Federal Reserve Bank of St. Louis

May 2005, revised June 2005

Abstract

This paper examines and compares the recent business cycle experiences of the seven states that lie partly or wholly within the Eighth Federal Reserve District (Arkansas, Illinois, Indiana, Kentucky, Mississippi, Missouri, and Tennessee). For the period surrounding the 1990-91 NBER recession, six of the seven states had recessions that were much shorter than for the country as a whole. For the period surrounding the 2001 NBER recession, four states—Arkansas, Indiana, Kentucky, and Tennessee—entered and exited recession earlier than the country as a whole. Recessions in the other three states began earlier and ended later than for the country as a whole.

JEL codes: E32 R12
Keywords: Markov-switching, business cycles

The view expressed in this paper are those of the authors and are not necessarily the official views of the Federal Reserve Bank of St. Louis or the Federal Reserve System.
This paper examines and compares the recent business cycle experiences of the seven states that lie partly or wholly within the Eighth Federal Reserve District (Arkansas, Illinois, Indiana, Kentucky, Mississippi, Missouri, and Tennessee). We pay particular attention to the period surrounding the 2001 national recession. Our analysis relies on the supposition that state-level business cycles can be characterized as a series of distinct recession and expansion phases, as is commonly held to be true of the national business cycle. The primary example of this characterization of the national business cycle is the activity of the National Bureau of Economic Research’s (NBER) Business Cycle Dating Committee, which provides semi-official recession and expansion dates.

Because the NBER chronology is available only for U.S. national economic activity, alternative methods must be used to identify business cycle turning points in state-level data. To this end, we follow a recent paper by Owyang, Piger, and Wall (2005), hereafter simply OPW, in estimating state-level turning points with a version of the regime-switching model of Hamilton (1989). As with the NBER, the Hamilton model is based on the notion that the business cycle can be split into distinct recession and expansion phases. In fact, the Hamilton model can be thought of as a non-judgmental, statistical alternative to the committee-consensus method of the NBER.

A significant hurdle in determining business cycle turning points at the state level is the inadequacy of data relative to what is available for the national economy. When applied to the national economy the Hamilton model is typically applied to gross domestic product (GDP), which has a quarterly frequency and has been found to provide distinct turning points in and out
of expansion and expansion phases.¹ At the state level, however, the analog to GDP—gross state product (GSP)—is produced only with an annual frequency and with a two to three year lag, making it of little use in detecting phase shifts. The solution in OPW is to use the state-level coincident index (SCI) produced by the Federal Reserve Bank of Philadelphia and described by Crone and Clayton-Matthews (2005). The SCI uses the dynamic factor model of Stock and Watson (1989) to combine four variables—the unemployment rate, payroll employment, average weekly manufacturing hours, and real wage and salary disbursements—into a single indicator of state-level labor-market activity.

The main advantage of the SCI is that, as demonstrated by OPW, it provides timely and frequent observations of series that tend to have distinct state-level business-cycle turning points. Further, it provides a much cleaner and well-behaved variable than any of its components, which are much noisier and erratic than their national-level counterparts. The disadvantage of the SCI is that, because it uses labor-market variables only, it is not as broad a measure of activity as is GDP. As such, it is probably best viewed as an indicator of overall state-level labor-market conditions rather than as a coincident indicator of GSP or other broad measure of state-level conditions. With this in mind, we also apply the Hamilton model to national nonfarm payroll employment to provide more-relevant national recession and expansion dates to compare to our state-level ones.

¹ Boldin (1994) and Chauvet and Piger (2002), among others, have found that the Hamilton model does quite well in mimicking the turning point dates of the NBER.
MODEL AND ESTIMATION

In the Hamilton (1989) Markov-switching model, different business cycle phases are treated as arising from different models, each with its own mean growth rate. Let \( \mu_0 \) be the mean growth rate when the economy is in expansion and let \( \mu_1 \), which is normalized to be negative, be the difference between the mean growth rates in expansion and recession. Specify a simple model for the growth rate of some measure of economic activity, \( y_t \), as

\[
y_t = \mu_0 + \mu_1 S_t + \varepsilon_t, \quad \mu_1 < 0. \tag{1}
\]

To introduce recession and expansion phases, the mean growth rate in (1) switches between the two regimes, where the switching is governed by a state variable, \( S_t = \{0,1\} \). Deviations from this mean growth rate are created by the stochastic disturbance \( \varepsilon_t \sim N(0, \sigma_{\varepsilon}^2) \). When \( S_t \) switches from 0 to 1, the growth rate switches from \( \mu_0 \) to \( \mu_0 + \mu_1 \). Because \( \mu_1 < 0 \), \( S_t \) switches from 0 to 1 at times when the economy switches from the high-growth phase to the low-growth phase (expansion to recession), or vice versa.

