Abstract

I use a dynamic stochastic general equilibrium model to study the effects of the 2019-20 coronavirus pandemic in the United States. The pandemic is modeled as a large negative shock to the utility of consumption of contact-intensive services. General equilibrium forces propagate this negative shock to the non-services and financial sectors, triggering a deep recession. I use a calibrated version of the model to analyze different types of fiscal policies: (i) government purchases, (ii) income tax cuts, (iii) unemployment insurance benefits, (iv) unconditional transfers, and (v) liquidity assistance to services firms. I find that UI benefits are the most effective tool to stabilize income for borrowers, who are the hardest hit, while savers favor unconditional transfers. Liquidity assistance programs are effective if the policy objective is to stabilize employment in the affected sector.

1 Introduction

The on-going COVID-19 outbreak is causing widespread disruption in the world’s advanced economies. Monetary authorities were quick to react, with the Federal Reserve and other major central banks returning to their 2008-09 Financial Crisis toolkits. Following these steps, fiscal authorities around the globe are in the process of designing and approving stabilization packages to help sustain household and firm balance sheets.

In this paper, I adapt an otherwise standard DSGE model to simulate the macroeconomic effects of a pandemic and to study the effects of different types of fiscal policy instruments. The pandemic is modeled as a sudden stop of a contact-intensive services sector. Through aggregate demand externalities, the shutdown of this sector propagates to the non-services sector. Through balance sheet linkages, it also propagates to the financial sector. The rise in unemployment leads to a wave of defaults, disrupting financial intermediation and amplifying the recession. The pandemic scenario is pessimistic: the shock lasts for three quarters (through the end of 2020) and results in about a 20% unemployment rate. Borrower households, who derive most of their income from employment and rely on bank credit to fund consumption, are the most affected group.

I use a calibrated version of the model to study the effects of different types of discretionary fiscal policy: (i) an increase in non-service government purchases, (ii) a decrease in the income tax, (iii) an expansion of unemployment insurance (UI), (iv) an unconditional transfer, (v) payment of wages by the government to service firms.

In terms of measuring the effectiveness of different measures, it is not clear that the traditional concept of GDP multiplier is appropriate in this context. The shut down of economic activity is largely intentional, and part of pandemic suppression measures, and focus on GDP stabilization could be detrimental to fight the pandemic. For that reason, I evaluate different policies based on consumption and household income multipliers, which measure the dollar impact of fiscal spending on consumption of either type of household, and on labor income net of government transfers. I find that there is considerable variation in the distribution effects of different types of policies. Borrowers, who are most affected by the crisis, receive a larger consumption boost from policies that resemble cash transfers, such as an increase in UI benefits. I find that unconditional transfers of the type that are currently being proposed generate similar distributional effects, with the added benefit of a potentially less costly implementation. Finally, I find that liquidity assistance to firms yields weaker effects per dollar spent on household income and consumption, but can be very effective if maintaining employment levels in the affected sector is a policy objective.

Finally, it is worth noting that the pandemic scenario is assumed to be a completely
exogenous shock to the economy. In practice, it is likely that the most effective type of fiscal policy would be one that targets the underlying source of the shock, i.e. investment in public health measures related to prevention, suppression, mitigation, and/or cure.

**Literature** The exercise in this paper is very similar to the analysis conducted by Drautzburg and Uhlig (2015) and Taylor (2018) for the American Recovery and Reinvestment Act of 2009, where the authors use a DSGE model to simulate a recession scenario and then consider the effects of a policy package. Faria-e-Castro (2018) conducts a similar analysis, while also taking into account financial sector interventions that involved asset purchases such as TARP, among others. I mostly abstract from issues related to financial sector interventions in this paper.

This paper also contributes to the modeling of a pandemic in a macroeconomic model. Fornaro and Wolf (2020) study how monetary and fiscal policy can be used to respond to the current pandemic by preventing the economy from falling into stagnation traps following persistent negative shocks to productivity growth. Eichenbaum et al. (2020) embed a canonical epidemiology model (the SIR model) in a real business cycle model. Since they endogenize the dynamics of the epidemic, their model allows them to study optimal health policy responses. They find that a severe recession, generated by agents’ optimal decision to cut back on consumption and hours worked, helps reduce the severity of their epidemic. My analysis is complementary to theirs: I take the epidemic as exogenous and given, and study how a fiscal authority can help stabilize income and consumption during the epidemic.

Section 2 presents the model, Section 3 explains the calibration and describes the modeling of a pandemic, Section 4 discusses fiscal policy, and Section 5 concludes with an extensive discussion of the caveats of the present analysis.

## 2 Model

Time is discrete and infinite. There are two types of households: borrowers and savers. Financial intermediaries use deposits raised from savers as well as their own retained earnings to finance loans to borrowers. There are two sectors in this economy: a non-services sector (sector \( n \)), and a services sector (sector \( a \)). Labor markets are frictional in reduced form, and employment is demand-determined in both sectors. A Central Bank sets the interest rate, and a fiscal authority collects taxes and can undertake different types of discretionary interventions.

The model is adapted from Faria-e-Castro (2018) and many of its elements are standard in TANK models. For this reason, I mostly focus on what is different.
2.1 Households

There are two types of households in fixed types: borrowers in mass $\chi$ and savers in mass $1 - \chi$.

2.1.1 Borrowers, Debt, and Default

There is a representative borrower family that consists of a continuum of agents $i \in [0, 1]$. Each of these agents can be employed in the $n$-sector, employed in the $a$-sector, or unemployed. Let $N_t^{n,b}, N_t^{a,b}$ denote the mass of agents working in the $n$- and $a$-sectors, respectively, and let $1 - N_t^{a,b} - N_t^{n,b}$ denote the mass of unemployed agents.

