17 **Abstract**

18 The provincial government of Newfoundland and Labrador, Canada implemented  
19 a contact tracing program as part of a containment strategy during the COVID-19  
20 pandemic. A high proportion of cases were detected and contact traced, and our  
21 analysis provides insights into secondary case distributions and contact patterns in

22 Newfoundland and Labrador. We used a heuristic approximation of secondary  
23 cases to account for ambiguities in who infected whom. These approximate values  
24 provide an empirical distribution of secondary cases. These distributions are  
25 compared against the stringency of public health measures. Additionally, we  
26 visualised age- and contact-based patterns and compared these patterns with  
27 respect to stringency. The maximum number of contacts traced per week was  
28 4,645 and the mean number of contacts traced per case was 12.5. Approximate  
29 95% CIs of the effective reproduction number under Alert levels 2-4 were  
30 (1.02,1.21), (0.99,1.39), (0.84,1.06), and (1.20,1.47). We find that this level of  
31 contact tracing was sufficient, in combination with other public health  
32 interventions, to contain pandemic SARS-CoV-2 spread in Newfoundland and  
33 Labrador prior to the establishment of the Omicron variant. Understanding age-  
34 based contact patterns is necessary to describe disease spread and the risk of  
35 severe outcomes. A successful containment strategy requires that contact tracing  
36 capacity is not exceeded, making it necessary to understand the behaviour of high-  
37 contact individuals.

## 41 **Introduction**

42 The province of Newfoundland and Labrador (NL), Canada, announced its first  
43 COVID-19 case on March 14, 2020. In response to this the provincial government  
44 implemented a containment strategy to address the risk posed by the pandemic [1,  
45 p11-12]. The objective of a containment strategy is to prevent the spread of a

46 disease by minimizing the risk of transmission. Containment strategies consist of  
47 several policies that test, trace, and isolate infectious individuals, that restrict both  
48 the importation of new cases and infection spread, and that are intended to interact  
49 synergistically. These strategies are distinguished from elimination and  
50 eradication strategies, which seek to reduce transmission to zero, and mitigation  
51 strategies which aim to reduce overall impact while accepting some community  
52 transmission [2-4]. Containment strategies are typically only viable during stages  
53 of a pandemic with low case counts and limited community spread. This was the  
54 case in NL until the Omicron variant of the virus was detected on December 15,  
55 2021 [1, p59], at which point the existing containment strategies were deemed to  
56 no longer be effective. By early January 2022 the provincial government had  
57 switched to a mitigation strategy [1, p61].

58 Contact tracing involves identifying individuals that were potentially exposed by  
59 an infectious individual and is an important part of a containment strategy.

60 Contact tracing allows for the detection of asymptomatic and pre-symptomatic  
61 individuals, and the potential isolation of infectious individuals before they can  
62 generate secondary cases. The effectiveness of contact tracing, as a containment  
63 measure, often depends on both the number of contacts being traced and the  
64 proportion of cases that are successfully identified, and as capacity is reached,  
65 containment no longer becomes feasible [5-7]. Other public health measures that  
66 limit the number of people contacted by an infectious individual, or that prevent  
67 infection spread by other means, have a role in determining the efficacy of a  
68 contact tracing program, and in protecting contact tracing capacity [7-8].

69 In NL, contact tracing began with the first reported case on March 14, 2020 and  
70 consistent contact tracing was performed until January 4, 2022 [9], although data  
71 continued to be collected until June 2, 2022 in the pursuance of a mitigation

72 strategy. After the public health emergency was declared on March 18, 2020 [1,  
73 p10], the NL government issued changes to public health measures via Special  
74 Measures Orders (SMOs), where these measures may have contributed to contact  
75 tracing efficacy and protecting contact tracing capacity as part of a containment  
76 strategy. The initial response to the COVID-19 pandemic involved moving classes  
77 online for grades kindergarten to twelve, travel measures, closing recreational  
78 facilities, imposing limitations on indoor gatherings, and physical distancing  
79 recommendations [1, p14]. Subsequent SMOs relaxed or further restricted these  
80 measures in response to case counts and, later, vaccination rates.

81 As of April 30, 2020, the NL government introduced the Alert system, which  
82 bundled together many policies affecting local transmission. Alert level 5 was the  
83 strictest set of policies and consisted of small gathering limits and closures of  
84 many activities and non-essential businesses. Alert level 2 was the most relaxed  
85 set of policies that was implemented; it permitted larger gatherings and businesses  
86 to operate conditional on physical distancing and masking guidelines [1, p17-19].  
87 Alert level 1 was a return to a “new normal” and was never implemented, as  
88 instead the Public Health Emergency was repealed on March 14, 2022 [1, p71].  
89 The Alert level system did not encompass all of the component policies of NLs  
90 containment strategy. Travel measures, suspension of in-person kindergarten to  
91 grade twelve school, and mandates on indoor masking were issued in separate  
92 SMOs and were not directly linked to the Alert levels. Additionally, while  
93 gathering limits were not fixed for each Alert level, the stringency of the gathering  
94 limits tended to correspond to the stringency of the Alert level.

95 The implementation of stricter public health measures may change age-group  
96 contact patterns, and other aspects of contact assortativity. Characterizing such  
97 changes helps to accurately assess the risk of severe infection, which is greatest

98 for older individuals. Assortativity patterns, such as individuals with a high  
99 number of contacts also contacting other individuals with a large number of  
100 contacts, affect the risk of an outbreak that grows quickly due to consecutive  
101 super-spreading events. Understanding the risk of quickly-growing large  
102 outbreaks is necessary to understand whether contact tracing capacity is likely to  
103 be exceeded.