The switching variable \( S_t \) is unobserved, meaning that we need to place restrictions on the probability process governing it. We assume that the process for \( S_t \) is a first-order two-state Markov chain, implying that any persistence in the regime is completely summarized by the value of the state in the last period. More specifically, the probability process driving \( S_t \) is captured by the transition probabilities \( \Pr[S_t = j \mid S_{t-1} = i] = p_{ij} \). We estimate the model using the multi-move Gibbs-sampling procedure for Bayesian estimation of Markov-switching models implemented by Kim and Nelson (1998).\(^2\)

\(^2\) The Gibbs sampler draws iteratively from the conditional posterior distribution of each parameter given the data and the draws of the other parameters of the model. These draws form an ergodic Markov chain whose distribution converges to the joint posterior distribution of the parameters given the data. When we simulate the posterior
Our data are monthly observations of the SCIs over the period 1983 – 2004 for the seven states of the Eighth District. We restrict our estimation to post-1983 data so as to avoid possible problems with structural breaks. Clarida, Gali, and Gertler (2000) and Boivin and Giannoni (2003), for example, show how monetary policy shocks have much smaller effects on output in the post-Volcker period. Also, McConnell and Perez-Quiros (2000) demonstrate how national output growth has been significantly less volatile since the early 1980s.

Our first step is to use the Hamilton model to obtain a useful description of the national business cycle that we can compare to the state-level business cycles from the SCIs. As we have mentioned, because the SCIs are indicators of labor-market conditions, we use national non-farm payroll employment to describe the national employment cycle, which grew at an average monthly rate of 0.15 percent during our sample period. For reference, monthly growth of payroll employment over the period was 0.18 in Arkansas, 0.10 in Illinois, 0.15 in Indiana, 0.18 in Kentucky, 0.14 in Mississippi, 0.13 in Missouri, and 0.18 in Tennessee.

According to the model, this average growth rate is the average of the recession and expansion growth rates weighted by the frequencies of the two business cycle phases. The Hamilton model provides estimates of the average growth rates in each of the two phases and, for each observation, the probability that the labor market is in the recession phase. Applying the Hamilton model yields average monthly national employment growth rates of 0.22 percent during expansion and –0.04 percent during recession.

\[\text{distribution, we discard the first 2,000 draws to ensure convergence. Descriptive statistics regarding the sample posterior distributions are then based on an additional 10,000 draws.}\]

\[\text{We should note that the employment series from the household survey is of limited use for our purposes because its monthly growth rates does not exhibit the distinct breaks found in payroll employment.}\]

\[\text{The 90-percent coverage intervals for these growth rates are (0.20, 0.23) and (–0.07, -0.01), respectively.}\]
In divining the probability of recession, the model compares the actual growth rate to the average growth rates for the two phases. The model also considers how persistently this relative proximity is. Figure 1 shows actual average U.S. employment growth relative to the average growth rates for the two phases. The probability that the national labor market is in recession is provided by Figure 2, for which the shaded area indicates periods of national NBER recessions.\(^5\)

As Figure 2 shows, the model does a good job of separating the data into recession and expansion phases in that the probability of recession rises and falls rapidly as the national labor market switches between phases. The only period for which the model provides mixed signals is for August 1983. That month appears to be anomalous in that employment growth spiked down in August, only to spike up in September to more than make up for the previous months job losses.

The main result apparent in Figure 2 is the different timings and lengths of the NBER and national labor-market recessions. Using an admittedly arbitrary recession probability of 0.6 or higher to indicate months of recession, the first national labor-market recession began in June 1990 (two months before the start of the NBER recession) and ended in April 1992 (more than a year after the end of the NBER recession). This long lag between the ends of the NBER and labor-market recessions was the period of the so-called jobless recovery.

The 2001 NBER recession shared some of the features of the 1990-91 NBER recession. In particular, it did not last nearly as long as the associated labor-market recession did, which began much earlier and ended much later than did the 2001 NBER recession: The national labor

---

5 According to the NBER, the national economy was in recession twice during the sample period: August 1990 – March 1991 and April 2001 – November 2001.
market entered recession in June 2000—ten months prior to the April 2001 start of the NBER recession. Further, although the NBER recession ended in November 2001, it was not until a full two years later that the national labor market saw an end to its recession. Thus, the disjoint between the labor-market and the broader economy was significantly greater with the 2001 NBER recession than the 1990-91 NBER recession: In 2001, the national economy went into recession well after the national labor market did, and the jobless recovery lasted almost twice as long as in 1991-92.

