly reported grade ≥3 treatment-related AEs were neutropenia (20.8\%) and anemia (12.5\%); the most common grade 3 immune-related AEs were pyrexia (6.3\%) and rash (6.3\%). One sqNSCLC patient experienced a fatal myocarditis/myositis following one cycle of paclitaxel/cisplatin; all other treatment-related AEs were managed/resolved by study-drug interruption (n=15) or discontinuation (n=4) and appropriate treatment.

**P1.05 INTERVENTIONAL DIAGNOSTICS/PULMONOLOGY**  
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

**P1.05-01 INCIDENCE AND CLINICAL RELEVANCE OF NSCLC LYMPH NODE MICRO-METASTASIS DETECTED BY STAGING EBUS-TBNA**

A. Belanger1, J. Hollyfield2, G. Yacovone2, A. Seppe2, J. Akulian2, C. Turris2, A. Guignard2, M. Kandash1, P. Hadeed1, C. Lockwood1, D. Sepe1, M. Frechette1, D. Regez1, P. Chau2, A. Bonenfant1, I. M. K. D. Arora1, J. Etienne1, A. P. M. G. M. Landry1, D. A. Raymond1, J. S. Comeau1, M. A. Michaud1

1Pulmonary and Critical Care Medicine, University of North Carolina, Chapel Hill/US, 2University of North Carolina, Chapel Hill/US

**Background:** Appropriate staging of non-small cell lung cancer (NSCLC) patients is crucial to provide accurate prognostic information and select appropriate treatment. Several publications have reported an approximate 20% incidence of occult micro-metastasis (MM) in surgically resected lymph nodes (LN) pathologically interpreted as negative by hematoxylin and eosin staining (H&E). Detection of MM was associated with worsened survival. The majority of NSCLC lymph node staging is now conducted using endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA). The purpose of this study is to determine the frequency of detection of occult MM in EBUS-TBNA specimens and to evaluate the impact of the presence of MM on progression-free and overall survival.

**Method:** All patients undergoing EBUS-TBNA for NSCLC lymph node staging at our institution between September 2013 and October 2017 were eligible for inclusion. Patients were identified using provider-maintained case lists, operating or procedure room electronic schedules, and tumor board patient presentations. Patients were excluded if a definitive diagnosis of NSCLC was not obtained within 3 months of the EBUS-TBNA, patients underwent EBUS-TBNA for an indication of metastatic disease was present at the time of diagnosis. Patient cell blocks from the EBUS-TBNA procedure were evaluated by a cytopathologist using H&E staining according to standard guidelines. Patients with N2 or N3 disease on routine cytology examination were excluded. Cell blocks from the included patients were sectioned into five 5 mm sections spaced at least 10 mm apart and immunohistochemistry for pan-cytokeratin staining according to standard guidelines. The mean age and smoking history were 68 ± 10 years and 27 pack-year history, respectively. The patients were majority male (61%) and Caucasian (75%). Fifty-two percent of patients were stage III at the time of diagnosis, 34% were stage II, and 14% were stage Ia. Three patients (6.8%) were found to have pan-cytokeratin positive MMs. All MMs were confirmed by EBUS-TBNA needle aspiration examinations and were associated with poor clinical outcomes. If prospectively confirmed in a larger study, these results have significant implications for EBUS-TBNA specimen analyses and the current NSCLC staging paradigm.

**Conclusion:** Our results suggest that among PET-positive MMs, there is a significant correlation between SUVmax magnitude and likelihood of detecting true LN metastasis by EBUS. Additional studies should aim to further characterize this relationship.

**Keywords:** non-small cell lung cancer, maximum standardized uptake value, endobronchial ultrasound

**P1.05-02 ENDOBRONCHIAL ULTRASOUND-TRANSBRONCHIAL NEEDLE ASPIRATION FOR LYMPHOMA IN PATIENTS WITH MEDIASTINAL LYMPHADENOPATHY**

Y. Choi1,2,3,4,5

1Department of Pathology, Chonnam National University Medical School, Gwangju/KR

**Background:** Surgical excision and core biopsy are the current preferred sampling techniques for diagnosing lymphoma. However, In patients who present with intrathoracic adenopathy that is suspicious for lymphoma, endobronchial ultrasound-guided transbronchial needle aspiration (EBUS-TBNA) is an attractive option.

**Method:** The cases of patients who had undergone EBUS-TBNA for 31 cases of suspected lymphoma were retrospectively reviewed. **Result:** EBUS-TBNA diagnosis was that: 6 cases was diagnostic lymphoma, but not subtyping, 6 cases was specific lymphoma using cell block (2 cases of diffuse large B-cell lymphoma, 1 case of mantle cell lymphoma, 1 case of NK-T cell lymphoma, 1 case of anaplastic large cell lymphoma, and 1 case Hodgkin lymphoma), 5 cases was granuloma, 4 cases carcinoma, 6 cases diagnostic lymphoid tissue without specific diagnosis, and 4 cases non-diagnostic. Of 31 cases, 14 (45.2%) were finally diagnosed with lymphoma. In EBUS-TBNA, these cases were diagnosed as lymphoma (12 cases) and non-diagnostic (2 cases). Other diagnosis in EBUS-TBNA was not finally diagnosed as lymphoma. **Conclusion:** EBUS-TBNA is effective at diagnosing suspected lymphoma in patients with mediastinal lymphadenopathy. A specific EBUS-TBNA features, such as granulomas and carcinoma, are associated without a probability of lymphoma.