104 We use the data collected by NL through their contact tracing program to  
105 understand the efficacy of the containment strategy implemented by the NL  
106 government during the COVID-19 pandemic. We report contacts traced per week  
107 and contacts per case for different stringencies of public health measures (Alert  
108 levels) to understand the capacity of NL's contact tracing program. We report the  
109 number of travel-related and community cases, and estimate distributions of  
110 secondary infections and cluster sizes to evaluate the efficacy of NL's  
111 containment strategy. We visualize contact patterns for age-groups and  
112 assortativity based on the number of contacts to better understand the outbreaks  
113 that occurred in the NL population.

## 114 **Methods**

### 115 **Data collection**

116 The contact tracing program in NL was carried out by a core team of 15 public  
117 health officials. When an eligible individual was tested, a public health official  
118 would call the individual to inform them of their test result. If the test result was  
119 positive, a list of recent contacts was obtained, contacts being defined as any  
120 individuals who the case had close contact with within 72 hours of the case's  
121 episode date (episode date being date of symptom onset if the case was  
122 symptomatic, or date of specimen collection if the case was asymptomatic) [10].

123 Later in the pandemic, individuals could learn of their test result by checking an  
124 online system. When results were communicated online, public health officials  
125 monitored the test results database for the purpose of initiating contact tracing as  
126 quickly as possible when positive cases were reported. Contacts of a case were  
127 instructed by either a letter and/or a telephone call to test and isolate for 14 days.  
128 If the individual tested positive, then the duration of the isolation period would be  
129 reduced to 10 days from symptom onset, or date of positive test for those  
130 asymptomatic. Contacts of a case were usually contacted by the contact tracers  
131 within 24 hours. During periods of many cases, additional staff and third parties  
132 were contracted to support the core team of contact tracers. During the study  
133 period, all contacts were notified as described, such that contact tracing was  
134 conducted consistently. On December 15, 2021, it was stated by the Chief  
135 Medical Officer of Health that due to the short generation time of the Omicron  
136 variant, contact tracing could no longer be completed with the same efficiency as  
137 had occurred prior, and this is how we defined the end of our study period.  
138 For the duration of the study period, symptomatic individuals in NL could seek  
139 testing if they met testing criteria at that moment in time. Testing criteria shifted  
140 throughout the study period; at times one symptom could screen clients in for a  
141 COVID-19 test while at other times two symptoms were required, one of which  
142 had to be fever or cough. Furthermore, some asymptomatic individuals were also  
143 required to complete tests: rotational workers, with some modifications to the  
144 corresponding self-isolation rules [1, p24-25], close contacts of a confirmed case,  
145 and individuals that were asked to complete testing due to publicly issued  
146 exposure notifications corresponding to a venue, flight, or ferry. There were also  
147 testing requirements for entering some long-term care facilities, personal care  
148 homes, assisted living facilities [1, p17], and health care facilities.

149 For positive cases, the source is recorded as being related to travel, a close contact  
150 of a traveler, or a local source. Additionally, geographic information is recorded  
151 in the form of the Forward Sortation Area (FSA) of the individual. Due to the  
152 relatively small amount of local spread during the focal period of this study, the  
153 contact tracing networks observed are assumed to be mostly complete.

## 154 **Data preparation and cleaning**

155 We organized the contact tracing data into distinct contact networks, which are  
156 defined in this paper as a collection of individuals who are connected by at least  
157 one contact event. A contact event occurs between individuals A and B if A lists  
158 B as a close contact or vice versa. The contact event alone does not indicate who  
159 infected whom . Compiling connected contact events into clusters results in two  
160 categories of cases: those that are only travel-related and those that eventually  
161 result in local spread. If a contact network contains only individuals who are  
162 recorded as having a history of travel or as being a close contact of a traveler, then  
163 all individuals in the cluster are labeled “travel-related.” Otherwise, a network has  
164 at least one instance of a contact event which constitutes local spread. Since the  
165 policies of interest in this work are the Alert level measures, which target local  
166 spread, travel-related networks are removed for the analysis. Within each contact  
167 network is a case cluster, which contains all of the individuals in the network that  
168 tested positive.

169 The Alert level that was in place at the time and location of each contact event is  
170 not recorded during the contact tracing process. To compare the structure of the  
171 contact networks between Alert levels, each contact event was linked to an Alert  
172 level based on the FSA in which the contact happened. The Newfoundland and  
173 Labrador, Department of Health and Community Services Public Service

174 Advisories placed certain geographic regions under particular Alert levels at  
175 different times. Each geographic region was assigned a FSA that most closely  
176 matched it. The Alert level for each contact event was the Alert level assigned to  
177 the FSA at the time the contact was reported to have occurred. It is noted that  
178 since SMOs affecting the Alert level were not issued based on FSA there may be  
179 minor discrepancies between the assigned Alert level and the true Alert level for  
180 some contact events.

181 During the data cleaning process, any cases that occurred outside of the focal  
182 period were removed. Cases that were travel-related were removed as well as any  
183 entries that had missing or invalid FSA information.

#### 184 **Modeling the number of secondary infections**

185 The effective reproduction number,  $R_t$ , is the average number of secondary  
186 infections resulting from one index case in a partially susceptible population at  
187 time  $t$ . When complete contact tracing data is available,  $R_t$  can be estimated  
188 directly as secondary case counts are available for each case. In cases where  
189 available data is limited to time series of reported cases or symptom onset, direct  
190 estimation of  $R_t$  is not possible and some model structure needs to be applied to  
191 leverage some information about secondary case distributions from the data.