To generate realistic default rates in the context of a representative agent model, I assume that the members of the borrower household are subject to a cash-in-advance constraint and liquidity shocks. The borrower family enters the period with a stock of debt to be repaid equal to $B_t^{b-1}$. Each member of the household is responsible for repaying an equal amount $B_t^{b-1}$ at the beginning of the period. At this point, the only available resources are labor income, net government transfers, and a liquidity shock $\varepsilon_t(i) \sim F^e, F^u$, where $F^e, F^u$ are distributions with support in the real line.\(^1\)

Total cash in hand is therefore given by

$$\mathbb{1}[i \in N_t^{n,b}] w_t^n (1 - \tau_t^l) + \mathbb{1}[i \in N_t^{a,b}] w_t^a (1 - \tau_t^l) + \mathbb{1}[i \notin N_t^{n,b}, N_t^{a,b}] u_t + T_t^b + \varepsilon_t(i)$$

where $T_t^b$ is an unconditional transfer from the government, and $u_t$ is unemployment insurance. Default is liquidity-based: agent $i$ compares cash-in-hand to the required repayment $B_t^{b-1}$ and defaults if she does not have enough resources to repay. This allows me to define three thresholds that determine default rates for each of the possible employment states,

$$\varepsilon_t^a = \frac{B_t^{b-1}}{\Pi_t} - w_t^a (1 - \tau_t^l) - T_t^b$$  
$$\varepsilon_t^n = \frac{B_t^{b-1}}{\Pi_t} - w_t^n (1 - \tau_t^l) - T_t^b$$  
$$\varepsilon_t^u = \frac{B_t^{b-1}}{\Pi_t} - u_t - T_t$$

---

\(^1\)I allow the distribution of liquidity shocks to differ for the employed and unemployed agents as this allows me to jointly match replacement rates and different default rates for employed and unemployed.
The total default rate is then given by
\[ F^b_t = N^{a,b}_t F_e(\varepsilon^a_t) + N^{n,b}_t F_e(\varepsilon^n_t) + (1 - N^{a,b}_t - N^{n,b}_t) F_u(\varepsilon_u^a) \]

After default decisions are made, the borrower household jointly takes all other relevant decisions at the household level. The borrower solves the following program,
\[
V^b_t(B^b_{t-1}) = \max_{C^b_t, B^b_t} u(C^b_t) + \beta^b E_t V^b_{t+1}(B^b_t) \\
\text{s.t.} \\
C^b_t + B^b_{t-1}(1 - F^b_t) = N^{a,b}_t w^a_t (1 - \tau^l_t) + N^{n,b}_t w^n_t (1 - \tau^l_t) + (1 - N^{a,b}_t - N^{n,b}_t) u \varepsilon_t + T^b_t + Q^b_t B^b_t \\
B^b_t \leq \Gamma
\]

where \( C^b_t \) is non-service consumption, the first constraint is the budget constraint, and the second constraint is a borrowing constraint expressed in terms of a limit to total repayment.

### 2.1.2 Savers

Savers also supply labor to both sectors. They save in government bonds and bank deposits, and own all firms and banks in this economy. Additionally, they derive utility from consumption in the services sector, \( C^a_t \). They solve the following problem,
\[
V^s_t(D_{t-1}, B^g_{t-1}) = \max_{C^a_t, C^s_t, B^g_t, D_t} u(C^a_t) + \alpha_t (C^a_t)^{1-\sigma_a} + \beta^s E_t V^s_{t+1}(D_t, B^g_t) \\
\text{s.t.} \\
C^s_t + p^a_t C^a_t + Q_t (D_t + B^g_t) = N^{a,s}_t w^a_t (1 - \tau^l_t) + N^{n,s}_t w^n_t (1 - \tau^l_t) \\
+(1 - N^{a,s}_t - N^{n,s}_t) u \varepsilon_t + \frac{B^g_{t-1} + D_{t-1}}{\Pi_t} + (1 - \tau^k) P_t - T_t + T^b_t
\]

where \( p^a_t \) is the price of \( a \)-sector goods in terms of the numeraire (final \( n \)-goods), \( D_t \) is bank deposits, \( B^g_t \) is government debt, and \( \Pi_t \) is the inflation rate in terms of non-service goods. \( P_t \) is total profits from firms and banks, which are taxed at some flat rate \( \tau^k \). I assume that deposits are safe, and so they pay the same return as government bonds. \( T_t \) is a lump-sum tax paid to the government. It is useful to define the stochastic discount factor (SDF) of savers as
\[
\Lambda^s_t = \beta^s \frac{u'(C^s_{t+1})}{u'(C^s_t)}
\]

Finally, \( \alpha_t \) is a shock to the utility derived from the consumption of services. This shock
plays an important role in what follows. Demand for services is given by

\[ C_a^t = \left[ \frac{1}{\beta_t u'(C^s_t)} \right]^{1/\sigma_a} \]

### 2.2 Financial Intermediaries

Financial intermediaries are based on a version of Gertler and Karadi (2011). There is a continuum of intermediaries indexed by \( j \) that take deposits from savers and originate loans to borrowers. Intermediation is subject to two important frictions: first, there is a market leverage constraint that imposes that the value of the intermediary’s assets not exceed a multiple of its market value. Second, the intermediary must pay a fraction \( 1 - \theta \) of its earnings as dividends every period. The intermediary problem is

\[
V_t^k(D_{t-1}(j), B_{t-1}(j)) = \max_{B_t(j), D_t(j)} (1 - \theta)\pi_t(j) + \mathbb{E}_t \Lambda_{t+1} V_{t+1}^k(D_t(j), B_t(j))
\]

s.t.

\[
Q_t^b B_t^b(j) = \theta \pi_t(j) + Q_t D_t(j)
\]

\[
\kappa Q_t^b B_t^b(j) \leq \mathbb{E}_t \Lambda_{t+1} V_{t+1}^k(D_t(j), B_t(j))
\]

\[
\pi_t(j) = (1 - F_t^b) \frac{B_{t-1}(j)}{\Pi_t} - \frac{D_{t-1}(j)}{\Pi_t}
\]

The value of the intermediary is equal to dividends paid today, a fraction \( 1 - \theta \) of its earnings, plus the continuation value. The first constraint is a balance sheet constraint: assets must be financed with either retained earnings or deposits. The second constraint is a market leverage constraint: bank assets cannot exceed a multiple \( 1/\kappa \) of ex-dividend bank value. Finally, the third constraint is the law of motion for earnings: the bank earns revenues for non-defaulted loans and must pay out previously borrowed deposits.