**Keywords:** mediastinum, lymphoma, EBUS-TBNA

**P1.05-03 SIGNIFICANCE OF LYMPH NODE SUVMAX IN PREDICTING NODAL METASTASIS BY EBUS IN LUNG CANCER PATIENTS**

M. Guha1, S. Gilbert1, A. Seelyi, F. Shamji1, S. Sundaresan1, F. Villetreeve1, D. Mazaki1

1Faculty of Medicine, University of Ottawa, Ottawa/ON/CA, 2Ottawa Hospital Research Institute, The Ottawa Hospital, Ottawa/ON/CA, 3Division of Thoracic Surgery, The Ottawa Hospital, Ottawa/ON/CA

**Background:** Nodal staging of non-small-cell lung cancer (NSCLC) patients begins with imaging such as Positron emission tomography–computed tomography (PET-CT). It provides information about lymph node (LN) location, enlargement, and metabolic activity as measured by the maximum standard uptake value (SUVmax). However, more definitive information can only be obtained by direct sampling through cervical mediastinoscopy (Med) and/or endobronchial ultrasound-guided transbronchial needle aspiration (EBUS). There remains discrepancy when comparing the diagnostic accuracy of these two methods for detecting nodal metastasis. Further, there is inadequate data on the value of SUVmax in predicting nodal metastasis by EBUS.

**Method:** This was a retrospective analysis of 148 biopsy-confirmed NSCLC patients who underwent Med and/or EBUS for staging purposes from 2010-2015 (2013 excluded). Two groups matched by age, sex, and year of procedure were analyzed to determine if the diagnostic accuracy was comparable between the two methods. Primary tumour and LN SUVmax was correlated with the likelihood of finding LN metastasis by either method. Chi-squared tests and Student’s t-tests were used to assess for significance where appropriate.

**Result:** The mean SUVmax of true positive LNs was significantly higher than true negative LNs sampled by EBUS (7.77 vs. 4.06, p=0.0047, t-test). Among PET-positive LNs, there was a significant correlation between likelihood of positive findings by EBUS and increased SUVmax (p<0.001, Chi-squared test). There were no significant differences between Med and EBUS in sensitivity, specificity, PPV, or NPV. However, Med had significantly higher diagnostic yield (p<0.0001, Chi-squared test).

**Conclusion:** Our results suggest that among PET-positive LNs, there is a significant correlation between SUVmax magnitude and likelihood of detecting true LN metastasis by EBUS. Additional studies should aim to further characterize this relationship.

**Keywords:** non-small cell lung cancer, maximum standardized uptake value, endobronchial ultrasound
Background: CT guided transbronchial biopsy has been reported to have a high accuracy for the diagnosis of peripheral lung lesion. Recently, C-arm cone-beam CT (CBCT) with a flatpanel detector system has been developed and offers greater flexibility in orientating the detector around the patient than closed CT gantry systems. We have introduced CBCT to the transbronchial lung biopsy and report the usefulness of the method. Method: Patients with undiagnosed peripheral lung lesions 3 cm or less in size between June 2016 and August 2017 were enrolled. An ultrathin bronchoscope was inserted as far as possible to the target bronchus by comparing the direct vision and virtual bronchoscopic navigation images displayed simultaneously at monitor. After reaching the target bronchus, the biopsy forceps was introduced to the target bronchus under conventional fluoroscopy. After the biopsy forceps reach the target bronchus, a CBCT scan data was taken. We categorized the CBCT findings into three types according to the distribution of the lesion and the forceps as follows: (Type A: The forceps clearly reached within the lesion. Type B: It could not be categorized into either type A nor B. Type C: The forceps could not reach the lesion.). The diagnosis yields of biopsy or cytology results was examined. Result: Twenty-two patients (12 males and 10 females) were included in the study and age ranged from 50 to 87 with average age of 72.8 years. Thirteen lesions were located at the upper lobe, seven lesions at lower lobe and one lesion at middle lobe. Size of the lesions ranged from 9 to 29 mm with average of 20 mm. They included 13 solid lesions and 8 mixed GGO lesions. Regarding CBCT type, A was 16 cases, B was 4 cases, and C was 1 case. Bronchoscopic diagnosis was malignant in 11 cases, benign in 10 cases (4 mycobacterium infections and 6 non-specific inflammations) and undiagnostic in 1 case. There was one false negative case whose bronchoscopic diagnosis as non-specific inflammation was finally proved as adenocarcinoma. Overall the diagnostic accuracy was 91% (20/22). Based on the CBCT category, the accuracy was 100% (17/17), 75% (3/4), 0% (0/1) in Type A, B and C respectively. Conclusion: CBCT guided bronchoscopy is valuable in the diagnosis of peripheral lung lesions and useful for confirming the position of the forceps.

P1.05 INTERVENTIONAL DIAGNOSTICS/PULMONOLOGY MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.05-07 CLINICAL SIGNIFICANCE OF PLEURAL INDENTATION OF LUNG ADENOCARCINOMA PRESENTED AS GROUND GLASS OPACITIES
H.J. Kim, C. Lee
Internal Medicine, Seoul National University Bundang Hospital, Seongnam/KR

Background: After the emphasis on lung cancer screening, incidental detection of ground glass opacities (GGOs) has increased. Such GGOs commonly have peripheral location and pleural indentation, which may increase the risk of visceral pleural invasion (VPI). Although the impact of pleural indentation among solid lung cancers is well established, such impact among GGO lung cancers is not well known. Method: Patients who underwent lung resection with curative intention of GGO lung cancer from April 2007 to January 2016 were retrospectively evaluated. Demographics, radiographic findings, pathological findings, and clinical outcomes including recurrence were analyzed. Result: A total 404 of patients were analyzed, and pleural indentation was observed in 258 patients (63.9%). All cancers turned out to be adenocarcinoma. Older age, worse lung function, longer diameter, and tumor shadow disappearance rate were associated with indentation. VPI was observed in 36 (9.9%) patients, and indentation was independently associated with VPI (odds ratio 9.34, p = 0.032) after adjustment of pleural attachment, diameter, and tumor shadow disappearance rate. During a median follow-up duration of 48.3 months, 34 (8.4%) patients recurred. Although indentation was not associated with earlier recurrence (adjusted hazard ratio 2.16, p = 0.168), concurrent pleural attachment with indentation was associated with recurrence among those with solid portion > 6mm (adjusted hazard ratio 3.06, p = 0.019). Conclusion: Pleural indentation was associated with increased risk of VPI in GGO lung adenocarcinoma. Although indentation itself did not increase the risk of recurrence, concurrent pleural attachment with indentation may increase the risk of recurrence among selected patients.