192 Mechanistic models of transmission dynamics are common [11], as are models  
193 that have a more limited structure, assuming only a probability distribution over  
194 the interval of time between cases [12,13]. In both cases, the lack of direct  
195 observation of contact events between individuals necessitates some additional  
196 assumptions/structure. The contact tracing data used in this study is partially  
197 complete in that we observe contact events, but not directly who infected whom.  
198 As such, we adopt a heuristic approach, described below, which makes use of the

199 partial information available without having to rely on a structured model  
200 requiring additional parameters to be estimated or assumptions to be made.  
201 The number of secondary cases generated by a particular index case,  $i$ , is denoted  
202  $I_i$ . To account for heterogeneity in infectiousness,  $I_i$  is often modeled as a  
203 negative binomial random variable with mean  $R_t$  and precision parameter  $k$  [14].  
204 Under this parameterization of the negative binomial distribution the number of  
205 secondary cases has variance  $R_t + R_t^2/k$ . As the estimated value of the precision  
206 parameter for our data was large relative to  $R_t^2$ , we also consider a Poisson  
207 distribution with mean  $R_t$ , as it is the limiting distribution of a negative binomial  
208 as the precision parameter gets very large.  
209 Observing the number of secondary cases requires knowledge of the infector and  
210 the infectee in each contact event. As an example of a contact network for which  
211 the infector and infectee labels can be assigned, consider a contact network  
212 containing two individuals, A and B, such that A travels and tests positive, then  
213 lists B as a contact who then tests positive without coming into contact with  
214 anyone else. Clusters including multiple travellers or more interconnected  
215 individuals do not admit a clear infector/infectee label for each individual,  
216 therefore direct observations of  $I_i$  are not available. To compensate for this, an  
217 approximate number of secondary cases,  $\tilde{I}_i$ , is computed. Each individual in the  
218 dataset will either be an index case or they will have at least one other individual  
219 listing them as a contact. The number of cases listing an individual as a contact is  
220 the number of potential infectors that the individual has. Take three individuals,  
221 A, B, and C, who have  $n_A$ ,  $n_B$ , and  $n_C$  potential infectors, respectively. Now  
222 consider a fourth individual, D, who is a potential infector of all of A, B, and C.  
223 Individual D constitutes  $1/n_A$ -th of A's potential infectors, and similarly for B  
224 and C. So, to approximate the number of secondary cases attributable to D, we

225 define  $\tilde{I}_D = 1/n_A + 1/n_B + 1/n_C$ . These  $\tilde{I}_i$ 's are then modeled using a continuous  
226 version of the above negative binomial and Poisson distributions, swapping any  
227 factorials in the probability mass function for the appropriate gamma function.  
228 This weighting procedure is intended to be a heuristic approach, used so that a  
229 parametric estimate of the effective reproduction number can be obtained. A point  
230 estimate and an approximate 95% confidence interval about  $R_t$  is obtained via  
231 maximum likelihood estimation.

### 232 **Visualizing contact patterns**

233 Two types of plots are used to visualize the contact structure within the clusters.  
234 The first is an age-stratified contact matrix. Each individual is placed into an age  
235 group: [0,5), [5,18), [18,30), [30,40), [40,50), [50,60), [60,70), and 70+. The age  
236 groups were chosen to reflect pre-school-age ([0,5)), school-age ([5,18)), and then  
237 10-year bins after the age of 18. The grouping together of school-age individuals  
238 is supported by a study conducted in Tianjin, China [15], as well as contact  
239 matrices estimated in Canada [16] and the United Kingdom [17], which show  
240 very similar contact patterns for these ages. The number of contacts between each  
241 age group are counted and plotted as a heat map that shows the total number of  
242 interactions between age groups within the observed contact networks. Counts  
243 below five are shown as being exactly five to preserve anonymity. The second  
244 type of plot shows the relationship between the number of contacts reported by  
245 each pair of cases connected by a contact event. For each pair of connected  
246 individuals, the number of contacts reported by each was computed and plotted as  
247 a point, with the initial case on the horizontal axis and the contacted case on the  
248 vertical axis. Rather than plotting the individual points, this pattern is shown by  
249 applying 2-dimensional kernel smoothing to these points and plotting the contours

