Modulation is the process of varying one or more parameters of a carrier signal consistent with the immediate values of the message signal. The message signal is the signal that is transmitted for communication and the carrier signal is a high frequency signal that has no data but is used for long-range transmission. There are many modulation techniques, which are classified according to the type of modulation used. Of them all, the digital modulation technique used is Pulse Code Modulation (PCM). A signal is pulse code modulated to transform its analog information into a binary order, that is, 1s and 0s. The output of a PCM will look like a binary sequence. The following figure shows an example of PCM output regarding immediate values of a given sentence wave. Instead of a wrist train, PCM produces a range of numbers or digits, which is why this process is called digital. Each of these digits, though in binary code, represents the approached amplitude of the signal sample at that moment. In Pulse Code Modulation, the message signal is represented by a sequence of coded pulses. This message signal is achieved by representing the signal in discrete form in both time and amplitude. Basic elements of PCM The sender section of a Pulse Code Modulator circuit consists of Sampling, Quantization and Encoding, which is performed in the analog-to-digital converter section. The layers fit filtering before sampling prevents aliasing of the message signal. The basic operations in the receiver section are rebirth of impaired signals, decoding, and reconstruction of the quantified wrist train. Following is the block diagram of PCM that represents the basic elements of both the sender and the recipient sections. Low Fit Filter This filter eliminates the high frequency components present in the input analog signal that is greater than the highest frequency of the message signal, to prevent aliasing of the message signaling. Sampler This is the technique that helps collect the sample data on immediate values of message signaling, in order to reconstruct the original signal. The sampling rate should be greater than twice the highest frequency component W of the message signal, in accordance the sample theory. Quantizer Quantification is a process of reducing the excessive bits and limiting the data. The monster output when given to Quantizer, Quantizer, the excess bits and compresses the value. Encoder The digitisation of analog signal is done by the encoder. It designates each quantified level through a binary code. The sampling done here is the sample-and-hold process. These three sections (LPF, Sampler, and Quantizer) will act as an analog for digital converter. Encoding reduces the bandwidth used. Regenerative Repeater This section increases the signal strength. The output of the channel also has one regenerative repeater circuit, to compensate the signal loss and reconstruct the signal, and also to increase its strength. Decoder The decoder circuit decodes the wrist coded waveform to reproduce the original signal. This circuit serves as the demodulator. Reconstruction Filter After the digital-to-analog conversion is done by the regenerative circuit and the decoder, a low-fits filter is employed, called as the reconstruction filter to get back the original signal. From there, the Pulse Code Modulator circuit digitizes the given analog signal, codes it and samples it, and then sends it into an analog form. This whole process is repeated in a reverse pattern to obtain the original signal. Signal.