Keywords: Indentation, Ground glass opacity, visceral pleural invasion

P1.05 INTERVENTIONAL DIAGNOSTICS/PULMONOLOGY MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.05-08 SPREAD THROUGH AIR SPACES (STAS) IN INVASIVE MUCINOUS ADENOCARCINOMA OF THE LUNG: INCIDENCE, PROGNOSTIC IMPACT, AND PREDICTIVE FACTORS
M.A. Lee, H.Y. Lee
Department of Radiology, Samsung Medical Center, Seoul/KR

Background: Spread through air spaces (STAS) is a recently recognized as a novel negative impact on prognosis in lung adenocarcinoma, however was almost investigated non-mucinous adenocarcinoma. We investigated the incidence of STAS in invasive mucinous adenocarcinoma (IMA) of the lung and whether tumor STAS was a risk factor of disease recurrence even in IMA, and determined clinico-radiologic factors in patients with IMA harboring STAS. Method: We reviewed pathologic specimens and imaging characteristics of primary tumors from 132 consecutive patients who underwent surgical resection for IMA. On pathology, the presence of aeroogenous spread (AS), mucin, and STAS were evaluated. Two groups determined by STAS were compared with respect to clinical characteristics as well as CT imaging using the Pearson χ2 test or the Fisher exact test. Multivariate logistic regression was used to explore the clinico-radiologic features that facilitate the detection of STAS in IMA, for which receiver operating characteristic (ROC) curve analysis was performed to evaluate the predictive performance. The relationships between all variables including STAS and survival (overall survival [OS] and disease-free survival [DFS]) were analyzed by using Kaplan–Meier curves and Cox regression analyses. Result: Of 119 patients with full pathologic specimens, STAS was observed in 86 patients (73.2%). On multivariate analysis, IMA patients with STAS were significantly tended to be lobectomy (odds ratio [OR] = 7.120, 95% confidence interval [CI] = 1.184 to 42.825, P value = 0.032), older (OR = 2.979, 95% CI = 1.109 to 8.001, P value = 0.030) and the absence of peripheral GGO on CT (OR = 0.376, CI = 0.141 to 0.999, P value = 0.049), where the predictive model for presence of STAS showed discrimination performance with an area under the receiver operating characteristic curve (AUC) of 0.798 (95% CI = 0.711 to 0.884, P value < 0.005). The DFS was lower in patients with STAS compared with those without STAS, whereas there was no statistically significant difference (P value = 0.091). On multivariate analysis for DFS, STAS failed to be an independent predictor, but lymph node metastasis (hazard ratio [HR] = 2.505, 95% CI 1.288–11.089, absence of mucin on pathologic specimen (HR, 0.46; 95% CI 0.194–0.985) and CT angiogram sign (HR, 2.872; 95% CI 1.036–7.963) remained independent predictors for disease recurrence. Conclusion: IMA with STAS represented older age, absence of peripheral GGO on CT, more frequent lobectomy than limited resection. STAS was associated with reduced DFS, but failed to be a significant prognostic factor.

P1.05 INTERVENTIONAL DIAGNOSTICS/PULMONOLOGY MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.05-09 DIELECTRIC PROPERTY TEST FOR THE RAPID DIFFERENTIAL DIAGNOSIS OF LUNG NODULES/MASS
D. Lu1, X. Dong1, S. Feng1, X. Liu1, X. Shi1, H. Wu1, D. Diao1, P. Ren1, R. Cai1, Z. Huang1, H. Wang1, K. Cai1, X. Xin1, H. Ji1, Z. Wang1, C. Hong1, Y. Sun1, X. Yu1
1Thoracic Surgery, Nanfang Hospital, Guangzhou/CN; 2Thoracic Surgery, Nanfang Hospital, Southern Medical University, Guangzhou/CN; 3South China University of Technology, Guangzhou/CN; 4The First School of Clinical Medicine, Southern Medical University, Guangzhou/CN; 5College of Biomedical Engineering, Southern Medical University, Guangzhou/CN

Background: Developing new methods for rapid diagnosis for lung nodules/mass has always been one of the most attractive topics. And it has been found that the dielectric property, including permittivity and conductivity, varies from benign tissues to malignancies. However, no studies comparing the dielectric property between lung benign tumors to malignancies has been reported and whether dielectric property test could be used for differential diagnosis remains uncertain. Method: Patients with lung nodules/mass who received surgical resection were included for permittivity and conductivity test right after the occupying lesions were removed and before sent for pathological examination. The informed consents were obtained before surgery. Independent-samples T Test and multiple variables for ROC curve analysis were used. Result: More than 250 lesions were expected to be tested for calculating the differential diagnosing cutoff value. For each lesion, 4000 datasets of permittivity and conductivity at different frequencies from 1MHz to 4000MHz were collected. By far, 73 patients with 74 lung occupying lesions were enrolled for dielectric property test, including 19 lung benign tumors and 55 malignancies. Though the differences of mean permittivity and conductivity between the 2 groups were not statistically significant (p>0.05), there might be a tendency to distinguish the 2 groups. And the mean values of permittivity and conductivity and their independent values at frequency 1MHz, 500MHz, 1000MHz, 2000MHz, 2500MHz, 3000MHz, 3500MHz, 4000MHz were chosen as multiple variables for ROC curve analysis. With the false positive rate of 10%, the cutoff value P_cutoff was 0.8588 and the logistic regression formula for differential diagnosis were shown as followed, of which the area under ROC curve was 0.905. Funding The study was supported by the Presidential Foundation of Nanfang Hospital, Southern Medical University (2016B018).