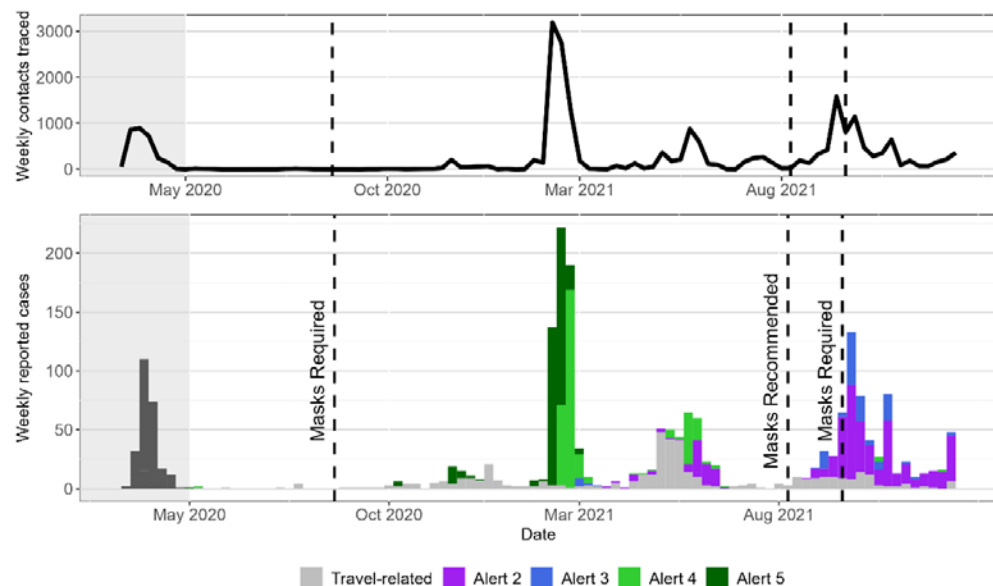

250 of the smoothed density. The darker contours represent regions of case/contact  
251 pairs where there were a relatively higher number of contact events with that  
252 pairing of reported cases.

253 Both visualizations are computed for all data in the focal period disaggregated  
254 into the Alert level during which the contact event took place. In addition to these  
255 aggregate plots, the same plots are computed for two individual clusters. The two  
256 clusters that are selected contain the most contact events. All analysis is done  
257 using the R programming language [18]; the ggplot2 package [19] is used to  
258 generate all figures.

## 259 **Results**

260 An overview of the history of the disease between the period of March 14, 2020  
261 and December 15, 2021 is given in Figure 1, which shows weekly aggregate cases  
262 in the province. Reported cases are separated into those that are travel-related and  
263 those constituting local spread; local spread is then further separated into the Alert  
264 level in effect when the contact event occurred. Changes to provincial masking  
265 mandates are shown separately from the Alert levels, as these policies were kept  
266 separate. The period between March 14, 2020 and April 30, 2020 is shaded grey  
267 and corresponds to the period prior to the Alert level system; bars in this period  
268 are coloured black because there is no Alert level to which they correspond. After  
269 an SMO that placed the province at Alert level 5, subsequent relaxations brought  
270 the Alert level province-wide down to level 2 by July 2020 when there were no  
271 instances of community spread. In late 2020 and early 2021, when the entire  
272 province was at Alert level 2 and there was an indoor mask mandate in effect,  
273 there were several weeks with reported cases. However, most of these cases  
274 remained travel-related and did not result in community spread. In February 2021,

275 when a large amount of community spread was detected on the Avalon peninsula  
276 of Newfoundland, the entire province moved to Alert level 5. The implementation  
277 of measures at the community-level, rather than province-wide, started shortly  
278 after this on February 27, 2021; the province continued to manage community-  
279 level policy changes for the remainder of our focal period. The case peak in early  
280 summer 2021 was largely restricted to travel-related cases, while the peak in late  
281 summer/early fall, which began shortly after the mask mandate had been lifted,  
282 was dominated by community spread and a mask mandate was reissued a few  
283 weeks later. Protecting contact tracing capacity was one stated rationale for re-  
284 issuing the mandatory mask requirement, and at this time more than 1,000  
285 contacts were being traced per week (Figure 1, top panel). At two points within  
286 the focal period, February 2021 and September 17, 2021 [1, p49; 17], the NL  
287 government reported a strain on contact tracing capacity. The core contact-tracing  
288 team in eastern Newfoundland consisted of fifteen public health officials [20].  
289 Figure 1 shows the weekly total of contacts traced during the period (top panel).  
290 Peaks in the number of contacts traced tend to correspond to peaks in reported  
291 cases, but on a larger scale.

293 **Fig. 1** Weekly cases (bottom) and contacts traced (top) in Newfoundland and Labrador until  
294 December 15, 2021 with colours indicating if the case is travel-related or if not, and which Alert  
295 level it occurred under. Vertical dashed lines indicate province-wide mandates on masking  
296 indoors.  
297 Between March 14, 2020 and December 15, 2021, 22,626 contacts were traced.  
298 Of these contacts, 2,111 were cases, 1,522 of which were related to local spread.  
299 Analyses of the Alert levels focused on data occurring after April 30, 2020,  
300 removing 203 cases. A further 7 cases were removed for having incorrect or  
301 missing FSA data. A numerical summary of the contact tracing efforts is supplied  
302 in Table 1. The table shows the total number of contacts traced, the total number  
303 of cases reported, the maximum number of contacts traced in one week, and the  
304 average number of contacts traced per person; these results are shown for the  
305 entire focal period as well as a breakdown by Alert level. Of the 1,522 cases,  
306 1,299 (85.3%) reported symptoms, 71 (4.66%) were hospitalized, and 17 (1.12%)  
307 died.

308 **Table 1** Numerical summaries of contact tracing during focal period

	Overall	Alert 2	Alert 3	Alert 4	Alert 5
Contacts traced	19269	5740	1484	3199	6004
Cases reported	1522	484	137	349	342
Max. contacts traced in a week	4645	1217	406	996	4645
Mean contacts traced per person	12.5	11.9	10.8	9.17	17.6

309

## 310 **Observed transmission clusters**

311 There were 166 distinct clusters containing more than one person during the focal  
312 period. The largest cluster contained 276 cases. The median cluster size was 3,  
313 with 90% of the clusters containing at most 11 cases. The distribution of cluster  
314 sizes across the whole focal period is illustrated in Figure 2. Both plots show a  
315 distribution of cluster sizes concentrated on small numbers of cases with a long  
316 tail.

317

318 **Fig. 2** Histogram of the cluster sizes across the focal period; inset contains the corresponding  
319 empirical cumulative distribution function, truncated to 15.