It is possible to show that the value function is homogeneous of degree one in earnings, thus allowing for aggregation. That is, letting \( \pi_t \) be the relevant state variable, we can show that \( V_t^k(\pi_t(j)) = \Phi_t \theta \pi_t(j) \), and that \( \Phi_t \) is the same for all banks. Define aggregate retained earnings as

\[
E_t = \theta \left[ (1 - F_t^b) \frac{B_{t-1}(j)}{\Pi_t} - \frac{D_{t-1}(j)}{\Pi_t} \right] + \varpi
\]

where \( \varpi \) is a small (gross) equity injection from savers. Then, we can work with a representative bank that has retained earnings equal to \( E_t \).
The first-order condition for lending takes the form
\[
\mathbb{E}_t \frac{\Lambda_{t+1}^s}{\Pi_{t+1}} (1 - \theta + \theta \Phi_{t+1}) \left[ \frac{1 - F_{t+1}^b}{Q_t^b} - \frac{1}{Q_t} \right] = \mu_t \kappa
\]
where \(\mu_t\) is the Lagrange multiplier on the leverage constraint, and \(\frac{\Lambda_{t+1}^s}{\Pi_{t+1}} (1 - \theta + \theta \Phi_{t+1}) \equiv \Omega_{t+1}\) is the bank’s SDF. When the constraint binds \(\mu_t > 0\), this generates excess returns on lending over and above what would be warranted by pure credit risk. The constraint will typically bind when the bank is undercapitalized, i.e. when its value is low. Binding constraints allow the bank to recapitalize itself by generating a positive wedge between the cost of borrowing \(1/Q_t\) and the return on lending \((1 - F_{t+1}^b)/Q_t^b\). This means that when banks are in bad shape, they tend to lend less and at higher interest rates.

2.3 Production

There are two sectors in this economy: non-services and services.

2.3.1 Non-Services Sector

The \(n\)-sector is the largest sector in this economy, and \(n\)-sector final goods work as the numeraire. This sector operates like the single sector in a standard New Keynesian model. Goods in the \(n\)-sector are produced by a continuum of producers that operate under monopolistic competition and are subject to costs of adjusting their prices. The final-goods aggregator for \(n\)-sector intermediates is
\[
Y_t = \left[ \int_0^1 Y_t(l) \frac{dl}{l} \right]^{\frac{1}{\epsilon}}
\]
Firms in the \(n\)-sector operate a linear technology that produces variety \(l\) using labor,
\[
Y_t(l) = A_t N_t^n(l)
\]
where \(A_t\) is an aggregate TFP shock. They sell their good at price \(P_t(l)\) and face adjustment costs a la Rotemberg (1982),
\[
d[P_t(l), P_{t-1}(l)] = Y_t \eta \left[ \frac{P_t(l)}{P_{t-1}(l) \Pi} - 1 \right]^2
\]
where \(\eta\) measures the degree of nominal rigidity and \(\Pi\) is steady state inflation (indexing). From the aggregator, each producer faces a demand curve given by \(Y_t(l) = [P_t(l)/P_t]^{-\epsilon} Y_t\), where \(P_t\) is the price level for \(n\)-sector goods. Standard derivations and imposing a symmetric
equilibrium in price-setting yield a New-Keynesian Phillips Curve

\[ \eta \mathbb{E}_t \left\{ \Lambda^s_{t+1} \frac{Y_{t+1}}{Y_t} \frac{\Pi_{t+1}}{\Pi} \left( \frac{\Pi_{t+1}}{\Pi} - 1 \right) \right\} - \epsilon \left( \frac{\epsilon - 1}{\epsilon} - \frac{w^a_t}{A_t} \right) = \eta \frac{\Pi_t}{\Pi} \left( \frac{\Pi_t}{\Pi} - 1 \right) \]

where \( \frac{w^a}{A} \) is the real marginal cost. Aggregate production in this sector is

\[ Y^n_t = A_t N^n_t [1 - d(\Pi_t)] \]

where \( d(\Pi_t) \) is resource costs from price adjustment.

### 2.3.2 Services Sector

The services sector is smaller and operates differently. There is a continuum of firms indexed by \( k \). At the beginning of the period, each firm observes the aggregate state and draws an idiosyncratic cost shock \( c \sim H \in [0, \infty) \). It may choose to exit or operate and produce. If it exits, it receives a payoff of zero. If it operates, it hires one unit of labor and produces one unit of services output. Its value is

\[ V^a_t(A_t) = p^a_t A_t - w^a_t + T^a_t w^a_t + \mathbb{E}_t \Lambda^s_{t+1} \int_c \max\{0, V^a_{t+1}(A_{t+1}) - c\} dH(c) \]

It is possible to show that there exists a threshold \( \bar{c}_t(A_t) \) such that a firm decides to operate if its cost is below this threshold, and exit otherwise. This threshold is \( \bar{c}_t(A_t) = V^a_t(A_t) \).