Keywords: Indentation, Ground glass opacity, visceral pleural invasion

Conclusion: With more data collected, dielectric property test might become another rapid way of distinguishing lung malignancies from benign tumors.

Keywords: Dielectric property test, rapid diagnosis
P1.05-10 USEFULNESS OF RESPIRATORY DILATATION BALLOON IN TRACHEOBRONCHIAL STENOSIS REQUIRING SILICONE Y-STEMENT TREATMENT

Osaka City General Hospital, Osaka/JP

Background: The Dumon silicone Y-omentum (Novatech SA, La Ciotat, France) is useful for releasing tracheobronchial stenosis but requires sufficient predilation because of the weak expansion force of silicone Y-ments. We have performed mechanical expansion (debubling or coreout) by rigid bronchoscopy, microwave coagulation, and balloon expansion (Fogarty catheter). In recent years, however, we have used a respiratory dilatation balloon (CRE Pulmonary Balloon Dilator; Boston Scientific, Marlborough, MA). We investigated the feasibility, efficacy, and safety of stenting using a silicone Y-omentum or additional self-expanding metallic stent (SEMS), focusing especially on the usefulness of a pulmonary balloon dilator in patients with malignant tracheobronchial stenosis. Method: From May 2012 to November 2017, 75 patients (54 male, 21 female; mean age, 64 years; range, 30–91 years) who underwent Dumon silicone Y-omentum placement for malignant tracheobronchial stenosis in our department were retrospectively examined. Forty-six patients had lung cancer, 20 had esophageal cancer, 5 had tracheal carcinoma, and 4 had other carcinomas. All procedures were performed in the operating room under general anesthesia, and the patients were intubated via rigid bronchoscopy. The patients were divided into three groups according to the method of predilatation before stenting: no use of balloon expansion (Group N, n=36), use of a Fogarty catheter (Group F, n=22), and use of a respiratory dilation balloon (Group B, n=17). Result: Stents were implanted and symptoms were resolved in all patients. No operative death occurred. The types of indwelling stents were only a Y-omentum in 46 patients and a Y-omentum with additional SEMS in 29. Although the mean number of additional SEMS was significantly higher in Group B (0.7 stents/patient) than in Groups N and F (0.3 stents/patient, respectively), there was no difference in the median (range) operation time among Groups N, F, and B: 55 (32–115), 59 (29–110), and 49 (17–102) minutes, respectively. In the 46 patients who underwent placement of only a Y-omentum without a SEMS, the operation time was significantly shorter in Group B (n=6, 39 (17–64) minutes) than in Groups N and F (n=25, 53 (32–115) minutes) and F (n=15, 59 (29–106) minutes) (p=0.028). There were no differences in the amount of bleeding, postoperative performance status, or hospitalization days. Conclusion: A respiratory dilation balloon is useful for predilatation in patients with tracheobronchial stenosis requiring a silicone Y-omentum. Such balloons also contribute to a shorter operation time and more efficient procedure for severe stenosis requiring additional stenting.

Keywords: tracheobronchial stenosis, silicone Y-omentum, respiratory dilation ball

P1.05-11 ROLE OF EBUS-TBNA IN EVALUATION OF MEDIASTINAL LYMPHADENOPATHY AND Masses in patients with known or suspected extra-pulmonary malignancies

A. Nambrirajan1, M. Longchar1, S. Mallick1, A. Kakkar2, K. Madan2, S. Mathur1, D. Jain1
1Pathology, All India Institute of Medical Sciences, New Delhi/IN, 2Pulmonary Medicine, All India Institute of Medical Sciences, New Delhi/IN

Background: Endobronchial ultrasound guided transbronchial needle aspiration (EBUS-TBNA) has recently emerged as a minimally invasive and safe modality for the evaluation of mediastinal lymphadenopathy, particularly in staging of lung carcinoma patients. Our aim was to evaluate its utility in patients with non-pulmonary malignancies presenting with mediastinal lymphadenopathy. Method: A computerized database search was performed for all EBUS-TBNA aspirations performed from 2015 to 2017 on patients with known or suspected extra-pulmonary malignancy and presence of mediastinal lymphadenopathy and/or masses on imaging. All archived cytology material was reviewed and categorized as positive, negative and unsatisfactory. Follow-up histology samples served as comparison standard. Result: One-hundred-twenty-one patients were included. In 99 patients with known malignancy, primary sites were in the head and neck (25%), breast (22%), female genital tract (9%), lower gastrointestinal (GI)-tract (8%), genitourinary tract (7%), and upper GI-tract (5%). Six patients had history of hematolymphoid malignancy while primary site or type of malignancy was unknown in the remaining (18%). EBUS-TBNA diagnosed metastases or lymphoma relapse in 48 (40%), identified new malignancy in 18 (15%), granulomatous inflammation in 15 (12%), tuberculosis in 2 (3%), reactive lymphadenitis in 21 (17%) patients and was inadequate in 17 (14%) patients. Cell block was adequate in 43% (23/53) cases and was indispensable for diagnosis in 13% (7/53) cases. Subcarinal and right paratracheal lymphnodes were most commonly aspirated (77%) while hilar and paratracheal masses of non-lymphnode origin were assessed in 10% cases. Follow-up histology samples (available only in 13 cases) showed 100% concordance with EBUS-TBNA results (no false positive or false negative cases). Two cases unsatisfactory on EBUS-TBNA were positive for malignancy on histology. Conclusion: EBUS-TBNA is a highly efficient modality for the evaluation of mediastinal lymphnodes and masses in patients with extra-pulmonary malignancies with an overall diagnostic yield of 86%.