320 The largest contact network during the focal period is shown in Figure 3. In  
321 addition to the case cluster itself, shown with the larger opaque points, Figure 3  
322 also shows individuals who were traced but did not test positive in the smaller,  
323 translucent points. This network is linked to an outbreak in eastern Newfoundland  
324 between February and April, 2021. Of the contact events that comprise the  
325 network, 38.7% occurred under Alert level 5, 60.8% occurred under Alert level 4,

326 and 0.5% occurred under Alert level 2. At the centre of the cluster most of the  
327 contacts fall within the 5-17 age group. There are also several contacts that are in  
328 the 30-59 age groups. The smaller points indicate contact events which did not  
329 produce secondary cases either because transmission did not occur or because  
330 contact tracing contained the infection.

331  
332 **Fig. 3** Graph of the largest contact network in the dataset. Large, opaque points are the cases  
333 which comprise the cluster itself and the smaller, translucent points are contacts which were traced  
334 but did not result in further local spread. The opacity of the edges corresponds to the number of  
335 subsequent contacts resulting from that infection.

### 336 **Effective reproduction number**

337 The smoothed empirical distributions of secondary cases are visualized in Figure  
338 4 for the period from October 2020 until the end of the focal period. The values of  
339 approximated secondary infections,  $\tilde{I}_v$ , are smoothed over weekly periods and are  
340 disaggregated by Alert level. The corresponding plot of weekly cases is shown

341 above. There are three predominant peaks visible during this period; the first  
342 occurring under Alert levels 4 and 5, the second under Alert levels 2 and 4, and  
343 the final mostly under Alert levels 2 and 3. For most weeks the distribution of  
344 secondary cases appears to be centred around 1, skewing more towards 0 as the  
345 outbreaks taper off.

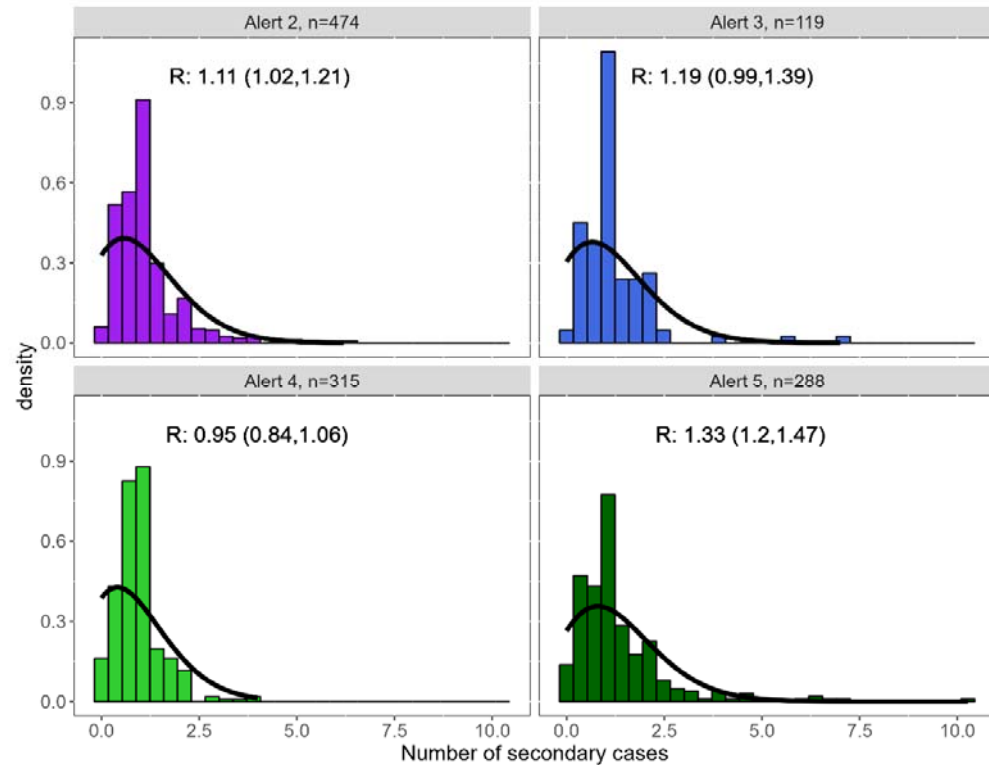

346

347 **Fig. 4** Weekly cases between October 2020 and December 15, 2021 (top) and smoothed empirical  
348 distribution of secondary cases, pooled over a weekly period, (bottom).

349

350 The secondary cases were then aggregated across the entire focal period for each  
351 Alert level; the corresponding histograms are shown in Figure 5. Both the  
352 negative binomial and Poisson distributions were fit to the data in each Alert level  
353 via maximum likelihood and compared using the Akaike Information Criterion  
354 (AIC). The fitted Poisson distribution resulted in a lower AIC for all Alert levels,  
355 so the estimates below correspond to the Poisson distribution. It is noted that the  
356 point estimates for the reproduction number were very similar under the negative  
357 binomial distribution, however the likelihood function was very insensitive to the  
358 value of the precision parameter. Maximum likelihood estimates (MLEs) for the

359 reproduction numbers and precision parameters, as well as the AIC for each Alert  
 360 level are shown in Table 2. The MLEs of  $R_t$  for each Alert level are also shown in  
 361 Figure 5 along with an approximate 95% confidence interval (CI). The probability  
 362 mass functions, computed using the MLEs, are drawn over the histograms.

363

364 **Fig. 5** Histogram of the estimated number of secondary cases caused by each index case under  
 365 each Alert level. Probability mass functions evaluated at the MLEs are shown with a solid line.  
 366 Approximate 95% CIs for  $R_t$  are shown in the top right corner.