**ESTIMATION OUTPUT FOR THE STATES**

*Growth Rates*

The estimated state-level average monthly growth rates in expansion and recession are provided in Table 1, along with the actual average monthly growth rates. Of the seven District states, Tennessee had the highest average growth rate over the sample period (0.34 percent), which was quite a bit higher than the state with the second highest average growth rate, Indiana (0.30 percent). At the other end, Mississippi had the lowest average growth rate (0.25 percent), which was not far from the performances of Missouri and Illinois (0.26 and 0.27 percent, respectively).

Because the Hamilton model allows states to switch between expansion and recession phases, these actual average growth rates can be broken down into their two component growth

---

6 We should note that this overstates the difference between the start of the NBER recession and the surrounding national labor-market recession. The NBER determined the start of the recession before data for 2000 were revised downward significantly. Using revised versions of the same data used by the NBER, Chauvet and Piger (2005) determine that the national economy entered recession in November 2000.
The second and third columns of Table 1 provide the estimated average growth rates in expansion and recession for the seven District states. Of these states, Tennessee’s average growth during expansion (0.46 percent) easily outpaced that of Illinois (0.41 percent) and Indiana (0.39 percent). Of the remaining states, Mississippi has the lowest average expansion growth rate (0.34 percent).

It is during their recession phases that the differences between states are most glaring. Three states—Arkansas, Mississippi, and Tennessee—have average recession growth rates that are positive, although the 90 percent coverage interval around the estimates includes negative numbers. At the other end are three states—Illinois, Indiana, and Missouri—whose average recession growth rates are well below zero. These are also the states that suffer the most during a month of recession in that they have the greatest differentials between their average expansion and recession growth rates. In each of these states, a month of recession tends to mean about one-half of a percentage point lower growth. Tennessee is not far behind these states in terms of the opportunity cost of a month in recession. Although Tennessee tends to experience positive growth during a month of recession, its average growth rate in expansion is so high that its average output lost during recession is also relatively high.

In trying to explain the differences in average growth rates across states, OPW found that the factors that might explain recession growth rates are not the same as those that explain expansion growth rates. Specifically, they found that demographic factors such as education and age distributions were related to expansion growth rates, but were not related to recession growth rates. On the other hand, they also found that states’ shares of employment in manufacturing and
construction and mining were related to recession growth rates, but were not related to expansion growth rates.

**Pre-2001 Recession/Expansion Experiences**

For reference, Figure 3 provides the actual monthly growth rates for the District states, along with the estimated average growth rates in the two business cycle phases. The Hamilton model also determines the probability that the data for a particular month indicates either a recession or expansion. It is not just data for the month in question that matters, however. For a given month, the probability of being in recession also depends on the preceding and subsequent months.

The recession and expansion cycle for the seven District states are illustrated by Figure 4, which provide the probability of recession for each month of our sample period. In these charts, the light-shaded areas indicate the national labor-market recessions determined above and the dark shaded areas indicate NBER recessions. The model does a good job of separating the data into two phases in that the probability of recession is usually close to either one or zero, although Indiana experienced several idiosyncratic spikes. On the whole, however, the model provides a clear picture of recent state-level recession/expansion experiences in the District.

Even though we deal with only a small subset of states, Figure 4 illustrates that some of the business cycle characteristics found by OPW for the 50 states apply to the seven District states: While state-level recessions tend to occur alongside national recessions, there have been occasions of state recessions that were independent of national recession. In addition, there are
significant state-level differences in the timing of recession episodes, both relative to each other and the country as a whole.

For the most part, District states experienced labor-market recessions that were roughly in line with the NBER recession of 1990-91. In this regard, the District differed from other parts of the country, particularly the coasts, where labor-market recessions began much earlier and ended much later than the NBER recession. As described by OPW, there was a strong geographic pattern to the state-level labor-market recessions of the period: States in the Northeast and Far West switched into labor-market recessions up to two years before the start of the NBER recession. Recession spread from the coasts into the interior of the country and receded back to the coasts, ending for some Eastern and Western states more than two years after the end of the NBER recession.