Keywords: mediastinal lymphadenopathy, extra-pulmonary malignancy, EBUS-TBNA
Conclusion: This study demonstrated that $^{18}$F-FDG PET/CT findings may predict postoperative acute exacerbation of IIP in lung cancer patients.

Keywords: acute exacerbation, Interstitial pneumonia, FDG PET/CT

P1.05-12 THE DEMONSTRATION OF THE POSSIBILITY OF THE PLEURA CRYO BIOPSYS – A PRELIMINARY REPORT
Thoracic Surgery and Lung Transplantation Department, Pomeranian Medical University, Szczecin/PL

Background: The demonstration of the possibility of diagnosing changes located in the parietal pleura by means of cryo probe guided by videopleuroscopy. Method: The study consisted of five patients with lesions of the parietal pleura and accumulation of fluid in the pleural cavity. The previous diagnostic procedures did not confirm the etiology of the hydrothorax, therefore, the patients were qualified for the videopleuroscopy under local anesthesia and sedation. The ultrasound examination confirmed the presence of the pleural fluid and videothoracoscopy introduced into the pleural cavity. The videopleuroscope was inserted into the pleural cavity, the fluid was removed and the parietal lesions were visualised. The 1.9 mm cryo probe was introduced through the 2 mm working channel of the videopleuroscope and samples of the parietal pleura were taken. The sampling procedure was repeated with standard forceps. Talc slurry administration and drainage of the pleural cavity were performed eventually. All the patient were discharged a few days after the procedure. Result: Mesothelioma was confirmed in one case, primary lung adenocarcinoma in one case, metastatic adenocarcinoma in one case, Ewing sarcoma in one case and chronic pleuritis in one case. Histology samples taken with the cryo probe were much bigger and of better quality than the samples taken by the forceps. Conclusion: The cryo probe guided by the videopleuroscopy is an effective and safe procedure regarding diagnosing pleural lesions suspected of the neoplastic disease. The cryo probe provides very good samples of the parietal pleura for the pathologic and immunohistochemistry evaluation.

Keywords: pleura, Videopleuroscopy, cryo biopsy

P1.05 INTERVENTIONAL DIAGNOSTICS/PULMONOLOGY
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.05-14 AUTOFLUORESCENCE MODE OF THORACOSCOPE IMPROVES VISUALIZATION OF VISCERAL INVASION DIAGNOSIS IN NON-SMALL CELL LUNG CANCER
H. Tazawa1, T. Sawada1, M. Takashima1, T. Matsumoto1, N. Kawakita1, M. Tsuboi1, H. Toba1, M. Yoshida1, Y. Kawakami1, K. Kondo1, A. Tanguku1
1Department of Thoracic, Endocrine Surgery and Oncology, Institute of Biomedical Sciences, Tokushima University Graduate School, Tokushima City/JP, 2Department of Oncological Medical Services, Graduate School of Biomedical Sciences, Tokushima University, Tokushima/JP

Background: Visceral pleural invasion of non-small cell lung cancer is an important prognostic factor, and tumors with visceral pleural invasion are classified as T4a, even if they are 3 cm or less. However, visceral pleural invasion is usually diagnosed by postoperative pathologic examination and it is difficult to diagnose it by preoperative imaging or intraoperative macroscopic inspection. This study was conducted to evaluate the usefulness of autofluorescence mode of thoracoscope for the diagnosis of visceral pleural invasion of non-small cell lung cancer compared with white light mode diagnosis. Method: Two thoracic surgeons blind to pathologic diagnosis reviewed operation videos of 56 cases and evaluated visceral pleural invasion under white light and autofluorescence modes using a D-Light Autofluorescence system (Karl Storz, Tuttingen, Germany). 4 Lung tumors were resected and evaluated histopathologically using elastic stains. The mean age was 67 years (18–85 years). 33 patients (55%) were male. They included 43 adenocarcinomas, 11 squamous cell carcinoma and 2 others. The mean tumor size was 22 mm (7–30 mm). There were 9 pathological visceral pleural invasion positive cases. For white light mode, if either one of the following pleural invasion was observed, ++ (2 or more), + (1 or more), grade 3 (hypervascular). However, ++ (2 or more), + (1 or more), grade 3 (hypervascular) was observed at the tumor site, the tumor was diagnosed as visceral pleural invasion positive. For autofluorescence mode, we defined attenuation or a defect in autofluorescence of the pleura at the tumor site as a positive finding of visceral pleural invasion. Result: The sensitivity, specificity, and accuracy of visceral pleural invasion diagnosis by white light and autofluorescence mode were 77.8% vs 77.8%, 66.0% vs 83.0%, and 67.9% vs 82.1%, respectively. Conclusion: The specificity, and accuracy of visceral pleural invasion diagnosis was improved through the additional use of autofluorescence mode compared with white light mode alone.