Every period, firms that exit are replaced by an equal mass of entrants so that the total number of firms is constant and equal to 1. Entrants cannot produce in the first period, but do not draw a shock either. The mass of active firms is therefore given by

\[ H^n_t = H[\bar{c}_t(A_t)] \]

Since each firm hires one worker, this will also be total demand for labor in this sector. Total output from this sector is therefore given by

\[ Y^a_t = A_t H^n_t \]
2.3.3 Labor Markets

Since there is no disutility of work, I assume that both savers and borrowers supply as much labor as firms demand. I assume reduced-form rules for wages in each sector,

\[ w_t^n = \xi^n A_t(N^n_t)^\zeta \]
\[ w_t^a = \xi^a A_t(N^a_t)^\zeta \]

where \( \xi^n, \xi^a \) are sector-specific constants. Wages comove with labor productivity \( A_t \), and also respond to a measure of market tightness in each sector. Similar wage rules could be derived from more complicated models that make labor market frictions explicit (Christiano et al., 2016; McKay and Reis, 2016). I assume that labor is rationed in equal proportion among savers and borrowers so that

\[ N^b,a_t = N^{s,a}_t = N^a_t \]
\[ N^b,n_t = N^{s,n}_t = N^n_t \]

2.4 Fiscal and Monetary Policy

2.4.1 Central Bank

The Central Bank (CB) follows a standard Taylor Rule subject to an explicit zero lower bound,

\[ \frac{1}{Q_t} = \max \left\{ 1, \left( \frac{\Pi_t}{\Pi} \right)^{\phi_{\Pi}} \left( \frac{p_t^a}{p_{t-1}^a} \right)^{\phi_{p^a}} \left( \frac{GDP_t}{GDP} \right)^{\phi_{GDP}} \right\} \]

I allow the CB to respond to fluctuations in inflation in the \( n \) (numeraire) sector and in the services sector. GDP is defined as

\[ GDP_t = Y^n_t + p_t^a Y^a_t \]

2.4.2 Fiscal Authority

The fiscal authority has outflows related to non-service consumption \( G_t \), unemployment insurance \( u_i_t \), and debt repayments \( B_{t-1}^g/\Pi_t \). Its inflows are labor income/payroll taxes \( \tau_l^i(w^n_t N^a_t + w^n_t N^n_t) \), capital income/profit taxes \( \tau^k P_t \), debt issuance \( B^g_t \), and lump-sum taxes \( T_t \). Additionally, the fiscal authority can engage in a variety of other types of spending. Net
spending of other types is denoted $\mathcal{N}_t$. The government budget constraint is

$$G_t + \frac{B^g_{t-1}}{\Pi_t} + u_{it}(1 - N^a_{it} - N^n_{it}) + N_t = \tau^l_t(w^a_{it}N^a_{it} + w^n_{it}N^n_{it}) + \tau^kP_t + B^g_t + T_t$$

Lump-sum taxes adjust to ensure government solvency in the long-run. The adjustment rule is standard (Leeper et al., 2010),

$$T_t = \left[ \frac{B^g_{t-1}}{B^g_t} \right]^{\phi}\tau - 1$$

and $\phi$ controls the speed of adjustment. A low value means that current spending is mostly deficit-financed.

**Discretionary Fiscal Policy** I assume that the fiscal authority has access to an additional set of instruments. Given their extraordinary nature, these interventions will be treated as one-time shocks that are completely unexpected, but once deployed their paths are perfectly anticipated. These components of $\mathcal{N}_t$ are: (i) unconditional transfers to all agents in the economy, $T^b_{it}$, and (ii) transfers to service-sector firms that are proportional to their wages, $T^a_{it}w^a_{it}$. Thus,

$$\mathcal{N}_t = T^b_{it} + T^a_{it}w^a_{it}H^a_t$$

Additionally, I assume that the government can also conduct one-time changes to existing fiscal instruments: (i) an increase in non-service consumption $G_t$, (ii) an increase in unemployment insurance transfers $u_{it}$, and (iii) a reduction in the income tax $\tau^l_t$.

### 2.5 Resource Constraints

The resource constraint for non-service goods is

$$\chi C^b_t + (1 - \chi)C^a_t + G_t + \Psi[\bar{c}_t(A_t)] = A_tN^n_t[1 - d(\Pi_t)]$$

where $\Psi[\bar{c}_t(A_t)] \equiv \int_0^{c(A_t)} cdH(c)$ is total operating costs paid by non-exiting service sector firms, expressed in terms of non-service goods. The resource constraint for service goods is

$$(1 - \chi)C^a_t = A_tH^a_t$$

A full list of equilibrium conditions is in Appendix A.
3 Numerical Experiment

3.1 Model Calibration

The model steady state is calibrated to the US economy in the eve of the coronavirus pandemic. The model calibration is very preliminary at this stage and is very much work in progress. The calibration is summarized in Table 1.

In terms of functional forms, the utility of non-service consumption is isoelastic, 

\[ u(C) = \frac{C^{1-\sigma}}{1-\sigma}. \]

The distributions of liquidity shocks \( F^e, F^u \) are gaussian with mean zero and variances \( \sigma^e, \sigma^u \), which are calibrated to match total average charge-off rates and default rates for unemployed households. The distribution of cost shocks for service sector firms is assumed to be log-normal with mean 1 and variance \( \sigma_k \).

Table 1: Summary of the calibration.
3.2 What is a Pandemic in a DSGE model?

The main purpose of this paper is to study the dynamic response of the economy to different types of fiscal policy instruments during a pandemic event. It is not obvious, in principle, how to model a pandemic in an otherwise standard DSGE model. It seems to be widely accepted that a highly contagious pandemic results in a reduction in economic activity as households start isolating themselves from others. This leads to a sharp reduction in activity in sectors of the economy that are contact-intensive, such as hospitality and leisure, as well as certain types of retail (brick and mortar) and transportation (air travel).