367 **Table 2** Point estimates and 95% CIs for  $R_t$  under each Alert level

Alert Level	Poisson		Negative Binomial		
	$\widehat{R}_t$	AIC	$\widehat{R}_t$	$\widehat{k}$	AIC
2	1.11	1148	1.11	194.0	1151
3	1.19	298	1.19	58.7	301
4	0.95	680	0.95	107.0	684

5	1.33	825	1.33	46.8	826

369 **Contact patterns**

370 The visualizations of contact patterns within the clusters are shown for all clusters  
371 within each Alert level as well as for the two largest clusters observed after April  
372 30, 2020, with respect to the number of contact events. The first cluster is the  
373 largest observed cluster with 605 contact events and 276 cases, occurring in the  
374 former eastern health region (Newfoundland) between February and April, 2021  
375 and the second largest cluster contained 261 contact events and 91 cases and  
376 occurred in the former central health region (Newfoundland) between May and  
377 June, 2021. Of the contact events that comprise the central cluster, 65.9% of the  
378 contacts occurred under Alert level 4 and 34.1% occurred under Alert level 2.  
379 Subsequent references to these clusters will refer to the region in which they  
380 occurred. The four regional health authorities of Newfoundland and Labrador  
381 were amalgamated in April 2023.

382 Age contact matrices are shown in Figure 6. In Alert levels 2 and 3 the contacts  
383 are fairly dispersed across age groups and show minimal clustering around the  
384 diagonal. Alert level 4 shows a relatively large proportion of contacts occurring  
385 within and between the 5-59 age groups. Alert level 5 shows strong interaction  
386 between the 5-17 and 40-49 age groups. All four plots show the highest number of  
387 contacts occurring in the 5-17 age group.

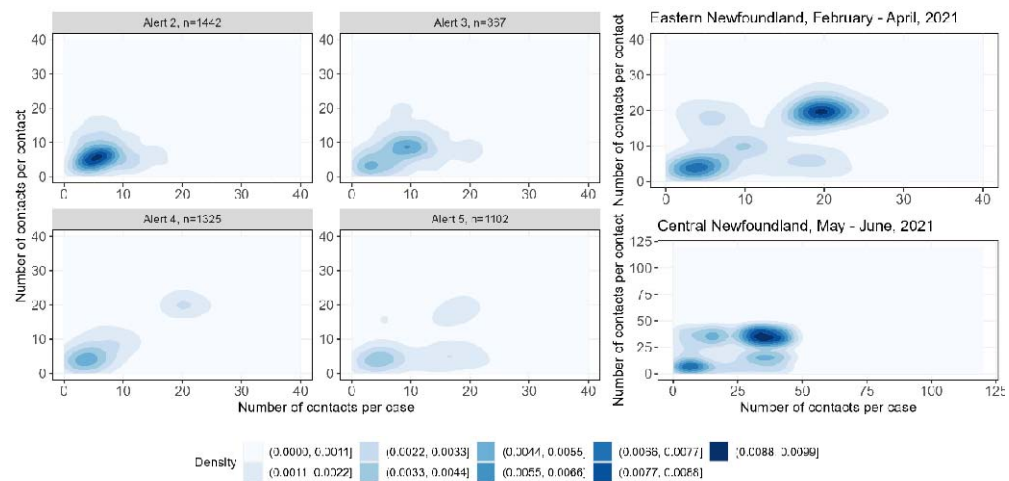

388 The eastern health cluster shows predominantly cases in the 5-17 and 40-49 age  
389 groups with interaction between these age groups. Other ages are present, in  
390 particular a collection of contacts in the 30-59 age groups. There are some  
391 similarities between the patterns present in the eastern health cluster and those for

392 Alert level 5. Given the relative scales of the two plots, an explanation for this  
393 could be that the eastern cluster is driving the pattern for the entire Alert level.  
394 The plot for the central health cluster shows an arrow-shaped pattern with a high  
395 concentration in the [18,30) age group as well as interactions between this group  
396 and the [30,60) age groups. Notably, there is much less interaction between the  
397 [30,60) age groups than there is between them and [18,30). There is also a more  
398 uniform pattern occurring between the [5,18) and [18,30) age groups. The pattern  
399 present for the central cluster does not bear a strong resemblance to any of the  
400 Alert level patterns. This is an example of a case where population-level trends in  
401 age assortativity for an Alert level are not reflected in individual clusters.

402  
403 **Fig. 6** Contact matrices indicating the number of contacts that occur within and between age  
404 groups. The panel on the left shows matrices computed for each of the Alert levels separately,  
405 aggregated over all contacts occurring under that particular Alert level. On the right are the same  
406 matrices computed from the eastern and central clusters.  
407 The density plots of the high-contact/low-contact interaction patterns are shown in  
408 Figure 7. Alert levels 2 and 3 both show patterns with a single point of  
409 concentration and some dispersion away from the diagonal as the number of  
410 contacts increases. In Alert level 2 the contact frequencies are centred about the  
411 point (6,6), meaning that for many of the cases with around 6 contacts, each

412 contact themselves produced around 6 contacts. Alert level 3 shows a similar  
413 pattern, but more dispersed and slightly more skewed towards high-contacts/high-  
414 contact pairs. Alert levels 4 and 5 differ in that they have multiple points of  
415 concentration and less consistent dispersion. Alert level 4 has one point of  
416 concentration around (5,5), but with another localized concentration at a high-  
417 contact/high-contact point on the diagonal. The number of contacts per-person in  
418 Alert level 5 is quite dispersed. In all cases, most individuals have fewer than 20  
419 contacts. The eastern cluster shows two concentrations: one in the low-contact  
420 corner and another at a higher number of contacts. This plot shows a clear  
421 interaction between high-contact and low-contact individuals (paler areas off the  
422 diagonal). The central cluster has three areas of concentration. The highest  
423 concentration is around 40 contacts per person, with a lower concentration at the  
424 low-contact/low-contact corner of the plot, and low-contact/high-contact mode  
425 located symmetrically about the diagonal. While the central cluster had few cases,  
426 it tends to show a much higher number of contacts per person.