Keywords: visceral pleural invasion, non-small cell lung cancer, autofluorescence

P1.05-15 BENIGN LUNG NODULE RESECTIONS IN THE ERA OF ADVANCED IMAGING AND CLINICAL GUIDELINES: IMAGING FEATURES AND HOW WE CAN REDUCE THE RESECTION RATE
M. Sayyouh, P. Cronin, E. Kazerouni
Radiology, University of Michigan, Ann Arbor/MI/US

Background: Evaluation of lung nodules is a long standing clinical problem. Despite advances in diagnostics, many nodules are still resected that are benign. Although certain imaging characteristic can distinguish benign from malignant lung nodules on CT and PET/CT, overlap exists. Our purpose is to understand the benign resection rate of PET and PET/CT, and to review the patient and imaging characteristics of benign resected nodules in the PET-PET/CT era. Method: We reviewed all 557 surgically resected nodules from 2003-2012. Patient demographics, smoking and cancer history, and PET/CT findings were collected prior to surgery, and pathology results were collected. All preoperative CT examinations were reviewed for nodule location, size, shape, border and attenuation, and PET/CTs for FDG-avidity. Result: Of 557 resected nodules in 543 patients, 39 nodules in 38 patients were benign (15 females, 23 male) for a benign resection rate of 7% (39/557). There was no significant difference between benign and malignant groups across sex, race, nodule size or attenuation. Patients with benign nodules were younger (mean age 59 vs. 65 years in the malignant group; p=0.005). 75% of patients with benign nodules were smokers versus 80% in the malignant group (p=0.04). In the benign nodule group, 14 patients (36%) had a cancer history. Benign pathology results were: 15 granuloma, 6 chronic inflammation, 5 hamartoma, 5 abscesses, 2 inflammatory pseudotumor, 2 organizing pneumonia and 1 case each of bronchogenic cyst, fibrous tumor, lipoid pneumonia and lymphoepithelioma. 62% of were in the right lung, and 46% were in an upper lobe. Nodule size was 10–95 mm (mean 29). CT nodule morphology was round/ovoid in 16, and triangular/angular in 3. Nodule border was lobulated in 4, smooth in 7 and speculated in 8. Cavitation was present in 4 nodules, 14 were exclusively soft tissue attenuation and one contained fat. By attenuation, 18 were solid, and 1 was non solid (ground glass). Of the 18/38 (47%) patients who underwent preoperative PET/CT scan, nodule FDG uptake was: 5 intense, 10 mild, 3 none. Conclusion: Our benign resection rate for lung nodules is 7%. While in many cases the imaging characteristics of surgically proven benign lung nodules and their clinical management are appropriate, following clinical guidelines for nodule management may further reduce the benign resection rate. The use of PET/CT and follow up low dose chest CT for PET/CT negative or mild uptake lesions to confirm nodule stability over time is a pathway for management that requires reinforcement.

Keywords: nodules, imaging, benign

P1.05 INTERVENTIONAL DIAGNOSTICS/PULMONOLOGY
MONDAY, SEPTEMBER 24, 2018 - 09:45-18:00

P1.05-16 CLINICAL UTILITY OF ELECTROMAGNETIC NAVIGATION BRONCHOSCOPY IN THE DIAGNOSIS OF LUNG CANCER
N. Singh1, A. Lee1, M. Al Ajami1
1Internal Medicine, Sunny Downstate Medical Center, Brooklyn/US, 2Pulmonary and Critical Care Medicine, New York Harbor Healthcare System, Brooklyn Campus, Brooklyn/NY/US

Background: Lung cancer remains the leading cause of mortality from malignancy in the United States despite significant advances. With the recent validation of low dose helix computed tomography (LD-CT) as a screening modality, there have been an increased number of diagnosed peripheral lung nodules that require evaluation. Electromagnetic navigation bronchoscopy (ENB) has emerged in recent years as a novel diagnostic modality that is purported to be equivalent to CT transbronchic needle aspiration (CT-TNA) in diagnostic yield with a superior safety profile. We set out to evaluate the diagnostic yield and the number of adverse events of ENBs performed at the Brooklyn Veterans Affairs
Background: The association of lung cancers with emphysematous bullae (EB) remains unclear. This study aims to retrospectively compare with those in the patients having lung cancer not associated with EB (non-EB group). Result: The median follow-up duration was 42 months (range, 2–85 months). The median age of the EB group was 70 (39–79) years, while that of the non-EB group was younger (51–83) years (p = 0.07). The EB group included more men (94 vs. 6%, p < 0.01), smokers (97 vs. 63%, p < 0.01), and the patients with low FEV1.0% (70%) (91 vs. 27%, p < 0.01). In the EB group, frequency of cancer in the right upper lobe was significantly higher than in the non-EB group (60 vs. 25%, p < 0.01). Histologically, non-adenocarcinomas, including squamous cell carcinoma, neuroendocrine tumor and large cell carcinoma, were common in the EB group compared with the non-EB group (57 vs. 24%, p < 0.01). Among the EB group, 16 patients (45%) were p-stage I, 16 (45%) were p-stage II, three (9%) were p-stage III, and none (0%) were p-stage IV (last classification). The 5-year overall survival (OS) rate for EB and non-EB groups was 75% and 88%, respectively, without significant difference (p = 0.20). The 5-year recurrence-free survival (RFS) rate was also not different between EB and non-EB groups (75 vs. 79%, p = 0.85). The multivariate analysis did not demonstrate that the association with EB to be a significant prognostic factor (p = 0.39). Conclusion: Lung cancers associated with EB have clinicopathological features including the predominance of men, heavy-smoking history, and non-adenocarcinoma histology compared with lung cancer not associated with EB. However, in the current analysis, the survival was not different between patients with lung cancers with and without EB.