Arguments can be made for a negative shock to the marginal utility of consumption / discount factor, or a positive shock to the disutility of labor (Baas and Shamsfakhr, 2017). Neither of these is ideal in isolation, for different reasons. A shock to the marginal utility of consumption leads to a fall in aggregate demand that results in unemployment in this model. But this could be easily counteracted with an increase in non-service government consumption, for example. In practice, it is very unlikely that any type of stimulus based on government consumption can restore activity in, say, leisure. A shock to the marginal disutility of labor, on the other hand, generates counterfactual implications in terms of wages and potentially welfare. A more sophisticated approach is taken by Eichenbaum et al. (2020), who embed an epidemiology model in a real business cycle framework. In their model, agents can become infected by “meeting” other infected agents while purchasing consumption goods or working. For this reason, the outbreak of an epidemic results in a contraction of consumption and hours worked.

Since I want to be able to preserve some tractability so as to be able to talk about different types of stabilization policies, I decide to model a pandemic as a shock to the marginal utility of one particular sector in the economy. For technical reasons, I assume that only savers are subject to this type of shock. A sufficiently large shock to $\alpha_t$ leads to a large drop in employment in this sector. This affects mostly borrowers, who are constrained and have a very high marginal propensity to consume. As their income falls due to loss of employment, default rates rise. This constrains banks, which in turn demand higher interest rates on their lending. These two effects contribute to a decline in non-service consumption, which in turn triggers a fall in inflation and a fall in the demand for non-service labor. The central bank responds to these shocks by lowering interest rates. This helps banks by lowering their cost of funding, but eventually interest rates are constrained by the zero lower bound. If the shock is sufficiently severe, the economy hits the zero lower bound (ZLB) and a large recession can ensue.
3.3 Size and duration of the pandemic

To calibrate the intensity and duration of the shock, I adopt a pessimistic approach. The size of the shock is chosen so that the unemployment rate rises to 20%, following the worst-case scenario put forward by Treasury Secretary Mnuchin to Members of Congress on March 17, 2020. This can be achieved with a drop in $\alpha_t$ of 60%. I assume that the shock lasts for three quarters: from 2020Q2 through 2020Q4. Finally, I assume that there is an equal shock in each quarter, as it is highly unlikely that people will start using services again as long as the pandemic is active, but that the shock has no persistence. Once the pandemic is gone, saver utility from consuming services returns to normal.

Throughout, I take the intensity and duration of the pandemic as given; I do not explicitly model government investment in healthcare and mitigation or how it could potentially reduce both of these characteristics. That is outside the scope of this exercise.

3.4 Pandemic Experiment

Figure 1 plots the response of selected variables to the $\alpha_t$ shock. The path of the shock is plotted in the first panel. The shock causes a 40% drop in employment in the services sector (4th panel). The loss of these jobs affects borrowers, whose consumption falls by almost 10%. This drop in non-service consumption also leads to a drop in employment in the other sector, of about 6%. Combined, these drops in employment lead to a 20% contraction in GDP that lasts for the full three quarters. The 6th panel shows that this recession pushes the economy to the zero lower bound for the entire period. The bottom two panels show that the loss in employment leads to a doubling of (quarterly) default rates. This in turn affects the financial sector, and lending spreads rise. This further amplifies the drop in borrower consumption and rise in defaults. One thing to note is that while deep, the crisis is not very persistent. This is to be expected due to several reasons. First and foremost, the shock is assumed not to be persistent. Second, for simplicity, there are no slow-moving state variables on the production side of the economy (such as physical capital). The recession could be made more persistent by either adding capital (an additional state variable), or by imposing frictions/barriers to entry in the service sector.\footnote{A version of the model with limited entry is presented in Appendix B. While the dynamics are different, the main results are unchanged.}

\footnote{Source: https://blogs.wsj.com/economics/2020/03/18/newsletter-the-layoffs-are-starting/}
Figure 1: Response to a 60% negative shock to $\alpha_t$ that lasts for 3 quarters and has zero persistence.

4 Fiscal Policy Response to the Pandemic

I consider, separately, the effects of deploying the following instruments:

1. Increase in government consumption in sector $n$, $G_t$

2. Labor income tax cut, $\tau^l_t$
3. Increase in unemployment insurance, $u_{it}$

4. Unconditional transfers to all agents, $T^b_t$

5. Transfers to service sector firms, $T^a_t$

In all cases, I consider a one-time impulse with zero persistence for each instrument. The impulse arrives at the beginning of 2020Q2, as the pandemic starts. This is a very rough and simplistic exercise, but the point is to try to isolate the different effects of these policies. A richer analysis would consider policy packages consisting of multiple instruments, and more persistent policies. That is work in progress.

The model responses are nonlinear and computed with perfect foresight. This means that shocks are completely unanticipated, but once they hit, their path is perfectly anticipated.

I choose the impulses so that the resulting deficits are somewhat comparable, of similar magnitudes. I focus on packages that involve a quarterly increase in the deficit on impact of $200$ billion, or roughly $3.7\%$ of quarterly GDP. The size and intensity of the interventions certainly matter since the model features nonlinearities such as the zero lower bound. A deeper exploration into the ideal size of each impulse is left for further research. At the end of this section, I present tables with present-value fiscal multipliers, which partly account for differing sizes of the interventions.

Next, I describe in more detail the effects of these policies. Many of them generate similar effects from a qualitative perspective. The quantitative effects are different, however. For a summary of the quantitative effects, feel free to skip to the next section where I compare measures of fiscal multipliers.