428 **Fig. 7** Joint distribution over the number of contacts in each case/contact pair; each region (i.e.  
429 each colour) contains all pairs with similar estimated density values, as indicated in the quantile  
430 legend. The left panels show the contours constructed from data aggregated for each Alert level.  
431 The panels on the right show the contours for the eastern cluster and the central cluster.

## 432 **Discussion**

433 Between March 20, 2020 and December 15, 2021, the NL government  
434 implemented a contact tracing program as part of a COVID-19 containment  
435 strategy. The data provides information about secondary cases and contact  
436 patterns in the population. Secondary case distributions can indicate how effective  
437 policy measures are at suppressing local spread. Analyzing contact patterns under  
438 varying levels of policy stringency can either validate existing assumptions of  
439 contact homogeneity or provide a basis for more accurate models of disease  
440 transmission. NL's public health measures until the establishment of the Omicron  
441 variant were effective at containing SARS-CoV-2 spread (Figures 1 and 4), and  
442 the contact tracing effort to achieve these results is summarized in Figure 1 and  
443 Table 1.

444 The distributions of secondary cases (Figures 4 and 5) and the estimates of  $R_t$   
445 (Figure 5) offer insight into the efficacy of the Alert level system. The shapes of  
446 the secondary case distributions in Figure 4 are skewed above 1 during periods of  
447 increasing incidence and skewed below 1 as peaks taper off. The estimates of  $R_t$   
448 for each Alert level are mostly close to 1 with 95% lower confidence bounds of  
449 1.02, 0.99, 0.84, and 1.20. This is consistent with local spread being contained  
450 until late December 2021. The higher value for Alert level 5 could be a  
451 consequence of low compliance with public health measures prior to the February  
452 2021 outbreak in the eastern health region [1, p28], and delays between  
453 identifying the outbreak and the implementation of Alert level policies. The  
454 results here should be evaluated while keeping in mind that the heuristic nature of  
455 the estimation procedure precludes rigorous statistical interpretation. Furthermore,  
456 Figure 1 shows that the Alert levels are not distributed uniformly across the focal

457 period; a consequence of this is that factors such as variant or vaccination rates  
458 could be affecting our estimates of  $R_t$ .

459 Statistical evidence supporting the use of a Poisson distribution to model  
460 secondary cases over the negative binomial distribution typically coincides with  
461 low heterogeneity in transmission, which has not been characteristic of COVID-  
462 19 [21,22], though high uncertainty in the precision parameter has been observed  
463 in settings with very stringent control measures [23]. Additionally, it has been  
464 observed that imposing control measures can reduce overdispersion [24].

465 Therefore, one plausible explanation for this deviation from the existing COVID-  
466 19 literature, with respect to the secondary case distribution, is that control  
467 measures in place, even those with lower stringency, have reduced the occurrence  
468 of superspreader events and resulted in a more homogenous pattern of infectivity  
469 for our dataset.

470 The age contact matrices shown in Figure 6 show that the 5-17 age group had the  
471 most contacts and many of those contacts occur between individuals in that age  
472 group. Additionally, the matrix for the eastern cluster showed interaction between  
473 this age group and the 40-49 age group. These observations could be supported by  
474 transmission between high school students which either is preceded by or  
475 proceeded from transmission between students and their parents/guardians  
476 [10,17]. These patterns can also be seen in Figure 3, with many individuals in the  
477 [5,18) age group at the centre of the cluster and smaller clumps of individuals in  
478 the [40,50) age group. The pattern present in the central cluster suggests a form of  
479 transmission facilitated by the [18,30) age group with minimal interaction  
480 between the older affected age groups. This represents a very different form of  
481 interaction than the former cluster. Overall, trends in interaction between age  
482 groups are most pronounced under the most stringent set of public health

483 measures with trends becoming less apparent as stringency decreases. Comparing  
484 the contact matrices of the eastern and central clusters to the Alert-level clusters  
485 illustrates how contact patterns aggregated across multiple clusters may not be  
486 representative of patterns within particular clusters. This suggests that during the  
487 early stages of an outbreak, models which reflect contact patterns specific to the  
488 outbreak setting may be a more reliable basis for local policy decisions than  
489 aggregate models.

490 Age contact matrices have been estimated for all of Canada during the period May  
491 2020 to December 2020 [16]. These showed a relatively high number of contacts  
492 occurring within the same age group with the most contacts occurring within the  
493 5-17 age group. These contact matrices also show older age groups have more  
494 between-age interactions with a higher number of interactions among adults aged  
495 18-60 and a lower number for those of retirement age. These patterns are similar  
496 to, but less pronounced than, those found in the POLYMOD study [17]. These  
497 Canada-wide patterns are most similar to those observed in NL during Alert level  
498 2 (Figure 6). The block-like behaviour of the 18-60 age groups is also found in  
499 NL during Alert level 4. However, both the patterns observed during Alert level 5  
500 and those observed in the two selected clusters have no clear resemblance to either  
501 the Canada-wide study or the POLYMOD study. This underlines the importance  
502 of understanding local contact patterns when modelling the spread of an infectious  
503 disease in small populations, or during periods of low incidence.