Keywords: Emphysematous bullae, lung cancer

P1.05-18 PREDICTIVE PERFORMANCE OF SEMI-QUANTITATIVE METABOLIC METRICS ON FDG-PET/CT FOR THE IDENTIFICATION OF EGFR MUTATIONS

T. Tachibana
Thoracic Surgery, Tokyo Medical University Hospital, Tokyo/JP

Background: FDG-PET/CT is highly useful in evaluating biological malignancy of lung cancer cases. The maximum standardized uptake values (SUVmax) of the primary lesion is widely reported to be associated with prognosis in lung cancer while other metabolic metrics, metabolic tumor volume (MTV) and total lesion glycolysis (TLG) have also been explored as a measure of metabolic tumor burden in recent years. Several recent reports have shown that measurement of these metabolic metrics on PET/CT could be beneficial for the identification of driver gene mutational status such as EGFR and KRAS. The purpose of this study is to investigate the role of quantitative metabolic metrics (SUVmax, MTV, TLG) in identifying adenosquamous harboring EGFR mutations.

Method: We enrolled 247 patients with clinical stage I adenocarcinoma with or without EGFR/Erbb2 co-amplification. The patients underwent surgical resection after preoperative FDG-PET/CT imaging during the period from January 2012 to January 2018. SUVmax, MTV, TLG, and EGFR status were retrospectively reviewed. Patients with EGFR mutation status were classified into two groups, EGFR wild-type (WT) and EGFR mutant group.

Results: The EGFR mutation analysis was available in 195 patients (79.1%); 67 (34.3%) were EGFR mutant and 128 (65.7%) were WT. The association with EGFR mutation status was analyzed. Result: A total of 114 patients (60%) were identified as having EGFR mutations. Univariate analysis showed that sex (p = 0.001), smoking status (p = 0.013), SUVmax (p = 0.001), MTV (p = 0.001) and TLG (p = 0.014) were significantly associated with EGFR mutations. Multivariate analysis demonstrated that sex (p = 0.004) and SUVmax (p = 0.004) were independent predictors of EGFR mutations. The receiver operating characteristic curve yielded area under the curve values of 0.622, 0.604, and 0.609 for SUVmax, MTV, and TLG, respectively (SUVmax of 2.95, MTV of 0.10mm3, and TLG of 0.26, respectively). The frequency of EGFR mutations of patients with SUVmax < 2.95, MTV < 0.10mm3, TLG < 0.26, female and non-smokers were 64.2%, 64.2%, 64.2%, 63.5%, and 61.2%, respectively. Conclusion: In clinical stage I lung adenocarcinoma, SUVmax, MTV, TLG and EGFR status were associated with EGFR mutation status. Keywords: MTV, EGFR, TLG

P1.05-19 CT AND PET/CT PARAMETERS OF LEPIDIC PREDOMINANT PATTERN LUNG ADENOCARCINOMA AND INVASIVENESS ON PATHOLOGY

H. Takeda1, M. Takahashi2, D. Matsumoto2, N. Kawakita1, T. Sawada2, M. Tsuoi1, H. Toba1, M. Yoshida2, Y. Kawai2, K. Kondo1, A. Togoku1
1Department of Thoracic & Endocrine Surgery and Oncology, Institute of Biomedical Sciences, Tokyo University Graduate School of Medicine, Tokyo/JP, 2Department of Thoracic and Endocrine Surgery, Institute of Biomedical Sciences, Tokyo University Graduate School of Medicine, Tokyo/JP

Background: The 8th edition of TNM classification of lung cancer introduced new categories of Tis and T1mi for adenocarcinoma. Patients classified into these categories are estimated to present 100% or near-100% disease-free survival after complete resection. It is expected that we are able to identify them on preoperative imaging because they might fit for limited resection. A retrospective study was conducted evaluating preoperative radiologic parameters of lepidic predominant pattern lung adenocarcinoma to predict invasiveness on pathology.

Method: Pathologically classified 20 adenocarcinoma in situ (AIS), 27 minimally invasive adenocarcinoma (MIA) and 8 lepidic predominant
invasive adenocarcinoma (LPA) from 50 patients operated from January 2017 to March 2018 were evaluated. Preoperative CT parameters including maximum diameter, maximum area and mean CT value of the both whole lesions and solid components were evaluated. SUVmax of the lesions were measured at FDG-PET/CT images. Three experienced pathologist determined invasive size based on hematoxylin-eosin and Elastica van Gieson staining slides. Radiologic-pathologic associations were examined using Krukal-Wallis test and the Spearman correlation coefficient. **Result:** Increasing maximum diameter, maximum area and mean CT value of the whole lesions on CT were significantly associated with invasiveness (p < 0.01 and p < 0.001, respectively). Increasing maximum diameter and maximum area of the solid components were also significantly associated with invasiveness (p < 0.001 and p < 0.001, respectively). Higher SUVmax value of the lesions was significantly associated with invasiveness (p < 0.015). However, we were not able to find any correlation between the radiologic parameters including maximum diameter of solid components and pathologic invasive size when we analyzed MIA and LPA cases. And, when we evaluated clinical T according to the 8th edition of TNM classification, the sensitivity to diagnose AIS, MIA and IPA were 57.1%, 14.8% and 87.5%, respectively, and the specificity to diagnose AIS, MIA and IPA were 97.5%, 82.1% and 48.9%, respectively. **Conclusion:** Both whole tumor size and solid component size increase in association with tumor invasiveness. And SUVmax value also increases with tumor invasion. However, it is difficult to predict pathologic invasive size based on radiologic parameters. It is expected that novel preoperative or intraoperative diagnostic tools for tumor invasiveness of lepidic predominant pattern lung adenocarcinoma will be developed.