### 4.1 The Effects of Different Policies

**Government Consumption of Non-Services** This is comparable to the traditional increase in $G_t$ in one-sector New Keynesian models. I assume that it is not feasible for the government to purchase services directly: this would be roughly equivalent to a transfer to those firms, which is considered separately.

Figure 2 plots the effects of this policy on selected variables. The blue line corresponds to the crisis absent intervention (as in Figure 1), while the orange line includes the intervention. The key effect of the policy is seen in the 5th panel: a large increase in government consumption helps sustain employment in the non-service sector. This, in turn, somewhat moderates the drop in borrower consumption and in GDP. Finally, the fact that employment does not fall by as much also helps contain default rates and, via the banking system, credit spreads.
Figure 2: Response to a $\sim$200 bn increase in $G_t$, government consumption of non-service goods.

**Labor Income Tax Cuts** To achieve a total deficit of the same size, the intervention consists of a one-time tax cut of 50%, i.e. the tax rate is cut by half. The effects of the income tax cut look relatively similar, in Figure 3, with the main exception being that they do not stimulate labor in the non-service sector as much as the more targeted policy of government consumption. Tax cuts still help sustain borrower income, which in turn results in a slightly lower drop in GDP and a decrease in default rates. One important thing to notice is that this model may underestimate the effectiveness of tax cuts: due to the assumption of
labor market rationing, there are no direct benefits from removing labor market distortions.

Figure 3: Response to a $\sim$200 bn income tax cut.

Unemployment Insurance  Next, we consider a one-time increase in unemployment insurance payments. To achieve a $200$ bn intervention, the unemployment insurance transfer per agent is raised by 75%. The effects are noticeably larger on borrower consumption, as seen in Figure 4, which is now sustained on impact. This is somewhat predictable: income tax cuts benefit agents who remain employed, at a time when a large fraction of agents becomes unemployed. With unemployment insurance, it’s the opposite: it helps unemployed
agents at a time when a large fraction of agents becomes unemployed. The rise in borrower consumption helps sustain demand in the non-service sector, as seen in the fifth panel. This, in turn, results in a roughly 2.5% gain in GDP. Also note that while the intervention happens only in one quarter, the effects are relatively persistent. This has to do with the fact that borrowing costs remain low, as this increase in unemployment insurance considerably lowers default rates (as unemployed agents tend to have higher default rates than employed ones), and this results in an implicit recapitalization of the banking system.

Figure 4: Response to a $\sim$200 bn increase in UI.
Unconditional Transfers  Figure 5 plots the effect of a transfer that is given to everyone in this economy, including savers. The effects are similar to those of the payroll tax cut, which is not surprising as the incidence is effectively the same.

Liquidity Assistance to Service Firms  Figure 6 shows the effects of a per-wage subsidy to firms in the service sector. Unlike other interventions, this one is able to reduce the decline in service employment for one period. The general equilibrium effects are reflected in borrower consumption and labor in the no-service sector. This experiment is not totally fair
to this policy, to the extent that this is the only policy that explicitly targets the α-sector but does so for only one period, while agents expect the negative demand shock to last for an extra two periods. The remaining two periods without assistance affect the value of service firms, \( V_t(A_t) \), which does not rise by as much as it would should the assistance last for the duration of the pandemic.

Figure 6: Response to a ~$200 bn transfer to service firms.
4.2 Fiscal Multipliers

While the sizes of the interventions are calibrated to be of around $200 bn, or 3.7% of quarterly GDP, there are dynamic and general equilibrium effects that influence the path of government expenditure and revenue and that differ across instruments. One common way to control for these effects along with the size of the intervention, is to compute present value discounted multipliers as in Mountford and Uhlig (2009) or Ramey (2011). For a given outcome variable of interest \( x \), the multiplier is computed as

\[
M_T(\omega) = \frac{\sum_{t=1}^{T} \prod_{j=1}^{t} R_j^{-1} (x_t^{\text{Stimulus}} - x_t^{\text{No Stimulus}})}{\sum_{t=1}^{T} \prod_{j=1}^{t} R_j^{-1} (\text{Spending}_t^{\text{Stimulus}} - \text{Spending}_t^{\text{No Stimulus}})}
\]

The multiplier is computed for a given instrument \( \omega \in \{G_t, \tau_t, \varsigma, T^b_t, T^a_t\} \) and at a given horizon \( T \). Since the effects of shocks are not very persistent in this model, I set \( T \) equal to 20 quarters. Since the discount rate \( R_j \) differs across the economies with policy and with no policy, it is not obvious which one to use. I use the interest rate in the no-policy economy so as to keep the comparison between different tools as fair as possible.

Table 2: Fiscal multipliers.

Table 2 compares multipliers for income net of government transfers, borrower consumption, saver consumption of non-service goods, and GDP. Income net of transfers is defined as

\[
\text{Income}_t = (1 - \tau_t)(w^a_tN^a_t + w^n_tN^n_t) + (1 - N^n_t - N^a_t)\varsigma_t + T^b_t
\]

Largest income multipliers are generated by UI. Income tax cuts and unconditional transfers are also effective, but generate lower multipliers as they are less well-targeted to agents with lower incomes. UI is, furthermore, very well targeted in terms of its timing, as this transfer arrives precisely at a time when unemployment surges. Multipliers on borrower consumption are very similar to those of income, which is to be expected since borrowers are constrained and therefore have a high marginal propensity to consume out of their current income. Any differences reflect changes in the cost of credit from banks.
Multipliers on saver consumption are very low. Savers react relatively little to fiscal policy as they are unconstrained. Savers are “Ricardian” in the sense that they purchase public debt and pay lump-sum taxes and, therefore react to changes in the present value of government liabilities. Note however that the GE effects are strong enough to offset the usual fall in consumption for savers. Naturally, they react more positively to the unconditional transfer and more negatively to the increase in unemployment insurance, which is the closest instrument to a targeted transfer to borrowers in this environment.

