"How epigenetic traits are passed from generation unto generation"

Research in the Hodges Lab strives to understand how epigenetic features shape human genomes. We study this relationship on two levels; first, we are interested in how chemical modifications of DNA, DNA methylation, are established during the specialization of developing cell types. Second, we are interested in the relationship between genetics, DNA methylation state (epitype), and how this relationship affects cellular function (phenotype).

I. DNA methylation of genomic sequence elements in differentiating cells

Gene regulatory elements called “enhancers” are docking sites for protein-DNA interactions that control gene expression. They are the nodes of complex gene interaction networks that direct cell fate specification and maintain tissue homeostasis. Furthermore, they are believed to be a driving force behind the diversification of organisms. DNA methylation is an important component of this process but little is understood about how patterns of DNA methylation are established during development. Projects in our lab address these questions utilizing innovative biochemical, functional genomic and bioinformatic approaches.

II. Human methylation variation and disease susceptibility

Enhancers display higher DNA methylation variability between species and human individuals than other genomic elements. These differential patterns of enhancer methylation may reflect individual differences in gene regulation and disease susceptibility. We integrate our understanding of cell-type specific DNA methylation patterns with genetic and phenotype information from the electronic health record to triangulate specific functional relationships between genetic variation and disease risk.