P.01.05-23 EVALUATION OF THE 8TH EDITION OF THE TNM CLASSIFICATION FOR LUNG CANCER AT A SINGLE INSTITUTION

J. Wang, Y. Yang, W. Nan
Department of Thoracic Surgery II, Peking University Cancer Hospital & Institute, Key Laboratory of Carcinogenesis and Translational Research (Ministry of Education), Beijing/CN

Background: The 7th edition has been used more than 10 years and has proven reliable, but various problems had been indicated. The latest 8th edition of the lung cancer staging classification was published in 2017. The purpose of this retrospective study is to make a external validation to the 8th edition of the lung cancer staging system. Method: Subjects included 3,229 patients who underwent pulmonary resection for primary non-small cell lung cancer. Survival characteristics were compared using the 7th and 8th editions of the staging system. Result: According to the 7th edition, there was no significant difference between pStages IIb and IIIA (P = 0.650), however, according to the 8th edition, there were significant differences between each adjacent pT classification, either according to the 7th edition or the 8th edition. Conclusion: The UICC 8th edition staging system is considered valid for non-small cell lung cancer patients and appears to be superior in defining different prognostic groups than the 7th edition.

Keywords: lung cancer, stage, 8th

P.01.05-24 CLINICAL CHARACTERISTICS AND PROGNOSTIC ANALYSIS OF MULTIPLE PRIMARY MALIGNANT Neoplasms in Patients with Lung Cancer

H. Wang1, J. Hou2, G. Zhang1, M. Zhang1, X. Zhang1, Z. Ma1
1Medical, Henan Cancer Hospital, Zhengzhou/CN, 2Henan Cancer Hospital, Zhengzhou/CN

Background: To investigate the clinical characteristics, survival status and prognostic factors of multiple primary malignant neoplasm (MPMN) with lung cancer. Method: The clinical and pathological data of 14,528 lung cancer patients who were diagnosed and treated in the affiliated cancer hospital of Zhengzhou University from January 2008 to August 2015 were retrospectively analyzed. Result: Of the total lung cancer patients, 2.5% (364/14,528) were MPMN cases and 3.6% (13/364) were diagnosed with 3 primary malignancies, whereas synchronous MPMN (SMPMN) accounted for 21.1% (74/350) and metachronous MPMN (MMPMN) accounted for 78.9% (276/350) of cases. Detection of first primary neoplasms were at an early stage for LCF patients and the age of the first lung cancer diagnosis was 59.3 years vs 55.4 years in the OCF group (P = 0.008), whereas the onset age of second primary neoplasm diagnosis was similar in both groups (62.5 and 61.6 years, P = 0.544). The median survival times of the OCF and LCF groups were 86 months vs 58 months (P = 0.001). The median survival times of SMPMN and MMPMN patients were 94 months vs 27 months (P < 0.001). Multivariate analysis showed that SMPMN, LCF and the age of the primary cancer diagnosed first (> 60 years) were independent factors for inferior prognosis of patients. Conclusion: Though LCF was diagnosed in earlier stages than OCF, the survival rate was inferior and the time until the development of the secondary primary malignancy was shorter than in the OCF group. MMPMN patients had a worse prognosis than SMPMN patients in both the LCF and OCF groups. Also > 60 years of age at the time of the primary cancer diagnosis was an independent factor for inferior prognosis in all patients.

Keywords: metachronous, multiple primary malignant neoplasms, synchronous

P.09 PATHOLOGY

H. Al-Najjar1, N. Nadira2, C. Higgins2, S. Thiryayi2, D. Shelton2, S. Bailey2, D. Rana2
1Respiratory Medicine, Central Manchester University Hospitals NHS Foundation Trust, Manchester/GB, 2Cytopathology, 1st Floor, Cs2, Central Manchester University Hospitals NHS Foundation Trust, Manchester/GB

Background: Immunotherapy, specifically pembrolizumab, is now approved in the UK as first-line therapy in patients with advanced non-small cell lung cancer (NSCLC) and no activating EGFR mutation or ALK translocation if high PD-L1 expression (≥ 50%) can be demonstrated on tumour samples. Furthermore, second line treatment is approved with PD-L1 expression ≥ 1%. Initial studies were performed exclusively on histological samples. We present our experience of PD-L1 testing purely on cytology samples. Method: Prospectively maintained cytology databases were analysed to identify all lung cancer cytology samples from our institute tested for PD-L1 expression between January 2017 and March 2018. Cell blocks from endobronchial ultrasound transbronchial needle aspiration (EBUS-TBNA) performed using rapid on-site evaluation (ROSE) were assessed for PD-L1 expression. Result: A total of 99 samples were tested for PD-L1. There were sufficient material for PD-L1 testing in 95% (n=94). Male 62%, female 38%. age range 26-84. EBUS-TBNA accounted for 79% of samples. (See next page)
Overall PD-L1 expression was high (≥50%) in 34/94 (36%), low (1-50%) in 38/94 (40%), and negative in 22/94 (23%). The proportion of patients expressing high (≥50%) PD-L1 positivity in the different pathological subtypes were: adenocarcinoma 23/62 (37%), squamous cell carcinoma 8/21 (38%), NSCLC-NOS 3/9 (33%). The proportion of patients with low (1-50%) PD-L1 positivity were: adenocarcinoma 27/62 (44%), squamous cell carcinoma 9/21 (43%), NSCLC-NOS 2/8 (25%). Neither of 2 neuroendocrine NSCLC tested expressed PD-L1. Conclusion: Our experience demonstrates that cytological samples obtained at our institute are suitable for PD-L1 testing with an adequacy rate of 95%.