GDP multipliers are reported in the last column. As argued before, it is not clear that adopting measures that stabilize GDP is appropriate in this situation. Still, I report the multipliers for completeness. The measure that yields the largest GDP multiplier is government consumption. It is well known that it is “hard to beat” government consumption in this class of models (Oh and Reis, 2012), especially in the absence of very strong links between the balance sheets of households and the financial system. Income tax cuts, increases in unemployment insurance and unconditional transfers all deliver somewhat similar results. UI performs the best as it is the most well-targeted, while unconditional transfers perform the worst of those three as it is the least well-targeted. Liquidity assistance to firms seems to be the worst-performing policy, subject to the caveats pointed out in the next subsection.

4.3 Dissecting the Effect on Borrower Income

The change on borrower income, on impact, is shown in Figure 7. This Figure confirms that UI increases have the largest effect. Note that in this picture (and in subsequent pictures), we are comparing % changes for a given impulse, and not adjusting for dollars spent as in the previous paragraphs. Transfers generate better results than income tax cuts. It all boils down to how well targeted a policy is.
Figures 8 and 8 help us understand how well/poorly targeted each type of policy is, by decomposing the effect of each policy on prices and quantities (on impact). Figure 8 plots net income per worker in each sector ($n$, $a$, or unemployed), across policies. It shows, for example, that income tax cuts raise incomes for employed workers exclusively, while UI raises incomes for unemployed workers almost exclusively. Transfers and government consumption of non-services operate via traditional aggregate demand effects, thus raising demand for $n$-sector goods and therefore earnings in this sector, but having no effect in other types of workers. Finally, liquidity assistance to $a$-sector firms helps sustain wages in this sector somewhat. Figure 9 plots absolute changes in number of workers in each sector, in the baseline economy with no policy (blue bar) and in the economy with the policy impulse (yellow bar). While there are minor variations across policies, the overall pattern is the same across policies: the shock leads to a large reduction in sector $a$ employment, a moderate reduction in sector $n$ employment and large increase in unemployment. These two figures combined show very clearly why UI is the superior policy to stabilize household income, as they target the category of households that increases the most due to the shock.

\footnote{Absolute changes are easier to compare since the steady state/initial distribution across sectors is very uneven, with relatively few unemployed agents.}
Figure 8: % change on net income per worker due to policy, across sectors. Note that each panel has a different scale.
4.4 Liquidity Assistance Programs

Liquidity assistance policies to the services sector yield relatively low multipliers compared to transfer-based programs. There are two reasons for this. First, it may be that a $200 bn dollar program is simply not generous enough, and the wage subsidy is not large enough to keep a sufficient number of firms alive and workers hired. To investigate whether this is the case, I consider a larger and longer program where the government fully subsidizes wages
in the services sector for the full duration of the pandemic shock (3 quarters). That is, the government sets $T^a_t = 1$ regardless of the total cost of the program. The effects of this policy are shown in 10: under this policy, the government is able to completely offset any changes in services employment as well as in borrower consumption, even generating a small boom in the non-services sector. This small boom is not sufficient to offset the drop in the relative price of services that in turn causes a large drop in GDP, as to be expected.

This policy is, however, extremely expensive. Contrary to the baseline case, where public debt would increase by 15% at its peak, this new intervention now involves an increase in public debt of almost 50%. In fact, the multipliers are even smaller: 0.2056 for income, and 0.2051 for borrower consumption.\(^5\) This brings us to the second reason why the multipliers are low: this policy is currently treated as a pure cash grant to services firms. While this type of policy is currently being discussed by the US Congress, many other countries have opted instead for opening credit lines that would allow these firms to borrow from the government. The fact that the fiscal authority could recoup (at least part) of its cost with the policy is likely to raise the value of the multipliers. On the other hand, this could also reduce the stimulating effects of the policy, as firms internalize that the government intervention comes in the form of a liability. For this reason, it is not clear whether considering credit lines would raise or lower the multipliers for this policy.\(^6\) If the objective is, however, to preserve services-sector employment, then a large liquidity assistance program is a very effective policy.

\(^5\)The multiplier on saver consumption is 0.0002, the multiplier on GDP is 0.1235.

\(^6\)See Faria-e-Castro (2018) for a discussion on how to compute fiscal multipliers for government credit facilities.
5 Caveats and Discussion

In the context of a simple DSGE model, for an intervention of a fixed size equal to 3.7% of GDP, the most effective tool to stabilize household income and borrower consumption in the context of an exogenous shock that leads to the shut down of the services sector seems to be an increase in unemployment insurance benefits. Overall, programs that involve transfers of some kind to households seem to be effective, with UI being the best targeted. Unconditional
transfers are likely to be less costly in terms of implementation, may be favored by savers, and deliver somewhat similar (weaker) results. Firm liquidity assistance programs are effective at maintaining employment in the quarantined sector.

The analysis in this paper is very simple, takes many shortcuts, and abstracts from many important things. Many of these caveats were already mentioned in the main analysis but are worth repeating. First, for the sake of comparison, I consider only one-time “fiscal impulses.” In practice, fiscal policy packages are likely to be persistent and implemented over a certain horizon. As discussed, this is especially important for the case of liquidity assistance to service sector firms, and potentially for unemployment insurance. Second, these impulses are of a fixed size. In practice, size does matter and multipliers can be nonlinear (Brinca et al., 2019). Third, I consider each policy separately, in single-instrument packages. There can be strong complementarities and substitutabilities between policies. In a previous paper (Faria-e-Castro, 2018), I argue that there were strong complementarities between financial sector bailouts and transfers to households during the 2008-09 Financial Crisis and subsequent recession. None of that is considered here. Fourth, the absence of an endogenous labor supply decision tends to underestimate the effects of an income tax cut and overestimate the effects of UI, as it does not consider the efficiency gains/losses from these policies. Fifth, the macroeconomic scenario caused by the pandemic is possibly too extreme, with a complete shutdown of the services sector for three full quarters and a GDP contraction of 15% per quarter. I completely abstract from the possibility that fiscal policy can be deployed to reduce the duration and intensity of the shock caused by the pandemic. Finally, I also abstract from the fact that stimulating economic activity may actually be detrimental in fighting the pandemic.