504 The interaction between low-contact and high-contact individuals was shown in  
505 Figure 7. These plots provide some information about how the distribution of the  
506 number of contacts per case varies across the population. A containment strategy  
507 requires that contact tracing capacity not be exceeded, as such it is valuable to  
508 investigate potential pressure on contact tracing demand arising from high-contact

509 individuals. Alert levels 2 and 3 both show a pattern of high concentration in one  
510 area of the plot with greater dispersion as the number of contacts per case  
511 increases. This suggests that given an individual has a high number of contacts,  
512 there will be higher variance in the number of secondary contacts associated with  
513 them, compared to an individual with a small number of contacts. This pattern  
514 could be explained by each individual's number of contacts being drawn from a  
515 common distribution with one mode and a skew to the right. On the other hand,  
516 Alert levels 4 and 5 exhibit less consistent behaviour with multiple points of  
517 concentration. This could be explained by the more stringent measures both  
518 limiting gathering sizes (low-contact modes) while still permitting some essential,  
519 high-contact jobs to be performed (higher-contact modes). That we observe a  
520 concentration of low-contact cases in each Alert level is another indication that  
521 the Alert level system was effective in limiting community spread. The results for  
522 the two example clusters are less neatly concentrated patterns. In the eastern  
523 cluster there appear to be two main concentrations of contacts per case, with an  
524 additional, smaller concentration reflected off the diagonal. Comparing this plot to  
525 the corresponding age contact matrix suggests a potential relationship between the  
526 age of a case and the distribution of the number of contacts per case. The patterns  
527 of the central cluster are quite similar to the eastern cluster, although at a slightly  
528 greater magnitude. Contrasting this with the age-based contact patterns, which  
529 were different between the two example clusters, suggests that whatever  
530 demographic or environmental variables drive one form of contact patterns do not  
531 affect the other in the same way. The difference in magnitude between the eastern  
532 and central clusters also provides additional support for the efficacy of the Alert  
533 system since many of the individuals in the central network had a high number of

534 contacts, even though the resulting cluster had fewer cases than the eastern  
535 cluster.

536 Many infectious disease transmission models rely on strong assumptions about the  
537 contact patterns, e.g. homogeneous mixing, or on contact patterns which are  
538 estimated *a priori*. The observed contact patterns do not support a model of  
539 homogeneously mixing populations and supports previously made observations  
540 [15] that contact patterns change considerably in response to public health  
541 measures. This degree of change, which goes well beyond simply having overall  
542 contact volumes rise and fall with control measures, should raise notes of caution  
543 for infectious disease transmission modelling that relies on network and contact  
544 structure. Contact tracing provides a double benefit to infectious disease  
545 modellers and public health officials. In addition to its role in effective  
546 containment strategies, clear contact tracing data can provide modellers with  
547 information about person-to-person contact patterns which enable more effective  
548 modelling of low-incidence disease outbreaks, such as those in small populations  
549 and during the early stages of an outbreak.

550

## 551 **Conclusion**

552 Estimated effective reproduction numbers are consistent with periods of contained  
553 local spread. Further analysis needs to be done to determine the individual effects  
554 of the Alert system, vaccination rates, and variant, as well as the interactions  
555 between them. The data revealed heterogeneity in contact patterns within the  
556 population. The patterns varied between contact networks as well as between  
557 individual networks and patterns aggregated over multiple networks. These  
558 suggest that population-specific age-based contact patterns are important to  
559 modelling disease spread in small populations. Additionally, given the importance

560 of contact tracing to a containment strategy, understanding the behaviour of high-  
561 contact individuals may be crucial to keeping cases within contact tracing  
562 capacity.

## 651 **Declarations**

### 652 **Ethics approval and consent to participate**

653 Ethics approval for this project was granted by the Newfoundland and Labrador  
654 Health Research Ethics Board (reference # 2021.013).

### 655 **Consent for publication**

656 The Newfoundland and Labrador Health Research Ethics Board approved the  
657 research involving secondary use data without requiring further consent to  
658 participate from the participants (i.e., Article 5.5A of the Tri-Council Policy  
659 Statement 2).

### 660 **Availability of data and materials**

661 Data requires ethics approval and can be requested from Newfoundland and  
662 Labrador Health Services, Digital Health, the data custodian.

### 663 **Competing interests**

664 AH was a member of the Newfoundland and Labrador Predictive Analytics  
665 modelling team and previously received funding from the Newfoundland and  
666 Labrador Department of Health and Community Services.

### 667 **Funding**

668 This research was funded by the Canadian Network for Modelling Infectious  
669 Diseases (560516-2020) and the Discovery grant (RGPIN-2019-06131) from the  
670 Natural Sciences and Engineering Research Council of Canada.

### 671 **Authors' contributions**

672 RD performed the analysis, generated visuals, and wrote the first draft of the  
673 manuscript. SS and AM lead the contact tracing process. RD, AH, LW, and CC  
674 conceived of the project and designed the analytical approach. All authors edited  
675 the manuscript.

#### 676 **Acknowledgements**

677 The authors would like to acknowledge the substantial efforts of Newfoundland  
678 and Labrador Public Health, the Department of Health and Community Services,  
679 Regional Health Authorities and all individuals involved in contact tracing and the