There were interesting intra-District differences in the period. Of the District states, Illinois stands out in that its labor-market recession was very similar in timing to the national labor-market recession. Less glaring than the difference between Illinois’ experience and the rest of the states’ is that labor markets in Tennessee and Missouri went into recession 10 and four months, respectively, before the start of the NBER recession. Finally, the labor-market recessions in Arkansas, Indiana, Kentucky, and Mississippi were somewhat shorter than the NBER recession. It should also be noted that Indiana experienced a brief labor-market recession in 1989 that was not experienced in the rest of the District. Although some coastal states were in recession at this time, it is likely that Indiana’s recession was idiosyncratic and unrelated to the recessions experienced in other parts of the country.
Although there were only two national recessions during our sample period, OPW found that there were two periods during which significant numbers of states went into recession while the national economy remained in expansion. The first such period was in 1985-86 when, following simultaneous downturns in the petroleum and agricultural sectors, nearly every state geographically between Idaho and Louisiana was in recession for at least one quarter. As Figure 4 shows, Mississippi was the only District state to have experienced this non-national recession, although Arkansas and Indiana experienced enough of a slowdown for their probabilities of recession to blip upwards.

The second period during which states experienced labor-market recessions while the national economy is expanding was in 1995. OPW found that several states—although no District states—experienced recessions beginning in 1995 that lasted between one and five quarters. As shown in Figure 4, we find that two District states—Mississippi and Tennessee—switched into recession during 1995 and that Arkansas and Indiana saw their probabilities of recession rise during the year without becoming high enough to indicate an actual recession. The difference between our results and those of OPW with regard to District states is likely due to our sample period, which, as mentioned above, was chosen to account for possible structural breaks during the 1980s.

THE 2001 RECESSION

As OPW showed, many state-level labor markets were not in sync with the NBER recessions of 2001. States in the Mississippi valley, the Ohio valley, the Southeast, and the
Northwest had switched into labor-market recessions in 2000. Also, many states located geographically between Montana and Texas had not switched into labor-market recession until mid-2001. Further, OPW found that most state-level labor-market recessions continued past the end of the NBER recession. Because their sample period ended in mid-2002, however, OPW was unable to provide a complete picture of the labor-market recessions at the state level. In this paper, with revised data through the end of 2004 in hand, we are able to analyze the entire labor-market recession experience of the states of the Eighth District surrounding the 2001 NBER recession. Also, because of the differences in our sample period, we find presently that the labor-market recessions in District states began much earlier than had been documented by OPW.

In contrast with the 1990-91 recession, the states of the Eight District had labor-market recessions that were much more in line with the national labor-market recession than with the NBER recession. Like the national labor market, the seven state labor markets went into recession well before the start of the NBER recession and went into expansion long after the end of the NBER recession. As shown by Figure 5, which provides a close-up view of District states between 1999 and 2004, there were interesting differences within the District and between District states and the country as a whole. In the figure, a “■” indicates that a state’s labor market was in recession during that month. The dark-shaded area shows the eight-month long NBER recession and the light-shaded area shows the 42-month-long national labor-market recession. The cross-state comparisons are summarized by Table 2, which compares the timing of each state’s labor market recession to that of the national labor-market recession.
Arkansas

Arkansas’ labor market switched into recession in April 2000, two months before the national labor market made the same switch, and a year before the start of the NBER recession. As one can see from Figure 3, Arkansas’ growth dropped off dramatically during this month, and remained low long afterward. Throughout the first half of 2003, growth began to rise until the labor market switched into expansion in August 2003, four months before the national labor market switched into its expansion phase. Overall, then, Arkansas’ labor-market recession, which lasted 40 months, was four months shorter than the national labor-market recession. Among District states, only Indiana spent fewer months in recession.

Illinois

Illinois’ labor market switched into recession in July 2000, one month later than the national labor market did, and nine months before the start of the NBER recession. Of the District states, Illinois was the last to switch into recession. Figure 3 shows the clear drop-off in growth that occurred at that time and which continued into 2001 and beyond. It was only in late 2003 that growth began be positive, although it was not until July 2004 that it had become persistently high enough for the probability of recession to go below the 0.6 threshold, signaling the end of the labor-market recession. Note that even by the end of 2004, the expansion in Illinois was not a clear as in other states. This lack of clarity can be seen in Figure 3: Although growth had been persistently positive for several months, it was still languishing between the expansion and recession growth rates. Other states had made up more of the growth gap and
had, therefore, seen a clearer signal that expansion was ongoing. In total, Illinois spent 49 months in labor-market recession during the period surrounding the 2001 NBER recession.