There are also other important caveats that were not previously discussed. There are implementation lags that can be made worse by attempts to better target policies. Better targeted policies may additionally entail extra costs associated with bureaucracy. It may sometimes be better to undertake a slightly worse policy whose implementation requires less information and time, i.e. unconditional transfers vs. expansion of unemployment insurance eligibility. Also, I completely abstract from other potential policies that have been part of the debate: the role of state fiscal policy, health insurance, debt forgiveness and restructuring, moratoria on debt (and bill) repayments, etc. For a detailed discussion of some of these policies, see Dupor (2020).

Household-banking interactions are extremely simplified and abstract from many important feedback effects. In particular, I abstract from endogenous collateral, which can have a large effect on the consumption response to shocks and stimuli. As I show in previous research, many interventions that look like transfers to borrowers serve as implicit recapita-
lizations of the banking system and can have very strong spillovers to other sectors. For this reason, I am likely understating the effects of this type of interventions. Finally, I abstract from any direct intervention in the financial system. This is the main reason I abstract from unconventional monetary policy as well as the extraordinary measures taken by the Federal Reserve to restore confidence in financial markets. I also abstract from linkages between the financial system and the corporate sector. These are likely to be very important, especially at a time when corporate debt is at unprecedented levels in the US. This would be a natural first step in terms of extending the model.

\[ Q_t = \mathbb{E}_t \frac{m_{t+1}^s}{\Pi_{t+1}} \]

\[ C_t^a = \left[ \alpha_t \frac{1}{\beta_t^a u'(C_t^s)} \right]^{1/\sigma_a} \]

Non-services sector, 

\[ \eta \frac{\Pi_t}{\Pi} \left( \frac{\Pi_t}{\Pi} - 1 \right) + \epsilon \left[ \frac{\epsilon - 1}{\epsilon} - \frac{w_t^n}{A_t} \right] = \eta \mathbb{E}_t m_{t+1}^s \frac{Y_{t+1}^n \Pi_{t+1}}{Y_t^n \Pi} \left( \frac{\Pi_{t+1}}{\Pi} - 1 \right) \]

\[ Y_t^n = A_t N_t^n \left[ 1 - 0.5 \eta \left( \frac{\Pi_t}{\Pi} - 1 \right)^2 \right] \]

\[ C_t = C_t^a + C_t^b \]

\[ C_t + G_t + \Psi(\bar{c}_t) = Y_t^n \]

\[ w_t^n = \xi^n A_t (N_t^n)^\zeta \]

Services sector, 

\[ \bar{c}_t = A_t p_t^a - w_t^a + w_t^a T_t + \mathbb{E}_t m_{t+1}^s \left[ G_{t+1}^a \bar{c}_{t+1} - \Psi(\bar{c}_{t+1}) \right] \]

\[ N_t^n = H_t^a \]

\[ H_t^a = \int_{0}^{\bar{c}_t} dH(c) \]

\[ \Psi[\bar{c}_t] = \int_{0}^{\bar{c}_t} cdH(c) \]

\[ w_t^a = \xi^a A_t (N_t^n)^\zeta \]

\[ (1 - \chi) C_t^a = A_t N_t^n \]
Government and Central Bank

\[ G_t + \frac{B_{t-1}^g}{\Pi_t^g} + (1 - N_t^a - N_t^n)\omega_t + T_t^b + T_t^a w_t^a H_t^a \]
\[ = (w_t^n N_t^n + w_t^a N_t^a)t^l + \tau^k [Y_t^n(1 - d_t) - w_t^n N_t^n + (p_t^a - w_t^a)N_t^a - \Psi(\bar{c}_t)] + Q_t B_g^t + T_t \]

\[ T_t = \left( \frac{B_{t-1}^g}{B_g^t} \right)^{\phi_T} - 1 \]

\[ \frac{1}{Q_t} = \max \left\{ 1, \frac{\phi_T}{\phi_{GDP}} \left( \frac{p_{t-1}^a}{p_t^a} \right) \left( \frac{GDP_t}{GDP} \right) \phi_{GDP} \right\} \]

\[ GDP_t = Y_t^n + p_t^a Y_t^a \]

B Model with Limited Entry

Instead of assuming that \( 1 - H_1^a \) service firms enter the economy every period to replace firms that exit, the mass of entrants is limited by some parameter \( \varsigma \). This means that the mass of service-sector firms in the economy is now a state variable, given by \( f_t \). The law of motion for this state variable is

\[ f_t = f_{t-1} H_t^a + \varsigma \]

and the labor market clearing condition for this sector is now given by

\[ N_t^a = f_t \]

Finally, the resource constraint for the \( n \)-good is now given by

\[ C_t + G_t + f_{t-1} \Psi(\bar{c}_t) = Y_t^n \]

Other than this, nothing else changes in the model. Figure 11 plots the crisis path in this alternative version of the model. Qualitatively, the main results hold, but the crisis is now more persistent due to the presence of this new slow-moving state variable. I set \( \varsigma = 2\% \) to match a business entry rate of 8\% yearly. Table 3 presents the result for the fiscal multipliers of different instruments. While the numbers are different, the same qualitative analysis holds.
Table 3: Fiscal multipliers for model with limited entry.