**Indiana**

Between the beginning of 2000 and the end of 2004, Indiana experienced two distinct labor-market recessions interrupted by a brief expansion. Indiana’s first recession began in April 2000, two months before the start of the national labor-market recession. The state switched back into expansion in May 2002, five months into the NBER expansion. As illustrated in Figure 3, growth in Indiana had returned to above the average expansion growth rate and remained high until August 2000. By September 2000, however, the Indiana labor market had returned to recession, where it remained until August 2003, the first month of an expansion that it has so far maintained. Although Indiana experienced a “double-dip” labor-market recession, the state spent fewer months in recession (36) than any other District state.

**Kentucky**

Kentucky’s labor-market recession began in May 2000, one month before the start of the national labor-market recession, and 11 months before the NBER recession. Figure 3 illustrates the obvious drop-off in growth that signaled the switch into recession. As with the other states, growth rose during 2003, sustaining a level close to the average expansion growth rate by the middle of the year. The final month of Kentucky’s single recession episode was July 2003, four months before the final month of the national labor-market recession and more than a year and
one half after the end of the NBER recession. In total, Kentucky spent 39 months in a labor-market recession.

**Mississippi**

The labor market of Mississippi was the first of any District state to switch into recession and was the last to enter a sustained period of expansion. Further, Mississippi’s labor market experienced a “triple dip” in that it saw two short periods of recovery between three periods of recession. The first recession period began in September 1999, nine months before the start of the national labor-market recession and 19 months before the start of the NBER recession. The first recovery period was in April and May 2002, but as shown in Figure 4, the model produces a relatively high probability of recession even during these months. The second recession phase lasted until June 2003, which was about the time that several other District states were switching into expansion. Mississippi’s expansion lasted only six months, however, and the third period of labor-market recession began in January 2004, two months after the last month of the national labor-market recession. By July 2004, this final, seven-month long recession period ended, eight months after the end of the single national-labor-market recession. Between September 1999 and July 2004, Mississippi’s labor market was in recession for 51 months and in expansion for eight months.

**Missouri**

Of the seven District states, Missouri spend the most months in recession (53) during the period surrounding the 2001 NBER recession. Whereas Mississippi’s overall recession
experience spanned a longer time period, Missouri’s labor-market was in recession for a single block of time that began in March 2000, more than a year before the start of the NBER recession and three months before the national labor-market recession. As Figure 3 shows, Missouri’s growth dropped off considerably at this time, providing a clear signal that its labor-market had switched into recession. Growth remained consistently negative through the rest of 2000 and all of 2001 and 2002. Although it picked up somewhat during 2003, the model had little doubt that the recession continued through to 2004. It wasn’t until August 2004, eight months into the national-labor market expansion, that growth was high and persistent enough to signal the start of the labor-market expansion.

**Tennessee**

Tennessee’s labor-market recession began in April 2000, two months before the start of the national labor-market recession. The drop-off in growth at this time is clear from Figure 3. Its recession ended shortly after those of Arkansas, Illinois, Indiana, and Kentucky, and three months earlier than the national labor market. In total, Tennessee’s labor market was in recession for 41 months, placing it among these four states in terms of the amount of time in recession. Within this single recession phase, Tennessee’s growth was relatively turbulent, falling well below its average recession growth for several months for all of 2001. Recovery was strong in 2003, however, and growth was above the average expansion growth rate by the beginning of 2004. More troubling for Tennessee was the rocky performance during the second half of 2004, when growth fell and the probability of recession rose as shown in Figures 3 and 4.
Growth had not fallen persistently close enough to the average recession growth rate, however, to have signaled a recession.

CONCLUSIONS

Typically, District states experienced labor-market recessions that were roughly in line with the NBER recession of 1990-91. This is in contrast with other parts of the country where labor-market recessions began much earlier and ended much later than the NBER recession. Illinois differed from the rest of the District states in that its labor-market recession was very similar in timing to the national labor-market recession. In addition, the labor-market recessions in Arkansas, Indiana, Kentucky, and Mississippi were somewhat shorter than the NBER recession was.

During the period surrounding the 2001 NBER recession, the labor markets of four District states—Arkansas, Indiana, Kentucky, and Tennessee—spent somewhat less time in recession than did the national labor market. Each of these states went into labor-market recession a month or two before the country as a whole, while entering expansion three to five months earlier than the country as a whole. On the other hand, the labor markets of three District states—Illinois, Mississippi, and Missouri—were in recession for more time than the national labor market was. All three switched into recession earlier than the country as a whole: For Mississippi the switch occurred 10 months earlier. Sustained labor-market expansion didn’t begin in these three states until seven or eight months after it did for the nation.
